## SURGICAL VENTRICULAR REMODELING BOARD REVIEW QUESTIONS (CHAPTER 52)

1. Which is true regarding the pathophysiology of ICM-induced ventricular remodeling?
   A. There is an increase in the end-systolic diameter and volume of the LV.
   B. Development of concomitant mitral insufficiency worsens global systolic function.
   C. Progressive dilation of the LV eventually leads to aortic insufficiency.
   D. The ventricle becomes more elliptical shaped.
   E. Wall stress is decreased as the ventricle thins and dilates.

2. Which is not an indication for SVR?
   A. Asynergy of greater than 35 percent of the LV
   B. Enlarged LV with end-diastolic volume index >120 mL/m$^2$
   C. Akinetic anterior wall
   D. Reduced right ventricular function
   E. Clinical evidence of CHF

3. Which of the following is a relative contraindication to surgical ventricular restoration?
   A. Single area of infarction
   B. Pulmonary hypertension
   C. Presence of concomitant coronary artery disease
   D. Presence of severe mitral insufficiency
   E. Presence of severe tricuspid insufficiency

4. Which is not a goal of surgical ventricular restoration?
   A. Revascularization of all viable territories
   B. A reduction in the size of nonfunctional anteroseptal myocardium
   C. Repair of concomitant valvular regurgitation
   D. Recreation of the elliptical shape of the LV
   E. Retention of nonfunctional myocardium to prevent arrhythmias

5. Physiologic changes following SVR include which of the following:
   A. Decrease in both LV end-systolic and end-diastolic volumes
   B. No change in LV ejection fraction
   C. Increase in plasma norepinephrine
   D. Reduced LV torsional mechanics
   E. Reduced peak filling rates

## ANSWERS

1. **Answer: B.** The development of concomitant mitral insufficiency worsens systolic function. There is an increase in the end-diastolic diameter and volume, and the ventricle becomes more spherical shaped. This dilation does not lead to aortic insufficiency and increases wall stress.
2. **Answer: D.** Biventricular failure is a contraindication to surgical ventricular restoration. Asynergy of greater than 35 percent of the LV, LVEDVI >120 mL/m$^2$, an akinetic anterior wall, and clinical evidence of CHF are all acceptable indications to consider surgical ventricular restoration.
3. **Answer: B.** Pulmonary hypertension is a relative contraindication. A single area of infarction is ideally treated with surgical ventricular restoration. Other concomitant cardiac disease, such as coronary artery disease or valvular insufficiency, can be successfully addressed at the same operation.
4. **Answer: E.** All nonfunctional myocardium should be removed to reduce the size of the ventricle. Retention of diseased, nonfunctional myocardium may be a focus of arrhythmogenesis. Concomitant coronary artery disease and valvular regurgitation should be addressed, and the LV restored to a more normal, elliptical shape.
5. **Answer: A.** Both LV end-systolic and end-diastolic volumes are decreased. LV ejection fraction, torsional mechanics, and peak filling rates are all increased. Plasma norepinephrine levels are decreased.

# Stem Cells for Cardiac Surgical Disease

*Peter V. Johnston*
*Gary Gerstenblith*

**KEY CONCEPTS**

- There are an estimated 5.8 million people in the United States with heart failure.[1]
- Stem cell therapy for the heart represents a novel method by which dysfunctional cardiac tissue might be repaired or replaced, thereby alleviating heart failure and decreasing or eliminating life-threatening arrhythmias.
- Potential sources of stem cell therapy for the heart include the bone marrow, circulating progenitor cells, embryonic stem cells, and the heart itself.
- Multiple modalities exist for delivery of stem cell therapy to the heart, including traditional and minimally invasive surgical methods as well as intravenous and percutaneous catheter-based techniques.

## INTRODUCTION/BACKGROUND

The heart was once thought to be a terminally differentiated organ, with no cell turnover or repair; the cardiac myocytes at the time of early adulthood were all the cells a person would ever have. It was for this reason that myocardial infarction (MI) was thought to be such a devastating event, as there was no native ability to repair or replace damaged heart tissue. This understanding began to change in the 1990s, when investigators first reported the presence of cardiac myocytes in various stages of cell division, found during histologic analysis of myocardial tissue.[2] Since that time it was learned that the heart does have the capacity for cellular repair, both from stem cells resident in the heart, and from so-called "circulating" progenitor cells, which, following release from the bone marrow, may traffic to and enter heart tissue to effect repair.[3–5] This endogenous repair system appears to have the capacity to handle routine cellular turnover, that is, normal "wear and tear" on the heart, but becomes overwhelmed in the setting of a sudden large insult, such as a MI, with the default fibroblast scar formation. With the discovery of the capacity for cellular repair of the heart, interest in augmenting or optimizing this system to the point that the damaged and failing heart could be biologically repaired has grown. For example, although the small number of resident cardiac stem cells (CSCs) might be insufficient to repair the damage of a large infarction, removal and expansion of these cells in ex vivo tissue culture might generate sufficient numbers of cells to result in a therapeutic benefit.

The interest in cell therapy is driven primarily by the nearly 6 million Americans with heart failure,[1] as well as millions of others throughout the world, many of whom, despite optimal medical therapy, suffer significant morbidity and mortality from their condition. In many cases, temporary mechanical support or heart transplantation is necessary, but supply constraints and large expense limit availability. Thus, the great hope for cellular therapy for the heart is that end-stage heart failure could be eliminated by preventing or reversing the deleterious remodeling that occur following significant injury to the heart. Although such benefits are reported in animal models, clinical cell therapy for the heart remains in its infancy, and numerous questions remain regarding which cell type (or types) might be most effective at cardiac repair, when and how those cells should be delivered, and finally, the mechanisms by which the cells achieve any benefit. Below, the current state of cell therapy for the heart, focusing on results and lessons learned from those clinical studies reported to date, will be discussed, couched in the understanding that this field at present is young and rapidly changing.

## STEM CELLS USED FOR THERAPY OF THE HEART

To date, numerous different types of stem cells have been studied in clinical trials of cellular therapy for the heart. Here we discuss these different cell types, their potential advantages and disadvantages, and the clinical results to date (see also Table 53-1).

### Bone Marrow–Derived Stem Cells

#### BONE MARROW MONONUCLEAR CELLS

Perhaps the best characterized and most widely studied form of cell therapy for the heart is that using stem cells isolated from the bone marrow. In addition to serving as hematologic precursors, certain populations of bone marrow cells (BMCs) are released into the blood in response to signals from injured tissue, and subsequently traffic to and enter injured tissues or organs to assist in repair.[6] BMCs were first shown to be capable of cardiac repair in 2001, in experiments in which cells were injected at the infarct border zone of small animals.[7] A portion of these cells engrafted and subsequently differentiated into cardiac tissue, forming myocytes, smooth muscle, and vascular cells. Little more than a year later, in late 2002, the first clinical trial of stem cell therapy for the heart was reported, when the results of the TOPCARE-AMI trial were published.[8] In this study, patients who had suffered a recent MI were randomized to receive intracoronary infusion of BMCs, circulating progenitor cells (CPCs), or to serve as a control. The results were promising, in that those patients who received either cell type had significantly improved left ventricular ejection fraction (LVEF) 4 months later compared with controls (results discussed in detail below).

Since the publication of TOPCARE-AMI, more than 800 patients have been enrolled in randomized control studies of BMC therapy for the heart, and generally these trials show a modest benefit.[9–27] In a meta-analysis of the trials published as of 2007, BMC therapy after MI resulted in modest, but statistically significant improvements in measures of left ventricular (LV) function and remodeling compared with placebo (see Fig. 53-1).[9] For example, patients receiving cell therapy had a 3.64 percent greater improvement in LVEF, compared with placebo (95 percent CI: 1.56 to 5.73). Similar modest, but significant relative benefits were seen in terms of infarct size and change in LV end systolic volume (ESV) across studies, as well as modest, but nonsignificant differences in end-diastolic volume. Perhaps most importantly, across studies BMC therapy was safe, suggesting that the modest beneficial effects did not come at a safety cost. These results have led to the question of how the beneficial effects of BMC therapy might be further augmented and optimized. Closer examination of specific BMC clinical studies led to certain conclusions that will guide future studies.

Of the studies of BMC therapy for the heart to date, the results of the Reinfusion of Enriched Progenitor Cells and Infarct Remodeling in Acute Myocardial Infarction (REPAIR-AMI) trial, published in 2006, are perhaps the most informative.[10] In this study, patients suffering an ST-elevation MI were randomized to receive autologous BMCs or placebo (carrier solution only) by intracoronary infusion in the infarct-related artery. A total of 204 patients were enrolled (101 receiving cells, 103 receiving placebo), and were followed for 1 year. As with the overall findings for BMCs, the effect of cell infusion on cardiac function in this

**TABLE 53-1: Comparison of Stem Cell Types Studied for Cardiac Therapy**

| Stem Cell Type | Advantages | Potential Disadvantages |
|---|---|---|
| Bone marrow cells (BMCs) | Readily available<br>Extensive clinical experience<br>Clinically safe | Ability to form new cardiac tissue unclear<br>Clinical effects modest to date |
| Mesenchymal stem cells (MSCs) | Immune privileged allowing for delivery to allogenic recipient<br>Evidence of benefit from systemic delivery<br>May reduce arrhythmias following infarction | Large cell diameter may limit certain delivery methods (e.g., intracoronary infusion) |
| Circulating progenitor cells (CPCs) | Participate in vascular repair and neoangiogenesis<br>Circulating levels correlate with clinical outcomes | Mixed results in clinical trials to date<br>May not be effective in chronic heart failure |
| Cardiac stem cells (CSCs) | Cardiac-specific<br>Capable of forming new myocardium<br>May be of benefit in nonischemic cardiomyopathy | Isolation and expansion can take weeks to months<br>Cell diameter may limit certain delivery methods (e.g., intracoronary infusion) |
| Skeletal myoblasts | Abundant source of stem cells<br>Resistant to hypoxia | Associated with malignant arrhythmias in MAGIC Trial |
| Embryonic stem cells | Unlimited differentiation potential | Intracardiac teratoma formation in animal models<br>Ethical concerns |

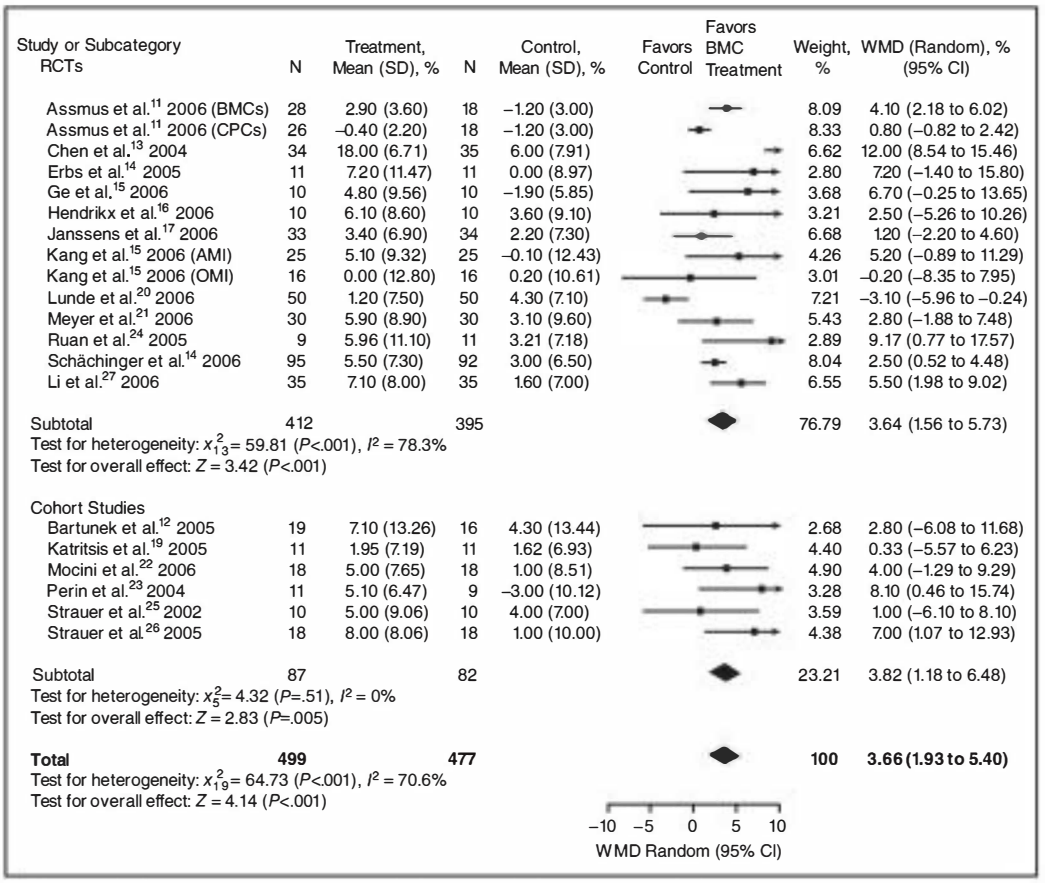

**FIGURE 53-1** Forest plot of unadjusted difference in mean change in left ventricular ejection fraction [with 95 percent confidence intervals (CIs)] in patients treated with bone marrow–derived cells (BMCs) compared with controls from multiple randomized control trials (RCTs) and cohort studies. The overall effect was statistically significant in favor of BMC therapy. (Adapted with permission from Abdel-Latif A, Bolli R, Tleyjeh IM, et al. Adult BMCs for cardiac repair: A systematic review and meta-analysis. *Arch Intern Med* 2007 May 28;167:989–997. Copyright © (2007) American Medical Association. All rights reserved.)

study was modest, but significant, with the LVEF at 3 months in those who received cell therapy significantly greater than in those who received placebo (53.8 vs. 49.9 percent, $p = 0.02$). Cell-treated patients also had a significantly greater absolute increase in LVEF over 3 months (5.5 vs. 3.0 percent, $p = 0.01$). Although the effects on systolic function were also modest, they were associated with significant clinical benefits at 1 year. There were two deaths, no infarctions, and 21 revascularizations in the BMC group and six deaths, five infarctions, and 35 revascularizations in the placebo group, for a significantly lower rate of the combined outcomes in the BMC group ($p = 0.01$).

This study was particularly informative, however, when the results were further scrutinized. First, the patients who suffered the largest infarcts (as evidenced by the most severe LV dysfunction) benefited the most from cell therapy. When patients were stratified by their LVEF prior to treatment to above or below the median (48.9 percent), those patients with an EF below the median who received BMCs had a mean absolute increase in LVEF of 7.5 percent compared with only 2.5 percent in those receiving placebo ($p = 0.002$). However, in those patients whose baseline LVEF was above the median, cell therapy resulted in a mean absolute increase of only 4.0 percent, nearly identical to the 3.7 percent increase in such patients treated with placebo ($p = 0.81$; see Fig. 53-2A). These results indicate that the overall benefit seen in the study was driven primarily by those with a baseline LVEF below the median, and this finding is not surprising, as those patients with an LVEF greater than the median had essentially normal systolic function (~55 percent in adults), suggesting that the damage suffered from their infarction was limited. This suggests that those patients with significant damage and dysfunction are the ones who stand to benefit the most from cellular therapy and should be targeted for future clinical study.

The REPAIR-AMI study was also informative in that the timing of cell delivery proved important, and the findings were contrary to what might be expected. While many believed that earlier delivery would be better, in fact the

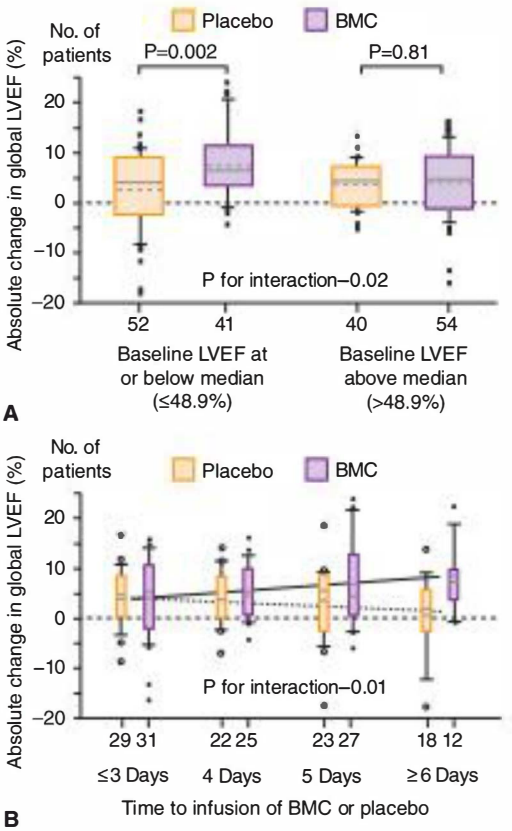

**FIGURE 53-2** Effect of baseline left ventricular ejection fraction (LVEF) and timing of intracoronary infusion of BMCs on absolute change in LVEF from the REPAIR-AMI Trial. Panel **A** shows that in those patients whose baseline LVEF was below the median (<48.9 percent), BMC treatment resulted in a significant increase in LVEF compared with placebo (left side of panel **A**). In contrast, no significant difference was seen between the treatment groups in those patients with a baseline LVEF above the median (right side of panel A). Panel **B** shows the effect timing of intracoronary infusion had on the relative effect of BMC therapy compared with placebo. When given <3 days after MI, there was no difference in absolute change in LVEF between BMC, and placebo-treated patients; however, the further from the time of MI, the greater the relative benefit of BMC therapy ($p = 0.01$ for interaction). (Reproduced with permission from Schachinger V, Erbs S, Elsasser A, et al. Intracoronary bone marrow-derived progenitor cells in acute myocardial infarction. *N Engl J Med* 2006 Sep 21;355(12):1210–1221. Copyright© (2006) Massachusetts Medical Society. All rights reserved.)

opposite proved true. In the study, patients received treatment between 3 and 7 days after their infarction. This variability resulted from differences in the time required for cell processing and other scheduling logistics, and was not a prespecified point of investigation. However, when patients were stratified by the day after infarction that they received their infusion, there was a direct relationship between time and absolute increase in LVEF, with those receiving BMCs later having greater improvement in systolic function, and the greatest difference compared to time-matched controls (see Fig. 53-2B). This would suggest that delivering cells to an area of new infarction, which is inflamed and filled with large numbers of dead or soon-to-be-dying myocytes, is delivering them to a hostile environment, which likely reduces BMC survival and engraftment, thereby limiting their effectiveness. It remains to be seen what the optimal time is for cell delivery to the heart after acute MI, as there is likely a point after which there are diminishing returns, but REPAIR-AMI has certainly indicated that early delivery is not optimal.

The TOPCARE-CHD Trial of BMC therapy in chronic LV dysfunction was published[11] at the same time as REPAIR-AMI. There are many patients who develop ischemic cardiomyopathy well after their infarction, or have unrecognized or "silent" MIs, and only present sometime later with heart failure. In many ways such patients are those who stand to benefit most from cell therapy, as when their cardiomyopathy is discovered, they often receive limited benefit from revascularization. In TOPCARE-CHD, 75 patients who suffered a MI at least 3 months prior to enrollment, with a well-demarcated area of LV dysfunction, and a patent infarct-related artery, were randomized to receive intracoronary infusion of BMCs, CPCs, or to serve as a control (no cell infusion). The cells were delivered via intracoronary infusion in the infarct-related artery. After 3 months, there was a cross-over phase in which all patients received a second infusion of cells. Patients receiving cells at the first infusion received the other cell type at the second infusion, and placebo patients were randomized to one of the two cell types. The subjects were then followed for three additional months.

The primary outcome of the TOPCARE-CHD study was absolute change in LVEF. Patients receiving BMCs had a modest but significant increase in LVEF (+2.9 percent, $p = 0.001$ compared with baseline), while CPC treated (−0.4 percent, $p = 0.60$), and control patients (−1.2 percent, $p = 0.12$) did not. The significant increase in LVEF following administration of BMCs was present regardless of whether they were given as the initial treatment, or following administration of CPCs. There was also a trend toward lower adverse clinical outcomes 3 months after initial treatment in patients receiving BMCs. Using the combined end point of death, MI, stroke, rehospitalization for heart failure, or ventricular tachycardia, no patients treated with BMCs experienced these events, compared with five patients in the CPC group (15 percent), and three in the control group (13 percent; $p = 0.07$ across groups). These results suggest that patients with remote prior MI can still benefit from cell therapy, from both LV function and clinical standpoints. This benefit, however, appears limited to BMCs, as CPCs did not produce the same results. Although these results would indicate that not all stem cells have equal benefit, it should be interpreted cautiously as the mean dose of BMCs in this study was 205 million cells, while that for CPCs was only 22 million. The lack of effect seen with CPCs in this study may therefore be a function of cell dose rather than type.

Together the results from the BMC clinical trials to date support the promise of stem cell therapy for the heart,

though admittedly the modest functional benefits have tempered clinical enthusiasm. There is the hope that the beneficial effects of BMCs can be improved upon in the future as parameters of patient selection, delivery timing, and dosing are further understood and optimized. Although the answers to these questions will require further clinical studies, the excellent safety profile of BMC cell therapy to date suggests that from an ethical standpoint, these can be pursued.

## MESENCHYMAL STEM CELLS

Mesenchymal stem cells (MSCs) are a subpopulation of the bone marrow, which are involved with repair of tissues of mesenchymal origin, including muscle, bone, and adipose tissue.[28,29] They are multipotent and directable in their ultimate fate, so they have been used experimentally to treat not only bone and connective tissue disorders, but heart disease as well. In addition, they have potent immunomodulatory effects resulting from their ability to alter T-cell activation, thereby limiting inflammation and cell killing. Most importantly for cell therapy of the heart, the immunomodulatory effects of MSCs mean that they are relatively immune-privileged, and do not stimulate a typical rejection response when delivered to an allogeneic recipient.[30] This has led to the concept that MSCs may be an ideal cell for early treatment of tissue injury, as allogeneic MSCs could potentially be stored like a drug, ready to be delivered at any time, "off-the-shelf."

The ability of MSCs to take on a cardiac phenotype when delivered to the heart was first reported by Toma and colleagues in 2002, and led to further trials of MSCs for "cellular cardiomyoplasty."[31] In this study, human MSCs, delivered by direct injection to the normal (noninfarcted) hearts of adult immunodeficient mice, engrafted, and over time came to resemble cardiac myocytes, both morphologically and by surface marker expression. This finding was followed quickly by multiple studies in large animal models. Perhaps most relevant to the content at hand are the results reported by Shake et al. later the same year. They reported that when autologous MSCs were delivered by direct surgical injection to the hearts of pigs 2 weeks after creation of an infarction, the cells engrafted and significantly attenuated the wall thinning and regional dysfunction typically seen after an infarction, as compared with control animals.[32] These findings were supported by multiple subsequent studies of MSC treatment in large animal models of MI and ischemic cardiomyopathy using various cell delivery modalities, including catheter-based endocardial injection.[33–36]

The first clinical trials of MSCs in the heart, like those involving BMCs, were performed using intracoronary infusion after MI. These studies by Chen et al.[13] and Katritsis et al.[19] were small (and in the latter only case-controlled), but showed promising effects in terms of attenuation of LV remodeling and preservation of cardiac function. Neither study reported complications related to intracoronary MSC infusion, which contrasted with multiple animal studies, which reported that such delivery can be complicated by MI due to vascular congestion.[37–39] This may reflect a difference between the coronary vascular capacitance of human and large animal models, though safety concerns have limited further trials using intracoronary infusion to deliver MSCs.

Perhaps one of the more important studies of MSC therapy to date is the Safety Study of Adult Mesenchymal Stem Cells to Treat Myocardial Infarction study, the results of which were published in 2008.[40] In this double-blind placebo-controlled study, patients within 10 days of a first ST-elevation MI were randomized to receive systemic intravenous infusion of allogeneic MSCs or placebo. Overall there was no significant improvement or difference in LVEF in those patients treated with MSCs compared with placebo, but in the subset of patients who had suffered an anterior MI, MSC infusion resulted in significant improvement in LV ejection fraction at 6 months (+7.3 ± 3.4 percent, $p = 0.044$, $n = 12$), while placebo treatment did not (3.4 ± 3.4 percent, $p$ = NS, $n = 8$). Anterior MIs are those most likely to result in significant LV dysfunction, and thus the results of this study are similar to those of REPAIR-AMI, in that those patients with more LV dysfunction experienced greater benefit from BMC therapy.[10] In addition, patients receiving MSCs had significantly fewer arrhythmic events over the 6-month follow-up period: only one patient in the MSC group (2.9 percent) had nonsustained ventricular tachycardia as compared with five patients who received placebo (26.3 percent; $p = 0.018$). Arrhythmic events after MI (and in heart failure in general) are a primary cause of morbidity and mortality, and therefore the antiarrhythmic effect of MSC treatment seen in this study is important. Furthermore, one of the potential concerns about cell therapy for the heart is that delivered cells could be a focus for arrhythmia,[41] thereby negating any functional benefit. Indeed, in the Myoblast Autologous Grafting in Ischemic Cardiomyopathy (MAGIC) trial of intramyocardial injection of skeletal myoblasts for treatment of LV dysfunction (discussed below), cell therapy proved proarrhythmic.[42]

In summary, based on the results of studies done to date, the use of MSCs to treat cardiac dysfunction and repair the heart after infarction is being actively pursued for treatment of both acute and chronic ischemic disease, as well as for dilated (nonischemic) cardiomyopathy. Numerous studies are currently underway to explore the best delivery method, and whether there is an efficacy difference between autologous and allogenic MSCs. If allogenic MSCs are as effective as autologous cells, their use would eliminate the need to isolate and expand cells from each patient, and potentially make cell therapy for the heart more practical and cost-effective.

## CIRCULATING PROGENITOR CELLS

First described by Asahara et al. in 1997,[43] CPCs, or endothelial progenitor cells (EPCs), as they are sometimes called, are a subpopulation of BMCs that can be found in the blood and express surface markers typical of both hematopoietic and endothelial cells.[44] They are able to differentiate into

mature endothelial cells, and contribute to vascular repair and creation of new blood vessels. They are stimulated by, and their concentration in the blood increases in response to, vascular injury or inflammation. Furthermore, their relative abundance in the blood is a predictor of vascular function and health and has been correlated with cardiac risk factor prediction models such as the Framingham Score.[45]

The ability of CPCs to contribute to neoangiogensis and vascular repair makes them a logical choice for the treatment of MI and ischemic cardiomyopathy, and to date CPCs have been studied in multiple clinical trials with mixed results. The potential beneficial effects of these cells were seen in the TOPCARE-AMI study. Twenty patients suffering an ST-elevation MI were randomized to receive intracoronary infusion of autologous BMCs ($n = 9$), or CPCs ($n = 11$).[8] Treatment with either cell type resulted in an increase in LVEF and a significant reduction in ESV, a marker of adverse remodeling, compared with baseline at 4 months after treatment. In the CPC group patients had an average absolute increase in LVEF of 8.2 percent (51.3–59.5 percent), and decrease in ESV of 8.0 mL (56.9–48.9 mL). These results were nearly identical to those seen in the BMC group, and when all patients receiving cell therapy were pooled, the changes in LVEF and ESV from baseline to 4 months were significant ($p = 0.003$ and 0.011, respectively). There was no placebo group in this study, but LVEF and ESV in case-matched control patients ($n = 11$) who were enrolled and followed in the study did not significantly change. At 4 months, patients receiving cell therapy (CPC and BMC pooled) had a significantly greater mean LVEF compared with control patients (60.1 vs 53.5 percent, $p < 0.05$), and a significantly different change in ESV (−13.8 mL vs + 7.8 mL, $p < 0.02$).

The same benefits of CPC infusion were not present, however, in the TOPCARE-CHD Trial, comprised patients with chronic LV dysfunction due to MI. As discussed above, in this study patients who had suffered an MI at least 3 months prior to enrollment were randomized to receive intracoronary infusion of BMCs, CPCs, or placebo[11] in the infarct-related artery, and only those patients receiving BMCs had benefit from cell infusion. There was a significant difference in terms of the number of cells delivered (205 million BMCs vs 22 million CPCs), although there was a similar difference in cell number in TOPCARE-AMI. The disparate findings of these two studies suggest that while CPCs may be of benefit in the acute phase following infarction, they are not of benefit in the chronic phase, or may require a much higher dose to be effective. The biology of the acutely and chronically infracted heart is significantly different, and it is conceivable that CPCs might be suitable for treatment of one condition, and not the other. BMCs, on the other hand, contain a mixed population of cells, including CPCs and MSCs, which may make them more capable of effecting repair in the chronically injured heart. In any case, the results of TOPCARE-CHD have tempered enthusiasm for the use of CPCs in patients with chronic ischemic cardiomyopathy.

Apart from the treatment of LV dysfunction, CPCs have also been investigated for the treatment of refractory angina. In a study reported by Losordo et al., 24 patients with severe angina despite optimal medical treatment and without options for revascularization were randomized to receive endomyocardial injection of escalating doses of autologous CPCs or placebo.[46] The injections were performed using a NOGA Myostar injection catheter that allowed for targeting of cell delivery using electrical activity of the myocardium to delineate areas of scar in conjunction with traditional fluoroscopy. This delivery method was found to be safe, and patients receiving EPCs had some improvement in both qualitative and quantitative measures of angina severity, though no significant differences were found. The lack of a significant difference was attributed to the small sample size.

In all, these results suggest that although CPCs (or EPCs) have potential application in the treatment of both acute MI and chronic angina, they do not appear to be of benefit in chronic ischemic cardiomyopathy, and there are questions about their relative effectiveness compared with BMCs. It remains to be seen whether CPCs might prove beneficial in disorders specifically of the vasculature, an area of study that is being actively pursued.

## Cardiac-Derived Stem Cells

Since resident CSCs was first reported by Piero Anversa and colleagues,[2,3] several studies in preclinical animal models have confirmed the existence of these cells and demonstrated their ability to regenerate myocardial tissue when returned to the heart after ex vivo expansion.[4,5,47] Although CSCs exist in the adult heart, they do so in relatively small numbers compared with the myocardium as a whole, and appear to be primarily responsible for routine cell turnover. They are activated by, and multiply in response to, injury to the heart, but resident CSCs do not appear able to repair large insults de novo. Isolation and ex vivo expansion of CSCs, at least in theory, would allow for large, potentially therapeutic numbers of cells to be grown and returned to the heart to treat dysfunction. Like other forms of cell therapy for the heart, CSCs delivered to the heart may effect repair both directly, by forming new cardiac tissue, and indirectly, by enhancing the function of endogenous, resident stem cells through the production of paracrine factors.[48,49] The predetermined cardiac fate of CSCs may make them more effective than hematopoietic stem cells in forming new cardiac tissue, but their relative effectiveness has yet to be compared.

Initially, there was uncertainty as to which combination of surface marker expression constituted a "true" CSC, but it is now generally accepted that one such marker is c-kit, the surface receptor for stem cell factor. Two methods have been employed to isolate and expand these cells. The first, employed by Anversa and colleagues, selects and expands only those cells that express c-kit. This technique results

in a uniform, clonogenic population of cells, but due to the relatively low density of c-kit+ cells in the heart, it requires harvesting a large amount of cardiac tissue to allow for culture and expansion of a therapeutically relevant number of cells. A different method involves propogation of a heterogenous population of cells, a portion of which are c-kit+. Called "cardiosphere-derived cells," or CDCs, these cells may be routinely isolated from endomyocardial biopsy samples (typically 5–10 mg), obtained using a minimally invasive percutaneous bioptome.[5,47,52] Cardiosphere-derived cells are derived from "cardiospheres," free-floating spherical clusters of undifferentiated cells, which may be generated from biopsied heart tissue. These CDCs feature a subpopulation of c-kit+ cells (~10–20 percent), as well as ones expressing markers typical of MSCs, and may be rapidly expanded to large numbers in culture.

Using the c-kit+ selective method to obtain CSCs, Beltrami et al. first showed that cells isolated from the adult rat heart could differentiate into the three main cardiac cell types, namely: cardiac myocytes, vascular smooth muscle, and endothelial cells.[3] When injected at the infarct border zone in rats, CSCs regenerated myocardial tissue within the infarct and border zones, resulting in reduced infarct size, limited adverse remodeling, and improved ejection fraction and contractility compared with placebo-treated animals.

The isolation and therapeutic use of CDCs were first reported in 2004, when it was demonstrated that CDCs delivered to the hearts of mice after MI formed new, functional cardiac tissue.[5] Further work reported by Eduardo Marbán and his group[47] showed that CDCs can be isolated from routine human endomyocardial biopsy specimens, and grown to large numbers in vitro. When these cells were delivered to immunodeficient mice with acute MI, the delivered CDCs formed all three cardiac cell lines, regenerated cardiac tissue within the infarct border zone, and preserved LVEF as compared with animals treated with placebo (using both the delivery solution and human fibroblast cells for controls). Subsequent study in large animals showed that CDCs delivered to the heart by intracoronary infusion 4 weeks after MI engrafted and formed mature cardiac myocytes and vascular cells (see Fig. 53-3), and compared with placebo, reduced relative infarct size and improved hemodynamic function.[30]

The results of these preclinical experiments prompted phase I clinical trials using both c-kit-selected CSCs and CDCs for the treatment of ischemic cardiomyopathy. In the Cardiac Stem Cell Infusion in Patients with Ischemic Cardiomyopathy (SCIPIO) trial, patients with ischemic cardiomyopathy undergoing coronary artery bypass grafting (CABG) received intracoronary infusion of autologous CSCs isolated from the right atrial appendage, which is surgically resected at the time of CABG. In the Cardiosphere-Derived Autologous Stem Cells to Reverse Ventricular Dysfunction (CADUCEUS) study, patients suffering a recent MI with significant LV dysfunction (LVEF 25–45 percent) underwent percutaneous endomyocardial biopsy, from which

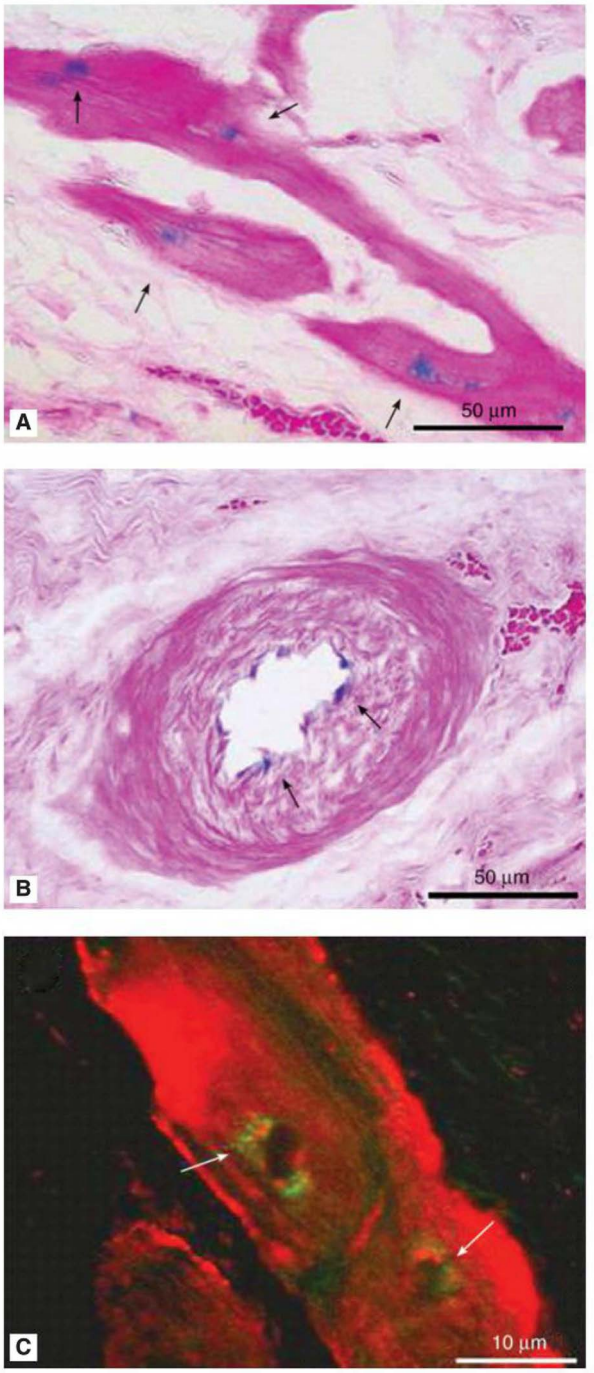

**FIGURE 53-3** Histopathologic slides of tissues taken from infarct border zone of pigs 8 weeks after intracoronary infusion of LacZ-labeled autologous cardiosphere-derived cells (CDCs) showing CDC engraftment, survival, and differention. In panel **A**, multiple mature cardiac myocytes with X-gal+ nuclei (arrows) are seen at the infarct border zone. In panel **B**, X-gal+ cells are incorporated in an arteriole at infarct border zone (arrows). Panel **C** shows immunohistochemical staining of the infarct border zone revealing adjacent cardiac myocytes with β-galactosidase+ nuclei (green) and expression of α-sarcomeric actin (red), indicative of a mature phenotype.

CDCs were isolated and later returned to the heart using intracoronary infusion. Both studies completed enrollment and reported positive results[50,51] that are expected to lead to phase II trials.

It should be noted that in contrast to the majority of trials using BMCs and MSCs, in the current trials of CSCs, patients receive cells weeks to months after the initial insult, in the subacute to chronic phase after infarction. This delay is in large part necessitated by the time required to isolate and expand autologous CSCs. If CSCs prove clinically effective at this time point, they will hold much promise for the treatment of those with chronic LV dysfunction, but one could also envision a treatment strategy for the treatment of acute MI with significant LV dysfunction in which such patients receive BMCs or MSCs in the acute phase, and those with residual dysfunction would later receive CSCs.

Although the majority of studies using CSCs focused on the heart damage caused by infarction, the concept of a population of resident CSCs responsible for routine repair and cell turnover has led to the concept that depletion or alteration of a patient's CSCs might result in cardiac dysfunction, and in turn, whether repletion of the CSC pool might reverse that dysfunction. In proof of this concept, De Angelis et al. published a study of a rat model of anthracycline-induced cardiomyopathy. In this study, treatment with syngeneic CSCs after the development of cardiomyopathy preserved LV function and limited adverse remodeling compared with placebo-treated animals.[53] If these results are confirmed, one could envision a treatment strategy in which patients undergoing a known cardiotoxic chemotherapy might "bank" autologous CSCs for therapeutic use in the event they develop cardiac dysfunction.

In summary, although it was once thought that the heart was incapable of repair, it is now known that a population of stem cells resides in the heart. In animal studies these cells have shown benefit for the treatment of both ischemic and nonischemic LV dysfunction. The clinical benefit of CSCs and relative effects of these cells compared with bone marrow–derived populations remain to be determined, but the mere recognition of the existence of resident stem cells in the heart presents an opportunity for the development of new therapeutic paradigms.

## Other Cell Types

### SKELETAL MYOBLASTS

Skeletal myoblasts offer a cautionary note in the use of progenitor cells for treatment of heart disease. One of the first types of cells used in clinical trials for the treatment of ischemic LV dysfunction, the theoretical advantages included the use of autologous cells, the ability to form large numbers, and resistance to hypoxia. The effects of direct epicardial injection of myoblasts at the time of surgery for CABG were examined in the MAGIC trial. In this trial skeletal myoblasts not only failed to significantly alter regional or global measures of LV systolic function compared with placebo, but were associated with a significantly higher rate of serious ventricular arrhythmias.[42] The latter finding could be explained by different electrical activation and coupling required of cardiac myocytes as compared with that of skeletal muscle cells; nevertheless, the realization that cell therapy could result in life-threatening arrhythmias gave the field pause.[41] This adverse outcome has instructed subsequent clinical trials of stem cell therapy for the heart, in which close monitoring for cardiac arrhythmias is imperative. To date, the use of BMCs and CSCs have not been found to be arrhythmogenic, and, as mentioned above, in at least one study MSC therapy reduced arrhythmias, an unexpected and reassuring finding.

### EMBRYONIC STEM CELLS

Embryonic stem cells (ESC), in theory, hold significant promise for the treatment of heart disease. Their clinical use has been limited, by reports that when used in animal models de novo, without differentiation or modification, injected ESCs can result in teratoma formation.[54] Using techniques to direct ESC differentiation along a cardiac pathway prior to delivery to the heart may eliminate this problem; however, further basic investigation is necessary before preclinical or clinical studies are performed. Induced pluripotent stem cells, created by genetic modification of fully differentiated adult cells, present another exciting source of potential cell therapy for the heart, though they have undergone only limited study at this point.

# STEM CELL DELIVERY METHODS

In addition to questions about which type of stem cell might be optimal for treatment of heart disease, a number of delivery methods have been studied, and the best remains to be determined. Techniques that have been used clinically include intracoronary infusion, epicardial injection (during surgery), endocardial injection (using catheter-based techniques), and intravenous infusion. In animal models, all of these techniques have been employed, as well as novel methods, employing gel or tissue matrices applied to the epicardium during surgery. The relative benefits and limitations of these delivery methods will be discussed below.

## Intracoronary Infusion

Of the delivery methods used to date, intracoronary infusion has been used most commonly.[8,10,11,13,19] Advantages of the intracoronary delivery method, whether using a standard angioplasty balloon catheter, or a specially designed catheter, include that it is minimally invasive, selective, and widely available clinically. In contrast to catheter-based endocardial injection, intracoronary infusion could be performed in a clinical cardiac catheterization laboratory,

utilizing techniques familiar to any interventional cardiologist. For these reasons, intracoronary infusion is the technique employed in most clinical studies of stem cell therapy for the heart. The major limitation of intracoronary infusion is that, at least when used in animal studies, intracoronary infusion of large numbers of cells has been at times complicated by vascular congestion and resultant infarction. For example, in preclinical animal experiments using miniature swine, intracoronary infusion of more than 300,000 CDCs/kg body weight was associated with raised troponin levels.[52] This extrapolates to approximately 30 million cells for the typical human subject (70 kg), which is far less than the 200–300 million BMCs that can be delivered by intracoronary infusion without reported complication in studies such as REPAIR-AMI and TOPCARE-CHD.[10,11] The difference is likely due to the diameter of these cell types: although BMCs have a typical diameter of 5–10 μm in suspension, CDCs and MSCs have a diameter of approximately 20 μm,[55] which is larger than the typical capillary lumen diameter of 7–10 μm. Another theoretical limitation of intracoronary infusion is that entry of cells into the myocardium requires crossing the vessel wall and tracking to the area of injury. Vascular permeability and the signals available to help stem cells track may be drastically affected by the stage of tissue injury and relative level of inflammation. Also, although large cells may clog the capillaries, a significant portion of smaller cells, due to their size, may pass directly from the arterial to venous network without ever coming in close enough contact with the vascular wall to enter the myocardium. Despite these potential limitations, the appeal of intracoronary infusion lies in its relative ease and wide clinical availability, and it is a technique that has proved effective in preclinical and some clinical studies to date.

## Epicardial Injection

Direct myocardial injection, via either the epicardium or the endocardium, has been widely employed in clinical trials as well. Epicardial injection during open heart surgery allows for visualization of the area of injury and exact targeting of the injections.[32,42] In addition, a potentially unlimited number of cells, regardless of size, can be delivered by this method. The obvious limitation, however, is that this technique, at least as it is currently employed, requires open chest surgery, a level of procedural invasiveness that in most cases is not felt to be justified for delivery of cell therapy alone. To date, epicardial stem cell injections have been performed only at the time of regularly scheduled surgery, most commonly during CABG. With the use of less invasive surgical methods, perhaps with thoracoscopic or robotic techniques, epicardial cell delivery may be performed in a less invasive manner that could make cell delivery alone an acceptable purpose for the procedure. Recent advances in epicardial mapping and ablation of ventricular arrhythmias using catheters placed in the pericardial space may also lead to methods by which catheter-based epicardial injections could be performed.

## Endocardial Injection

Endocardial cell injection has been performed using various catheter-based systems in a number of clinical trials.[46,56] These catheters are advanced to the left ventricle retrograde through the aortic valve using vascular access typical of interventional cardiology procedures. The Biosense NOGA system allows for electromechanical mapping of the ventricle prior to injection to delineate areas of scar and allow for targeted cell delivery.[46] Information gathered during the electromechanical mapping can be used with anatomic information from cardiac CT or MRI to provide even more precise targeting of injections. The Biosense system, however, is expensive, and is not available in the typical catheterization laboratory; its use therefore requires a substantial institutional commitment to cell therapy.

Other endocardial injection catheters do not require a dedicated mapping system, and instead use widely available fluoroscopic equipment. The Biocardia Helical Infusion System, for example, employs a deflectable guide catheter to advance a spiral-shaped injection needle to the endocardial wall (see Fig. 53-4).[56] Once in contact, the needle is rotated so that it advances into the myocardial wall similar to an active fixation pacemaker lead. After the injection is complete, the needle is rotated in the opposite direction to remove it from the wall. A possible advantage of this system is that by temporarily fixing the needle well into the myocardium, there is greater retention of the cell suspension as compared with a traditional straight needle. This, and other endocardial injection catheters, must be used cautiously, however, as myocardium scarred and thinned by prior infarction may be susceptible to perforation. Case selection is therefore critical to safe cell delivery by this method.

## Intravenous Infusion

Intravenous infusion is the least invasive technique used to date to deliver stem cells. The limited invasiveness of this technique must be balanced, however, with reduced delivery precision, as animal studies show that the majority of stem cells infused by this technique are retained in the lungs.[57,58] Nevertheless, hematopoietic stem cells are able to target areas of inflammation and injury, and the results of the PROCHYMAL study (described above) suggest there is potential benefit to intravenous infusion of MSCs within 10 days of a MI.[40] It remains to be determined whether the positive results seen in PROCHYMAL were primarily the result of MSCs targeting to and entering the area of myocardial damage. In addition, it is unclear whether such therapy would be beneficial in the setting of chronic ischemic cardiomyopathy, or nonischemic cardiomyopathy, in which an acute injury signal is not present and stem cell trafficking to the heart may be limited.

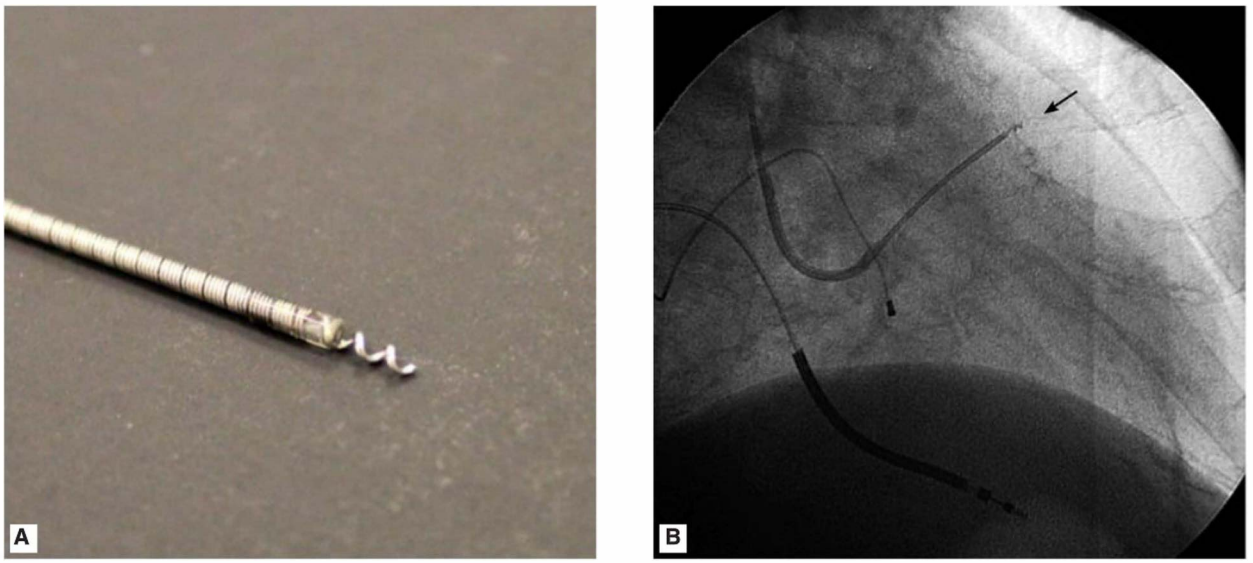

**FIGURE 53-4** The Biocardia Helical Injection Catheter (Biocardia, Inc, San Carlos, CA) is designed for endocardial delivery using percutaneous techniques. On contact with the endocardium, the helical needle at the end of the catheter (panel **A**) is rotated, advancing into the tissue and allowing for temporary fixation during cell infusion. Panel **B** shows the catheter advanced to the anterior wall for stem cell delivery in a patient with severe LV dilation and dysfunction.

## QUESTIONS AND FUTURE DIRECTIONS FOR CARDIAC STEM CELL THERAPY

As described above, stem cell therapy for the heart, with the exception of skeletal myoblasts, is safe, though the measured clinical effects on LV function remain modest to date. The failure to achieve the more robust benefits seen in animal models may reflect the complex nature of heart disease in adult humans, who most often have other comorbid conditions, and therefore may not respond in the same way to cell therapy as an otherwise healthy laboratory animal with experimentally induced cardiac dysfunction. Along the same lines, it remains to be determined whether, in cases where autologous stem cells are used, all stem cells are equally beneficial. For example, are the cardiac-derived stem cells obtained from an 80-year-old patient with diabetes and renal failure as efficacious clinically as those of a 48-year-old with premature coronary disease who is otherwise healthy? Furthermore, in cases where allogeneic cells might be used, might it be better to receive cells from a healthy 18-year-old donor as opposed to the patient with LV dysfunction? Although the cells of all patients may not have equal therapeutic efficacy, are there genetic or other modifications that could improve cellular efficacy?

Beyond the cells themselves, findings from the REPAIR-AMI trial and others suggest that certain patients benefit more than others from cell therapy, and point to unanswered questions about the optimal timing of cell therapy after injury. Perhaps most compelling is the finding across multiple studies that those patients with the greatest degree of LV dysfunction after MI benefit the most from cell therapy. This suggests that cell therapy can fill an unmet clinical need, and that the overall modest results to date may in part be due to dilution of studies with patients who have minimal LV dysfunction and therefore do not stand to benefit from cell therapy. The challenge going forward is finding ways to identify those patients that truly stand to benefit from cell therapy and focus study on these patients.

Finally, the results of multiple studies, both clinical and preclinical, suggest that although cell therapy can be efficacious, the benefit of cell therapy for the heart may not be the direct result of the cells themselves, but instead the paracrine factors and other signals the cells produce. The theoretical advantage of cell therapy is that delivered cells can adapt and respond to their environment in a manner far more complex than our current understanding. Regardless of whether it is ultimately understood that stem cells themselves are critical to generate adequate tissue repair, or only the factors they produce, the burden of cardiovascular disease warrants continued efforts to explore this new therapeutic modality.

## STEM CELLS FOR CARDIAC SURGICAL DISEASE BOARD REVIEW QUESTIONS (CHAPTER 53)

1. How many Americans are estimated to have congestive heart failure?

   A. 100,000
   B. 500,000
   C. 6,000,000
   D. 10,000,000
   E. 50,000,000

2. Which of the following stem cell lines have been used in clinical trials for treatment of cardiac disease?

   A. Mesenchymal stem cells
   B. BMCs
   C. EPCs
   D. Skeletal myoblasts
   E. All of the above

3. Based on the findings of the REPAIR-AMI trial of BMCs in patients with an acute myocardial infarction, which of the following patients would be expected to have the greatest improvement in LVEF from BMC-therapy compared with placebo?

   A. Baseline LVEF 30 percent, cells given within 12 h of infarction
   B. Baseline LVEF 30 percent, cells given 1 day after infarction
   C. Baseline LVEF 30 percent, cells given 6 days after infarction
   D. Baseline LVEF 55 percent, cells given 1 day after infarction
   E. Baseline LVEF 55 percent, cells given 6 days after infarction

4. Which of the following types of stem cells has been associated with an increased rate of cardiac arrhythmias in clinical study?

   A. Mesenchymal stem cells
   B. BMCs
   C. Skeletal myoblasts
   D. Cardiac-derived stem cells
   E. Embryonic stem cells

5. Which of the following cell delivery techniques has been used most often in clinical trials of stem cell delivery to the heart?

   A. Intracoronary infusion
   B. Epicardial injection
   C. Intravenous infusion
   D. Endocardial injection
   E. Coronary sinus infusion

## ANSWERS

1. **Answer: C.** The American Heart Association estimates that nearly 6 million Americans suffer from congestive heart failure, about 2 percent of the total population.
2. **Answer: E.** Mesenchymal stem cells were used in the Safety Study of Adult Mesenchymal Stem Cells to Treat Myocardial Infarction study. BMCs were used in REPAIR-AMI and numerous other studies. Endothelial progenitor cells, or CPCs, were used in TOPCARE-CHD. Cardiac stem cells are being used in the SCIPIO and CADUCEUS trials.
3. **Answer: C.** In the REPAIR-AMI trial, those patients with significant LV dysfunction who received BMC infusion longer from the time of MI (6 days or greater) had a greater likelihood of significant improvement.
4. **Answer: C.** In the MAGIC trial, epicardial injection of skeletal myoblasts was associated with an increased rate of arrhythmias compared with placebo.
5. **Answer: A.** Due to the ease of use, minimal invasiveness, and wide clinical availability, intracoronary infusion has been used most often to deliver stem cells to the heart in clinical trials.

# Minimally Invasive Cardiac Surgery

*D. Kalavrouziotis*
*Francois Dagenais*

**KEY CONCEPTS**

- Innovations in alternative methods for cannulation and cardiopulmonary bypass (CPB), new visualization systems, retractors and stabilizers, and robotic platforms have facilitated the development of minimally invasive cardiac surgery.
- Minimally invasive direct coronary artery bypass (MIDCAB) and totally endoscopic coronary artery bypass grafting (TECAB) remain hindered by inherent technical complexities.
- Minimally invasive approaches for mitral valve surgery include mini-right thoracotomy, partial sternotomy, parasternal approach, and robotic port access.
- Complications associated with the endoclamp include balloon migration/rupture and retrograde aortic dissection.
- Elevated atherosclerotic plaques greater than 2 mm in height in the descending thoracic aorta or arch may increase the risk of retrograde cerebral and other systemic embolization and constitutes a contraindication to femoral artery-perfused minimally invasive mitral valve surgery.
- Relative contraindications for a mini-right thoracotomy mitral approach include previous right thoracotomy with dense pleural adhesions, significant obesity, severe chest deformity (e.g., pectus excavatum), scoliosis, and prior breast implant or reconstruction.
- Other operations that can be performed through a small right thoracotomy include tricuspid valve surgery, atrial septal defect closure, atrial myxoma resection, and septal myectomy.
- Minimally invasive approaches for aortic valve surgery generally consist of limited sternotomies.

The midline sternotomy incision offers excellent access to all cardiac structures and has been the traditional route for the performance of most cardiac operations. However, the growth and advancement of percutaneous interventional techniques such as coronary artery stenting have been accompanied by a growing patient willingness to undergo procedures with less favorable mid- and long-term outcomes compared with coronary artery bypass grafting (CABG), largely to enjoy lower periprocedural risks and less invasiveness. In response to this, cardiac surgeons have progressively developed less invasive operations to provide the benefits of standard cardiac procedures with less morbidity. Through the use of innovative surgical approaches combined with new technology, cardiac surgeons have introduced a spectrum of novel, minimally invasive operations. The avoidance of cardiopulmonary bypass (CPB) and/or the full median sternotomy incision are the main features common to this new generation of procedures. This chapter describes and discusses the evolution and results of minimally invasive cardiac surgery, with an emphasis on minimally invasive mitral valve operations.

## MINIMALLY INVASIVE CORONARY ARTERY BYPASS GRAFTING

Although the first attempts to revascularize ischemic myocardium were accomplished on a beating heart, the advent of CPB with cardioplegic arrest offered a reliable and highly reproducible means to perform CABG. During the mid-1990s, in an attempt to circumvent the need for sternotomy, surgeons developed a procedure to create a left internal mammary artery (LIMA)-to-left anterior descending coronary artery (LAD) anastomosis through a small left anterior thoracotomy. In this procedure, termed minimally invasive direct coronary artery bypass (MIDCAB), the LIMA

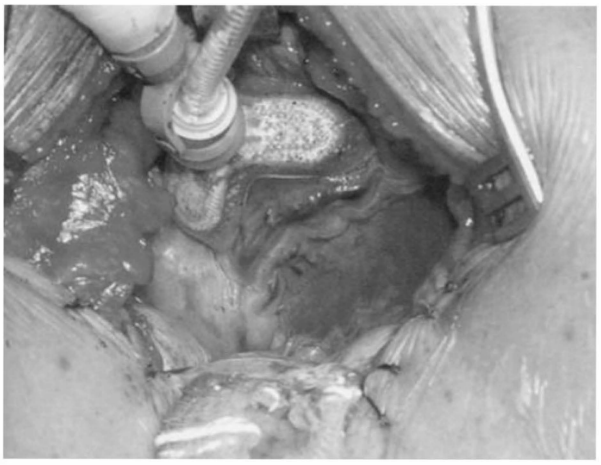

**FIGURE 54-1** Exposure and stabilization of right coronary artery (RCA) and posterior descending artery (PDA) using EndoStarfish via a transabdominal approach. (Reproduced with permission from Subramanian VA, Patel NU, Patel NC, et al. Robotic assisted multivessel minimally invasive direct coronary artery bypass with port-access stabilization and cardiac positioning: Paving the way for outpatient coronary surgery? *Ann Thorac Surg* 2005;79(5):1590–1596. Copyright Elsevier.)

is harvested through a left anterior thoracotomy or limited sternal split incision with the assistance of a variety of chest retractors. A stabilizer is subsequently applied on the beating heart, thus facilitating the performance of the coronary anastomosis (Fig. 54-1). Coronary occlusion is obtained proximally by snaring the coronary artery with a Silastic tape. Early experiences reported good graft patency rates.[1,2] In a meta-analysis including 17 studies of over 4000 patients, Kettering reported early and late mortality rates of 1.3 and 3.2 percent, respectively.[3] Conversion to sternotomy or CPB was 1.8 percent. At 6 months of follow-up, 3.6 percent of the 445 grafts that were studied angiographically were occluded; 7.2 percent had significant stenosis. Decreased postoperative pulmonary dysfunction and atrial fibrillation, as well as better pain management and quality of life indices have also been reported in patients undergoing MIDCAB.[4–6] MIDCAB procedures have also been applied with success to coronary reoperations.[7] Despite the purported advantages of MIDCAB, these minimally invasive procedures remain technically more challenging and require longer operative times with a higher rate of anastomotic revision compared with LIMA-to-LAD anastomoses performed through a standard sternotomy.[8,9] Furthermore, wound complications including incisional hernia, wound dehiscence or infection, and chronic pain, have been reported in up to 9.1 percent of patients.[10] Such wound complications, which are often a source of significant morbidity, are mainly linked to the excessive rib spreading required to harvest the LIMA through a limited thoracotomy. To minimize wound complications, surgeons developed a procedure to harvest the LIMA with a standard thoracoscope, thus minimizing rib spreading.[11]

Multivessel disease is also amenable to minimally invasive approaches without the use of CPB. The LIMA can be harvested and all myocardial territories can be revascularized via a small left anterolateral thoracotomy, with additional stab incisions made for the introduction of epicardial stabilizers and apical positioners. Proximal anastomoses are constructed either to the LIMA or to the ascending aorta using a proximal connector or direct suture after application of a side-biting clamp. A recent two-center consecutive series of 450 patients, including 7 patients with previous CABG, demonstrated acceptable procedural outcomes, with a 1.3 percent mortality rate, conversion to sternotomy in 3.8 percent, use of CPB in 7.6 percent, stroke in 2 patients (0.4 percent), and thoracic wound infection in 1 patient (0.2 percent).[12] However, these were a highly selected group of patients, with three-vessel disease present in only 28.4 percent of patients; 73.8 percent received only one or two grafts. All 34 patients requiring CPB received a graft to the circumflex coronary system. At a mean follow-up of 19 months, 3 percent of patients required percutaneous coronary intervention, mainly related to problems with the proximal LIMA T-graft anastomosis.

## TOTALLY ENDOSCOPIC CORONARY ARTERY BYPASS (TECAB)

Several dedicated centers have actively pursued the development of robot-assisted totally endoscopic coronary artery bypass grafting (TECAB) on the beating and arrested heart. The first successful TECAB on a human arrested heart was performed by Loulmet and colleagues in 1998.[13] With this approach, the LIMA is harvested, femoro-femoral CPB is initiated, and the heart is arrested by occluding the ascending aorta with an endovascular balloon and infusing cardioplegic solution into the aortic root. The LIMA-to-LAD anastomosis is performed in a running fashion using robotic instrumentation passed into the chest via modified thoracoscopic ports.

Despite its initial success, TECAB is associated with significant technical limitations. First, aortic cross-clamp and CPB times are usually much greater than with standard techniques.[14] Second, the duration of LIMA harvest is significantly prolonged and LIMA injury can occur in up to 6 percent of patients.[15] Third, the procedure is generally limited to single-vessel bypass of the LAD, although successful multivessel robot-assisted operations have also been reported.[16] In experienced hands, conversion rates to sternotomy or larger thoracic incisions are less than 10 percent. In one study, graft patency was 100 percent at discharge among the 22 out of 45 patients with predischarge angiograms.[17] Furthermore, recently published 5-year clinical outcomes in 100 patients demonstrate greater than 90 percent survival and freedom from angina.[18] However, multicenter randomized controlled data are needed to better define the role of TECAB in the current management of patients with coronary artery disease, especially given the higher prevalence of multivessel and diffuse disease, diabetes, previous percutaneous coronary intervention, and higher urgency in contemporary surgical cohorts. To ensure

a safer and more reliable operation, further technological refinements are needed. Improvements in imaging technologies, telemanipulation systems, and endoscopic stabilizers will optimize surgical exposure and anastomotic construction. Direct suturing of the coronary anastomosis remains difficult and time-consuming. Development of distal anastomotic devices may facilitate the performance of TECAB anastomoses on the beating heart. However, variations in patient anatomy, such as intramyocardial LAD or excessive epicardial fat, significantly limit the applicability of these techniques. In such circumstances, the use of endoscopic ultrasound or other imaging modalities may prove useful for the accurate identification of coronary vessels. Although the current literature supports the feasibility of TECAB on the beating or arrested heart using computer-assisted surgical robotic systems, cost issues, limited clinical indications, and a steep learning curve currently limit the widespread use of this technology. Robot-assisted minimally invasive coronary artery bypass surgery remains in its evolutionary stage. Its success will be predicated on a methodical approach, combining improvements in both technology and in surgical techniques.

## MINIMALLY INVASIVE MITRAL VALVE OPERATIONS

The era of mitral valve surgery began with the treatment of severe mitral stenosis by closed commissurotomy.[19] However, it was not until the development of the heart–lung machine in 1953 that direct access to the mitral valve became possible. Commissurotomy was then performed under controlled direct vision through a left or right atriotomy. Development of a replacement prosthesis for valves not amenable to repair progressed rapidly after the first mitral valve replacement performed in 1961 by Starr and Edwards.[20] The complications encountered with valve replacement with a prosthesis led surgeons to investigate alternative techniques to repair the mitral valve. The establishment of a physiologic classification system of mitral valve disease by Carpentier in the 1970s allowed for a systematic approach to repair the mitral valve.[21] Further developments in prosthetic rings ensured reproducible and durable mitral valve repairs.[22] With refinements in both operative technique and perioperative patient management, mitral repair surgery through a sternal approach can now be performed with mortality rates ranging from 1 to 4 percent with minimal morbidity.[23,24] Furthermore, freedom from reoperation after mitral repair is excellent, especially when the disease is localized to the posterior leaflet and the postoperative echocardiogram shows minimal residual mitral regurgitation.

## EVOLUTION IN MINIMALLY INVASIVE MITRAL SURGERY TECHNIQUES

Although right lateral thoracotomy with femoral cannulation was utilized to expose the mitral valve during the early days of open cardiac surgery, standard sternotomy became the preferred method to access the mitral valve. During the mid-1990s, efforts to avoid a midline sternotomy led to the development of alternate ways to expose the mitral valve. The Cleveland Clinic group initially advocated a parasternal approach but then shifted to an upper midline partial sternotomy. Using this technique, Cosgrove and colleagues reported results similar to a standard sternotomy.[25] Other partial sternotomy incisions have also been described, such as the subxiphoid approach consisting of a transverse skin incision overlying the xiphoid process with an inverted J-type mini-sternotomy.[26] Advantages of these approaches include central cannulation for CPB as well as good valve exposure. However, the need for sternal division is not obviated and incisions are less esthetically pleasing to patients when compared with the right mini-thoracotomy incision.

During the same time period, other surgeons revisited the right lateral thoracotomy approach to expose the mitral valve. Initial work demonstrated that the mitral valve could be accessed and operations adequately performed through a small right thoracotomy incision.[27] Experimental work by the Stanford group led to the development of the Port-Access Endo-CPB system.[28] This platform utilizes peripheral cannulation through the femoral vessels for CPB (Fig. 54-2). A branched femoral arterial cannula allows insertion of an endovascular balloon catheter which is positioned in the ascending aorta. Aortic occlusion is performed by inflating the balloon and cardioplegia may be administered through the distal lumen of the catheter. A percutaneous retrograde cardioplegia catheter was also developed and is positioned in the coronary sinus through a right internal jugular venous puncture (Fig. 54-3). Similarly, a venting catheter may be percutaneously positioned in the main pulmonary artery to ensure a bloodless operative field. The mitral valve is exposed using specialized left atrial retractors. Clinical studies performed with the Port-Access system (Edwards Lifesciences, Irvine, CA, USA) demonstrated the feasibility of the procedure.[29] However, device-specific complications such as endoclamp-induced retrograde aortic dissection led to further modification of the technique. In 1997, Chitwood introduced a percutaneous transthoracic aortic clamp (Fig. 54-4A), thus eliminating use of the endoclamp and its attendant potential risks such as balloon migration, rupture, and retrograde aortic dissection.[30] To enhance mitral valve visualization during the procedure, other groups have proposed the use of two-dimensional video endoscopes.[31] Robotic approaches involving the da Vinci system (Intuitive Surgical, Inc., Sunnyvale, CA, USA) have also emerged with good short- and midterm outcomes (Fig. 54-5).[32]

Throughout the development of the right mini-thoracotomy technique, the establishment of dedicated teams was recognized as a prerequisite to a successful outcome. Anesthesiology expertise in transesophageal echocardiography is of paramount importance for percutaneous catheter positioning. Effective communication between team members during the various steps of the operation is essential. Furthermore, perfusionists need to be facile in the management of novel CPB techniques to ensure optimal

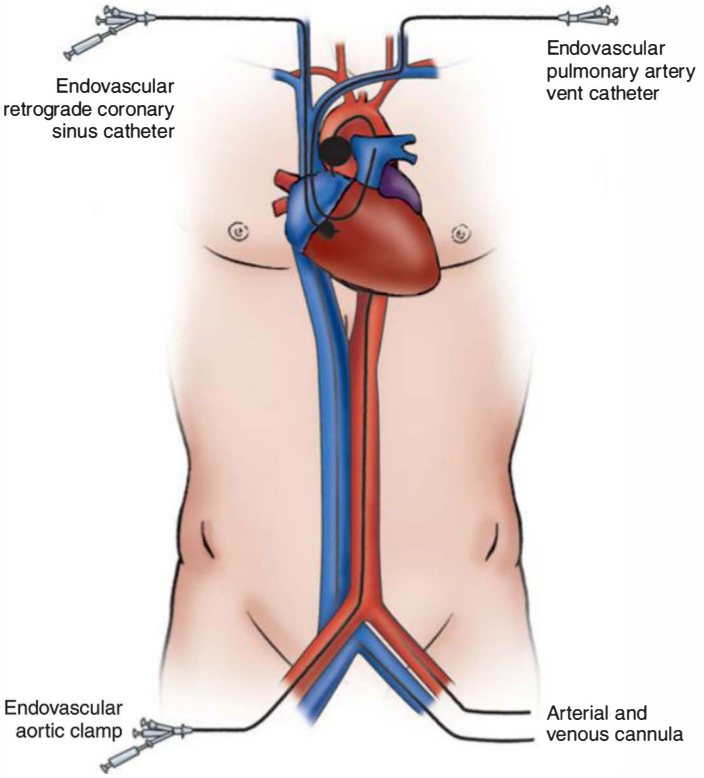

**FIGURE 54-2** Schematic diagram of the Port-Access EndoCPB system. The venous and arterial cannulas are connected to the bypass pump. The endovascular aortic clamp is inserted through the femoral artery. The pulmonary artery vent is inserted through the left jugular vein, and the percutaneous venting catheter is inserted through the right jugular vein. functioning of the Port-Access platform and a smooth conduct of the operation.

Currently, most centers favor the right lateral minithoracotomy approach for minimally invasive mitral valve operations. CPB is instituted through cannulation of the femoral vessels. Long-shafted specialized instruments are used for mitral valve manipulation (Fig. 54-4B). Although the majority of centers tend to avoid using the endovascular aortic clamp, its use has been proven to be safe in high-volume centers well-experienced in this technique.[33] Conversely, the Chitwood clamp adopted by numerous groups, has been shown to be safe and effective and requires

**FIGURE 54-3** Percutaneous retrograde cardioplegia catheter.

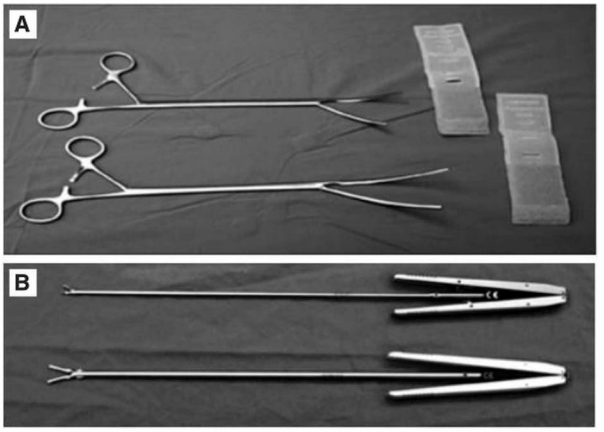

**FIGURE 54-4** Chitwood transthoracic aortic clamps (**A**) and long-shafted instruments (**B**) used in minimally invasive mitral valve surgery.

less aortic manipulation. Although cardioplegia may be administered by direct needle puncture of the ascending aorta, the use of a percutaneously inserted coronary sinus catheter for retrograde cardioplegia as well as percutaneous pulmonary artery catheterization for left ventricular venting facilitate exposure by allowing for a bloodless operative field without the presence of cumbersome catheters in the limited work space (Fig. 54-6).

## PATIENT SELECTION

Indications for minimally invasive mitral valve surgery are similar to those that are in effect during conventional mitral surgery through a median sternotomy. However, patient-related factors may influence the decision to proceed with a minimally invasive approach. For example, when considering retrograde aortic perfusion through the femoral artery during CPB, the presence of elevated atherosclerotic plaques >2 mm in height in the descending thoracic aorta or arch may increase the risk of retrograde cerebral and other systemic embolization and constitutes a contraindication to femoral artery-perfused minimally invasive mitral valve surgery. The surgeon must then evaluate alternative arterial cannulation sites or, if not available, resort to a conventional median sternotomy. Other relative contraindications are the presence of significant obesity, a previous right thoracotomy with dense pleural adhesions, a severe chest deformity such as a pectus excavatum or severe scoliosis, and previous breast implant or reconstruction. In our center, over 80 percent of patients referred for an elective isolated mitral valve operation are candidates for a right mini-thoracotomy. The principles of mitral valve replacement and repair during minimally invasive exposure of the mitral valve are no different than those that

FIGURE 54-6 View of a completed mitral valve repair through a limited right thoracotomy.

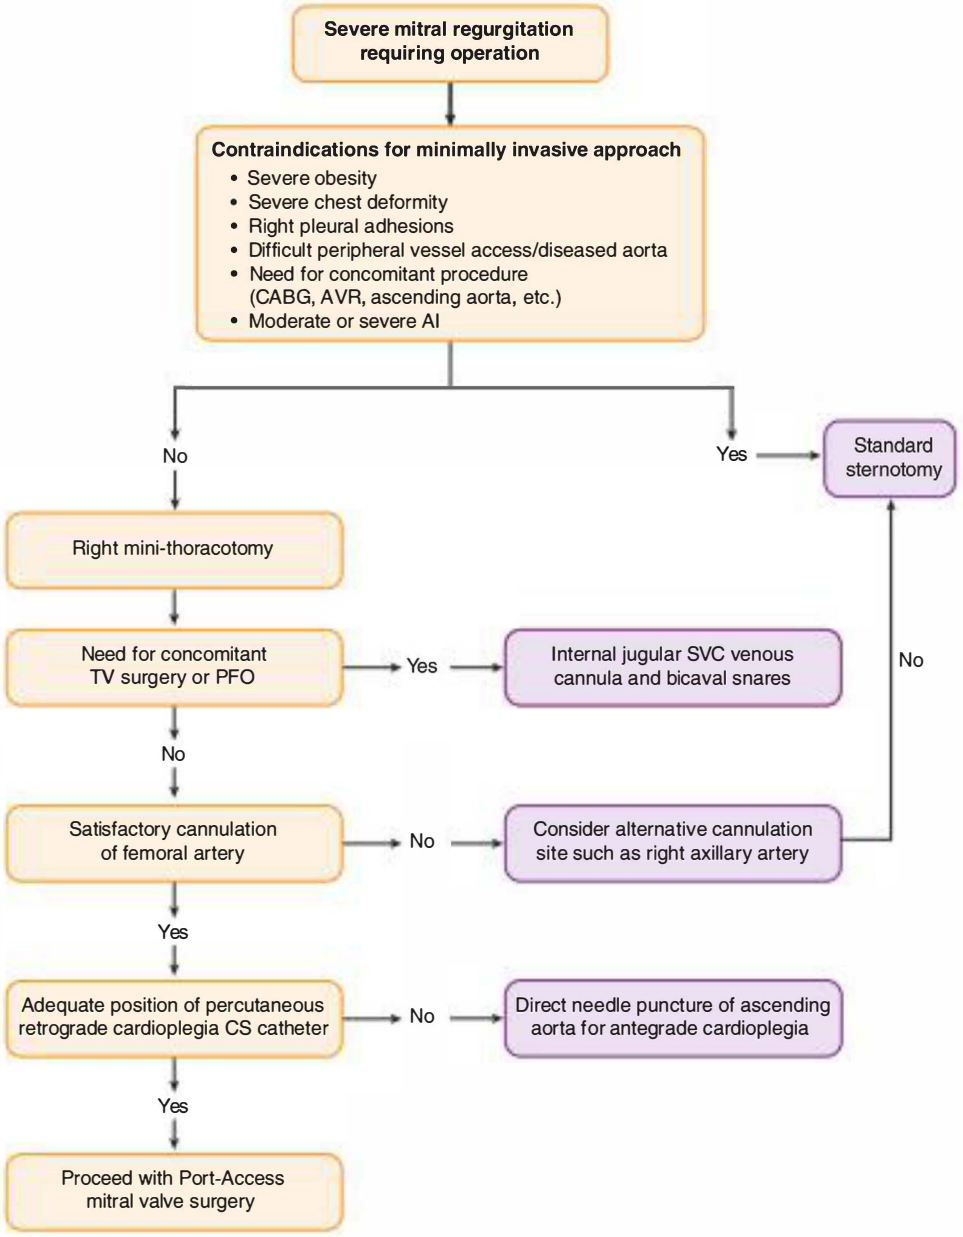

**FIGURE 54-7** Decision-making flowchart used during minimally invasive mitral valve surgery. AI, aortic insufficiency; AVR, aortic valve replacement; CABG, coronary artery bypass graft surgery; CS, coronary sinus; PFO, patent foramen ovale; SVC, superior vena cava; TV, tricuspid valve.

are now well-established in mitral surgery by standard sternotomy. A decision-making flowchart is shown in (Fig. 54-7).

## SURGICAL TECHNIQUE

At the Quebec Heart and Lung Institute, Quebec City, Canada, minimally invasive mitral valve surgery through a right mini-thoracotomy has been performed since 2003. Our technique has been standardized as follows. Following general anesthesia and endotracheal intubation, a retrograde cardioplegia coronary sinus catheter and a pulmonary artery venting catheter are inserted through the right internal jugular vein. Positioning of the coronary sinus catheter is guided by transesophageal echocardiography and fluoroscopy. A bronchial blocker is placed in the right mainstem bronchus to deflate the right lung, thus minimizing lung trauma during the procedure. The right side

of the thorax is elevated 30° from the operating table and a 3- to 5-cm fifth intercostal space right lateral mini-thoracotomy is performed. Soft-tissue and intercostal retractors are placed with care being taken not to over-spread the ribs to minimize postoperative pain and thoracic splinting. The pleural cavity is flooded with $CO_2$ to facilitate de-airing of the cardiac chambers. The femoral vessels are exposed through a 2- to 3-cm incision in the inguinal fold. A 22F or 25F venous cannula (Edwards Lifesciences, Inc., Irvine, CA, USA) is inserted in the common femoral vein with its distal tip positioned in the superior vena cava under echocardiographic guidance. A 20F-to-22F arterial cannula (DLP; Medtronic, Inc., Minneapolis, MN, USA) is inserted through the common femoral artery. CPB with mild passive hypothermia is then instituted with vacuum-assisted venous drainage. The aorta is clamped using a Chitwood transthoracic clamp inserted in the third intercostal space and myocardial protection is achieved with intermittent retrograde cardioplegia via the balloon-inflatable coronary sinus catheter every 15 to 20 min. Exposure of the mitral valve is performed through Sondergaard's groove and specialized left atrial retractors are placed. Visualization of the mitral valve and subvalvular apparatus is assisted by video thoracoscopy. The operation then proceeds as in standard mitral valve approaches.

[b]Serum creatinine > 1.7 mg/dL.

## RESULTS

Although a small, randomized clinical trial demonstrated the feasibility of minimally invasive mitral valve surgery,[34] no large, well-powered clinical trial has compared this approach to standard sternotomy with respect to clinical outcomes, durability of repair, and markers of patient satisfaction. Moreover, considering the growing global interest in the technique and an increasing patient recognition of the availability of minimally invasive approaches, such a trial may be difficult to perform. Therefore, available data on minimally invasive mitral valve surgery rely mainly on prospective observational single-center experiences. At the Quebec Heart and Lung Institute, 173 mitral valve procedures have been consecutively performed since 2003 using the right mini-thoracotomy Port-Access technique described above. The mean age of patients was 58 ± 12 years, and 33 percent were female. Most patients had normal left ventricular function, and approximately 40 percent of patients were in NYHA class III–IV (Table 54-1). Operative variables and in-hospital outcomes are shown in Table 54-2. Conversion to sternotomy was required in four patients (2.3 percent). There was one in-hospital mortality due to mesenteric ischemia, and two patients required reoperation for failed repair, one at 2 weeks and the other at 4 weeks following the initial operation. At a mean follow-up of 2.5 ± 1.5 years, 1-, 2-, and 5-year survival rates were 98.0, 96.4, and 94.4 percent, respectively. Midterm freedom from mitral valve reoperation is also excellent, 99.4 percent at 5 years.

Similar results using the right mini-thoracotomy approach have been reported by other groups.[35–38] Interestingly, renal complications appear to be less frequent with the right mini-thoracotomy approach.[39,40] Enhanced renal preservation may be related to increased renal perfusion associated with femoral artery cannulation during CPB. Although complications directly related to sternal incisions are eliminated, the surgeon must be aware of specific complications related to the minimally invasive approach that are not commonly observed with standard mitral valve surgery via sternotomy. Phrenic nerve injury, parenchymal lung trauma, and perioperative pleural effusion may be minimized by intraoperative right lung exclusion and extended pleural drainage for a minimum of 3 days. Transesophageal echocardiographic guidance has reduced the incidence of peripheral vessel complications to less than 1 percent during cannulation. In a large, single-center series, the incidence of aortic injury attributed to the use of the endoclamp was 0.9 percent, resulting in a mortality rate of 22.2 percent.[33] Coronary sinus trauma owing to percutaneous retrograde catheterization is less than 2 percent with the use of fluoroscopy during catheter positioning. However, in our experience, it may be impossible to achieve adequate positioning of the percutaneous coronary sinus catheter in up to 20 percent of cases, necessitating alternative cardioplegia delivery approaches.

To assess the rate and durability of valve repair in patients with degenerative mitral valve disease, we prospectively evaluated 36 patients with degenerative disease operated on through a right mini-thoracotomy at our center. Posterior

[a]Increase in serum creatinine of greater than 50 μmol/L.

leaflet prolapse was present in 22 patients, the anterior leaflet was involved in 2 patients, and bi-leaflet prolapse occurred in 12 patients. Thirty-three patients (91.7 percent) underwent mitral valve repair using conventional repair techniques with immediate postoperative transesophageal echocardiography showing no or trace residual mitral regurgitation. At a mean follow-up of 12.8 ± 8.4 months, all patients had stable repairs except for one patient who required reoperation for recurrent severe mitral regurgitation due to an early postoperative *Streptococcus mitis* endocarditis. Similar valve repair rates and outcomes were reported by other groups.[41–43]

Patient satisfaction and quality of life seem to be improved with the minimally invasive approach. Pain levels are usually well-tolerated with the common medications in current use during the initial postoperative days. Following the third postoperative day, pain level scores are significantly lower following right mini-thoracotomy compared with standard sternotomy.[44] Early mobilization is also improved. Following hospital discharge, patients do not face the same limitations to physical activity as those that have undergone sternotomy, and usually resume their normal activities within a month of the operation. Furthermore,

**FIGURE 54-8** Typical incision length in a patient that has undergone a right mini-thoracotomy.

patients appreciate the excellent cosmetic result afforded by the right mini-thoracotomy incision, which allows for a smaller visible scar without compromising the safety and efficacy of the procedure (Fig. 54-8). Costs of the procedure may be increased by US$3000 to US$7000 depending on the Port-Access catheters used during the operation. However, the potential reduction in length of hospital stay, the improvement in quality of life, and a more expeditious return to work may enhance the overall cost-effectiveness of the right mini-thoracotomy approach.

## EXTENDED APPLICATIONS AND FUTURE PERSPECTIVES

With slight modifications in technique, tricuspid valve surgery combined with a mitral valve procedure may be performed through a right mini-thoracotomy approach. Other procedures such as closure of an atrial septal defect, resection of atrial myxoma, and septal myectomy have also been reported using a small right thoracotomy. Exposure via a right mini-thoracotomy may also be a favorable option in cases of previous sternotomy especially in the presence of patent coronary artery bypass grafts. Although benefits have yet to be uniformly established, initial results are promising in patients with previous sternotomy.[45] In a series of 80 patients undergoing reoperative mitral or tricuspid valve surgery via a minimally invasive technique, Casselman and colleagues report an operative mortality of 3.8 percent and an incidence of stroke of 2.5 percent.[46]

The use of telemanipulators has been proposed by Chitwood in the early 2000s.[47] This procedure uses the da Vinci system in which the mitral valve operation is performed totally endoscopically. Feasibility of the procedure has been demonstrated by the Chitwood group and others.[48] However, CPB times are significantly prolonged and the current prosthesis technology still requires a 3-to-5-cm

thoracotomy. Furthermore, high purchase and maintenance costs of the robotic system may be prohibitive and most centers have not adopted this technique. In the near future, progress in stentless prosthesis technology may render this approach more appealing.

## MINIMALLY INVASIVE AORTIC VALVE SURGERY

The quest to reduce patient morbidity from cardiac operations led surgeons to develop approaches to avoid a complete sternotomy in performing aortic valve surgery. Various surgical incisions have been proposed, including an inverted "T" partial upper sternotomy, "J" upper partial sternotomy, "I" sternotomy performed between the second and fifth intercostal spaces, midline lower-half sternotomy, and a "C" mini-sternotomy, leaving the upper and lower ends of the sternum intact.[49–51] Right parasternal approaches have also been described, with or without resection of costal cartilages. All of these approaches permit central cannulation and good exposure of the left ventricular outflow track, aortic valve, and ascending aorta. Cardioplegia is usually administered in an antegrade fashion. A retrograde coronary sinus catheter may be directly inserted through the right atrium or percutaneously through the internal jugular vein. Continuous carbon dioxide is infused into the mediastinum to minimize the risk of air embolization after aortic unclamping. Following the initiation of CPB, the aortic valve operation is conducted using standard techniques.

Procedural mortality appears to be similar between minimally invasive aortic valve procedures compared to the conventional median sternotomy approach,[52,53] although no large, well-conducted randomized trial exists. Excellent results have also been reported in redo cases with patent coronary bypass grafts (Fig. 54-9).[54] Improved cosmesis, reduced duration of mechanical ventilation and length of hospital stay, and diminished postoperative pain with an earlier return to normal activity have been associated with the minimally invasive approach.[55,56] However, consistent reductions in blood product requirement, incidence of postoperative supraventricular tachyarrhythmias, and overall health care costs have been more difficult to demonstrate.

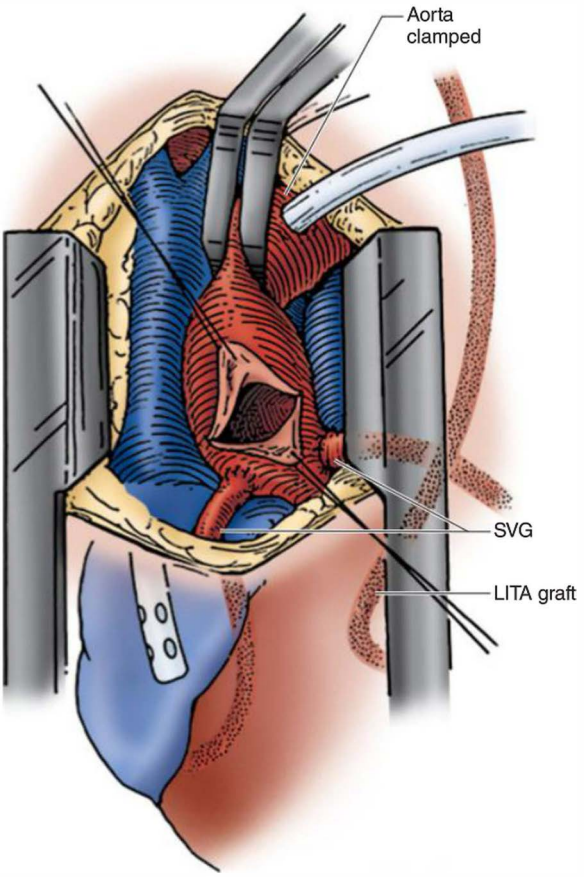

**FIGURE 54-9** Inverted "T" upper partial sternotomy approach to the aortic valve after prior coronary bypass. The previous sternotomy incision is exposed to the third (or fourth) intercostal space and extended laterally to the right or bilaterally, as needed, for exposure. After dissection of the ascending aorta, with particular attention to the position of patent CABG conduits and their proximal anastomoses, cannulation is performed. (In this example, the ascending aorta and innominate vein, but frequently other cannulation sites, are required because of space limitations.) The ascending aorta is cross-clamped and aortic valve replacement is conducted in standard fashion. LITA, left internal thoracic artery; SVG, saphenous vein graft. (Reproduced with permission from Byrne JG, Aranki SF, Couper GS, et al. Reoperative aortic valve replacement: Partial upper hemisternotomy versus conventional full sternotomy. *J Thorac Cardiovasc Surg* 1999;118(6):991–997. Copyright Elsevier.)

## OTHER MINIMALLY INVASIVE CARDIAC OPERATIONS

The acceleration of new technologies supporting minimally invasive cardiac surgery has encouraged surgeons to design new approaches to treat different cardiac diseases. Robotic surgery has been applied to correct some congenital defects, including coarctation of the aorta, atrial septal defects, and congenital mitral abnormalities.[57,58] With the combined development of new devices and innovative surgical techniques, the surgical treatment of atrial fibrillation ablation has seen a spectacular transformation from the classic time-consuming cut-and-sew Maze operations to fully robotic procedures for epicardial isolation of the pulmonary veins (Fig. 54-10).[59] Minimally invasive procedures have also been applied to epicardial biventricular lead placement, pericardial window, the excision of cardiac tumors, as well as transmyocardial laser revascularization.[60,61] Further research will be required to optimize patient selection for these types of procedures and determine the full benefits of these new operations.

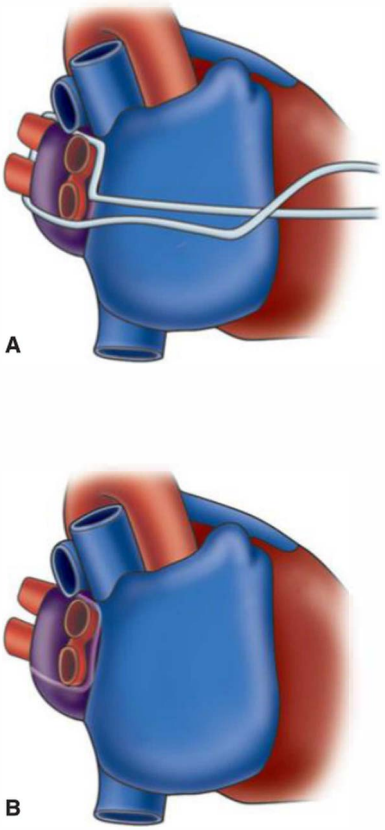

**FIGURE 54-10** Minimally invasive pulmonary vein isolation for atrial fibrillation. A flexible radiofrequency antenna is deployed around all four pulmonary veins via a minimally invasive technique (e.g., robotic right minithoracotomy). An isolating lesion is then created, thus ablating aberrant conduction pathways.

## CONCLUSIONS

During the last decade, innovations in alternative methods for cannulation and CPB, new visualization systems, retractors and stabilizers, and robotic platforms have paved the way for new and exciting developments in minimally invasive cardiac surgery. Compared with conventional surgical approaches, early experiences with minimally invasive valve surgery have produced excellent reproducible results in experienced centers with measurable benefits in the form of reduced perioperative morbidity and enhanced patient satisfaction. TECAB procedures remain hindered by the inherent technical complexities of the operation. Through further technological advancements and the development of new surgical strategies, TECAB procedures may be performed with more ease, safety, and reproducibility. Cardiac surgeons will apply these new technologies to other cardiac applications. Although this expensive technology is currently restricted to centers dedicated to minimally invasive approaches, technical refinements and evidence-based data confirming the benefits of these approaches should contribute to the widespread adoption of these techniques. To ensure the maintenance of the high standards set by conventional cardiac surgery, high-quality training programs in minimally invasive approaches will be required and will definitely constitute a challenge in the upcoming years.

## MINIMALLY INVASIVE CARDIAC SURGERY BOARD REVIEW QUESTIONS (CHAPTER 54)

1. Which of the following is *not* associated with minimally invasive mitral surgery?
   A. Higher incidence of renal complications
   B. Coronary sinus injury
   C. Phrenic nerve injury
   D. Reduced cost
   E. Lung trauma

2. Peripheral cannulation is required for which of the following incisions for minimally invasive aortic valve surgery?
   A. "J" partial upper sternotomy
   B. Midline lower half sternotomy
   C. Inverted "T" upper half sternotomy
   D. Parasternal incision
   E. Peripheral cannulation is not required for any of these incisions.

3. Which of the following is correct regarding minimally invasive coronary artery bypass surgery?
   A. Early mortality exceeds 2 percent for MIDCAB.
   B. Less than 5 percent of MIDCAB LIMA-LAD grafts have significant stenosis at angiography.
   C. Anastomotic revision is less common with MIDCAB compared with standard CAB.
   D. Wound complications occur in nearly 10 percent of MIDCAB patients.
   E. Stroke is more common after multivessel minimally invasive CAB compared with standard CAB.

4. TECAB surgery is associated with:
   A. Requirement for CPB and arrested heart
   B. Prolonged cross-clamp and CPB times
   C. Conversion to open incisions in about 20 percent of patients
   D. Reduced midterm freedom from angina compared with standard CAB
   E. Ideally suited for intramyocardial LAD

5. Which of the following is the strongest contraindication to minimally invasive mitral valve surgery?
   A. Obesity
   B. Pectus excavatum
   C. Atherosclerotic plaque >2 mm in height in aortic arch
   D. Previous right thoracotomy
   E. Breast augmentation

## ANSWERS

1. **Answer: A.** An increased incidence of renal complications is not associated with minimally invasive mitral surgery; in fact, renal complications may be lower due to proximity of perfusion with femoral arterial cannulation. Coronary sinus injury, phrenic nerve injury, and lung trauma are all associated with cannulation, positioning, and exposure for minimally invasive mitral surgery through the right chest. Minimally invasive operations, in general, cost more than standard operations.
2. **Answer: E.** Central cannulation is possible with any of the incisions, and therefore peripheral cannulation is not absolutely required for minimally invasive aortic valve surgery.
3. **Answer: D.** Wound complications are common after MIDCAB operation, occurring in nearly 10 percent of patients. Early mortality is less than 2 percent. Both intraoperative anastomotic revision and residual postop stenoses are more common after MIDCAB. Stroke is not more common after multivessel minimally invasive CAB.
4. **Answer: B.** Totally endoscopic coronary artery bypass is associated with longer cross-clamp and CPB times. Recent advances have made TECAB surgery possible on the beating heart. Conversion to open incisions is uncommon in experienced hands. An intramyocardial LAD is a contraindication to TECAB.
5. **Answer: C.** Significant atherosclerotic disease in the aortic arch can represent high risk for embolization during minimally invasive mitral surgery, particularly if endoaortic balloon occlusion is required. The other conditions make the surgery more difficult but are not contraindications per se.

# Cardiac Catheterization and Interventions

*Todd A. Dorfman*
*Jon R. Resar*

## KEY CONCEPTS

- The most common complications of cardiac catheterization include groin complications (0.43 percent) such as hematomas, retroperitoneal bleeding, pseudoaneurysm, and arteriovenous fistulas. Other complications include contrast reactions, renal failure, perforation, dissection, hypotension, and bradycardia.
- When performing coronary angiography, at least two orthogonal views are needed for each vessel to assess the severity of eccentric lesions, and at least five views are recommended to adequately evaluate the left coronary system.
- By coronary angiography, a lesion is considered to be severe if there is a greater than 70 percent narrowing of the luminal diameter.
- For intermediate lesions of uncertain significance on coronary angiography, intravascular ultrasound (IVUS) and fractional flow reserve (FFR) can be useful. IVUS delineates and quantifies the atherosclerotic burden and consistently demonstrates that lesions are underestimated using angiography alone. FFR is probably the best test to determine both physiologic ischemia (i.e., disease severity) and the need for revascularization.
- Balloon angioplasty alone is associated with a 5 percent risk of abrupt closure and a 50 percent risk of angiographic restenosis within 6 months. Bare metal intracoronary stents decrease restenosis by nearly 50 percent compared to balloon angioplasty with a 20 to 30 percent risk of in-stent angiographic restenosis after 6 months.
- Drug-eluting intracoronary stents are associated with lower in-stent restenosis rates as low as 5 percent at 12 months, but also carry a higher risk of late and very late stent thrombosis. Patients receiving drug-eluting stents (DESs) must take aspirin for life and clopidogrel for at least 12 months after implantation to mitigate the risk of stent thrombosis.
- Cardiac output measurements can be obtained during right-heart catheterization by the Fick and/or thermodilution method. The thermodilution method is more accurate at high-output states, whereas the Fick method is more accurate with low-output conditions and atrial fibrillation.
- Aortic valve gradients can be estimated by several methods: (1) Peak-to-peak gradient, (2) "pull-back" method, and (3) simultaneous pressure measurements in the left ventricle (LV) and aorta using a double-lumen catheter (most accurate). The modified Hakki equation can be used to measure the aortic valve area: aortic valve area = cardiac output/square root of the peak-to-peak pressure gradient.
- Balloon aortic valvuloplasty (BAV) rarely increases aortic valve area greater than 1.0 $cm^2$ and, although it improves symptoms, clinical deterioration frequently occurs within 6 to 12 months.
- Percutaneous patent foramen ovale (PFO) closure devices are associated with high procedural success and low complication rates. Complication rates are around 5 percent and include device migration, pericardial tamponade, and arrhythmias.

## INDICATIONS FOR CARDIAC CATHETERIZATION

The first coronary angiogram was performed by Dr. F. Mason Sones, Jr. at the Cleveland Clinic in 1958, and he published the results of approximately 1000 procedures in 1962.[1] With the development of improved catheter designs by pioneers such as Drs. Kurt Amplatz and Melvin Judkins, the number of diagnostic cardiac catheterizations performed annually began to expand exponentially. The rapid growth of cardiac catheterization coincided with Dr. Rene Favaloro's introduction of coronary artery bypass grafting (CABG) in 1968.[1] Presently, almost 2 million cardiac catheterizations are performed each year in the United States.[1]

The most common indication for cardiac catheterization is the diagnosis of coronary artery disease (CAD). Accepted indications for cardiac catheterization include the evaluation for known or suspected CAD, chest pain, myocardial infarction (MI), wide complex tachycardia, cardiac arrest, shortness of breath, cardiomyopathy, valvular disease, congenital heart disease, aortic dissection, pericardial disease, and heart transplantation.[1] Coronary arteriography determines the severity of obstructive CAD and identifies other etiologies of ischemia and infarction, including thrombosis, spasm, dissection, and myocardial bridges.[1]

Cardiac catheterization plays an integral role in the evaluation and management of patients with cardiomyopathy and heart failure by quantifying the degree of left ventricular (LV) dysfunction with ventriculography and by measuring both right- and left-sided filling pressures. Cardiac catheterization differentiates systolic from diastolic dysfunction, distinguishes pericardial constriction from restriction, and determines the severity of valvular disease. In patients with valvular disease, left-heart catheterization is indicated when there is a disparity between echocardiographic and physical exam findings, and coronary angiography is recommended prior to valve surgery in patients greater than 35 years of age.[1]

Although there are no absolute contraindications for cardiac catheterization, there are several relative contraindications such as severe contrast allergy, coagulopathy (INR greater than 1.8), renal failure, gastrointestinal bleeding, electrolyte imbalance (hypokalemia and hyperkalemia), acute stroke, infection, fever, severe anemia, uncontrolled hypertension, decompensated heart failure, high-grade heart block, uncontrolled arrhythmias, thyrotoxicosis, and medication toxicity.[1]

Cardiac catheterization is safe even in critically ill patients, but indications for catheterization should always be based on the risk–benefit ratio.[1] Major complications infrequently occur during catheterization. According to an analysis of approximately 60,000 cases, death occurred in only 0.11 percent of patients, and patients with either severe aortic stenosis or critical left main (LM) disease were at the highest risk.[1] Incidence of MI, stroke, and arrhythmias is 0.05, 0.07, and 0.38 percent, respectively.[1] The most common complications of cardiac catheterization include groin complications (0.43 percent) such as hematomas, retroperitoneal bleeding, pseudoaneurysm, and arteriovenous fistulas.[1] Obesity, anticoagulation, female gender, and advanced age are associated with an increased incidence of vascular complications, especially when performed from a femoral artery access site.[1] Other complications of catheterization include contrast reactions, renal failure, perforation, dissection, hypotension, and bradycardia.

## BASIC CATHETERIZATION TECHNIQUES

Cardiac catheterization is an invasive procedure and should only be performed by well-trained clinicians who understand the basic fundamentals of catheterization. The patient must be NPO after midnight for 6 to 8 h prior to catheterization. It is imperative to establish continuous electrocardiogram (ECG) monitoring and intravenous (IV) access for the administration of sedation, fluids, and medications. Patients with a contrast allergy should be treated with prednisone and Benadryl, and IV fluids are administered to those at risk for contrast-nephropathy to achieve greater than 200 mL/h of urine output. Acetylcysteine (Mucomyst) is also frequently administered prior to angiography in individuals at risk for contrast dye nephrotoxicity, although the efficacy of this drug in preventing this remains unproven. A crash cart and defibrillator must be charged and readily available during the procedure.

After the patient is draped in a sterile fashion and comfortably sedated, percutaneous vascular access is most frequently achieved via cannulation of the right common femoral artery. The femoral artery crosses the inguinal ligament, which is located beneath the inguinal skin fold, and divides the ligament into two-thirds lateral and one-third medial.[2] Needle entry should be 1 to 3 cm below the inguinal ligament, and the inguinal skin crease should not be used as a landmark as it can be misleading, especially in obese patients.[3] After palpation of the femoral pulse, a hemostatic clamp is placed over the presumed access site and fluoroscopy should be performed to ensure that the puncture site will be 1 cm lateral to the medial edge of the middle of the femoral head in the anteroposterior projection (Fig. 55-1). This increases probability of an infrainguinal puncture and cannulation of the common femoral artery. A more cranial puncture increases risk of retroperitoneal bleeding, while cannulation below the bifurcation into the superficial femoral artery is associated with an increased likelihood of a pseudoaneurysm.[1] Next, local anesthesia using 1 percent lidocaine should be administered with a 25-gauge needle superficially and then a 22-gauge needle into the deep tissue planes. An 18-gauge beveled needle is introduced into the artery at a 30° to 45° angle resulting in pulsatile bleeding, and slight and careful manipulation of the needle (shallower angle) might be required to improve or restore flow. Single anterior wall puncture is preferred over the Seldinger double-wall technique, and many operators use a micropuncture kit to minimize groin complications.[2] After cannulation of the femoral artery, a soft J-tipped 0.035-in guide wire is

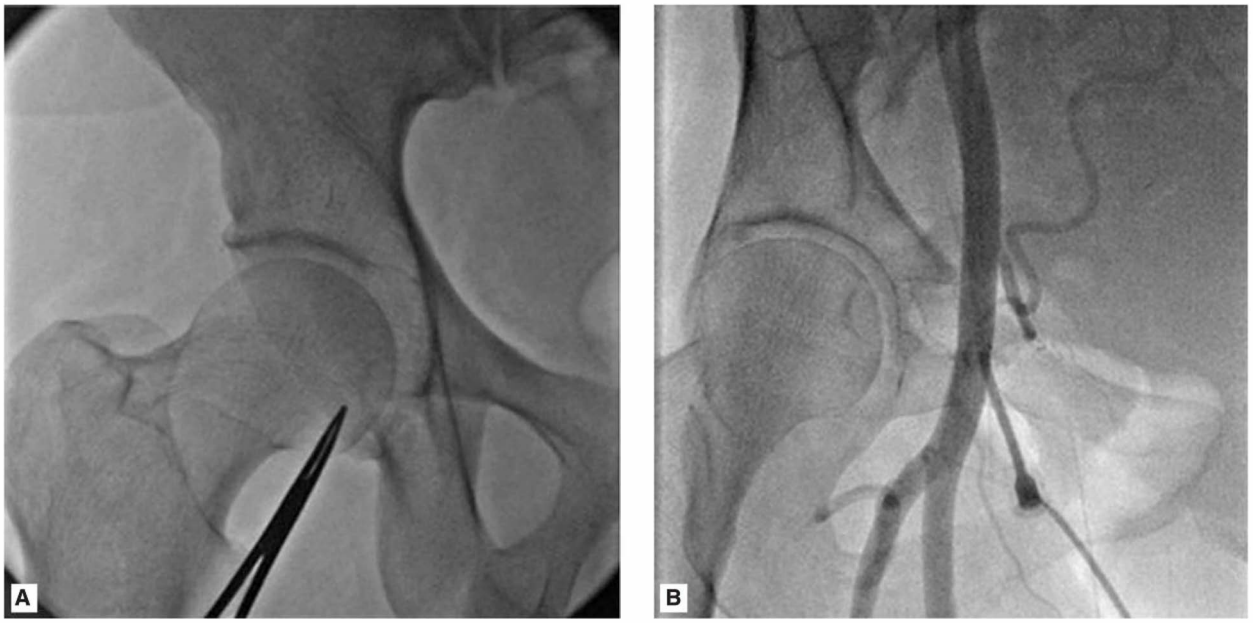

**FIGURE 55-1** **A.** The fluoroscopic landmark for access in the anteroposterior projection is approximately 1 cm lateral to the medial edge of the middle of the femoral head, which is marked by a hemostat. **B.** An iliofemoral angiogram in the right anterior oblique projection shows the sheath entering the right common femoral artery.

gently advanced through the needle and into the artery without resistance. If there is any resistance, the wire should be removed, and the needle should be repositioned if arterial flow is compromised. Hemostasis should be maintained for at least 2 to 3 min if the needle is withdrawn from the artery. Once the guide wire is easily passed through the needle, fluoroscopy is performed confirming wire placement in the abdominal aorta, which is left of the anatomic spine. At this point, the needle is removed, and typically a 5F or 6F sheath is inserted over the wire to ensure constant arterial access.

The most widely accepted technique for left-heart catheterization and coronary angiography is the Judkins method, which is associated with enhanced efficiency and low complication rates.[3] The LM coronary artery is usually engaged with the Judkins Left 4 (JL 4) catheter, while the Judkins Right 4 (JR 4) catheter is commonly selected for the right coronary artery (RCA). Engagement of the ostia is performed in the left anterior oblique (LAO) projection. In patients greater than 6 ft tall or in those with dilated aortic roots, a JL 5 or JL 6 may be necessary whereas a small aortic root might need a JL 3.5. Amplatz catheters are helpful when the ostia of the LM or RCA is more superior, anterior, or posterior than the typical aorta, but these catheters increase the risk of ostial dissection secondary to deep engagement.[3]

After coronary angiography, a pigtail catheter is introduced into the LV, and LV systolic and end-diastolic pressures are obtained. If the LV end-diastolic pressure is less than 30 mm Hg, left ventriculography is then performed in the 30° right anterior oblique (RAO) projection for a single-plane projection or 30° RAO and 60° LAO for biplane projection, using the pigtail catheter and a power injection of 30 mL of contrast media at 10 mL/s. A greater volume of contrast up to 60 mL or even 72 mL can be used if the LV is dilated or in the setting of chronic mitral regurgitation. The pigtail is then pulled back across the aortic valve while pressure is recorded on the hemodynamic monitoring system, and an aortic gradient is measured to assess for aortic stenosis. During catheterization, the patient's hemodynamics, oxygenation, ventilation, and level of consciousness must be continuously monitored. Once the catheterization is completed, the vascular sheath is removed, and hemostasis is achieved with manual compression for at least 10 to 15 min. Bed rest is mandatory for at least 3 to 4 h, and the patient must keep his or her leg straight to prevent hematoma.

Several vascular closure devices such as suture closure (Perclose, Abbott Laboratories, Abbott Park, Illinois), collagen plugs (Angio-Seal, St. Jude Medical, St. Paul, Minnesota), metallic clips, and hemostatic patches are available.[3] Closure devices minimize compression time, allow for early sheath removal in patients who have received anticoagulation, and enable patients to ambulate within 1 to 2 h following the procedure.[3] Prior to deployment, an iliofemoral angiogram must be performed in an oblique view to verify sheath entry above the femoral bifurcation (Fig. 55-1). Closure devices should not be used in patients with peripheral arterial disease, compromised immunity, or before valve surgery. A closure device is also discouraged if the vessel is less than 4 mm in diameter.[1] Although vascular access complications are probably not decreased with vascular closure devices they facilitate earlier ambulation and improve patient comfort. Use of vascular closure devices should be guided by proper patient selection and single anterior wall puncture.[4]

The femoral artery is the most common site of arterial access for cardiac catheterization, but brachial and radial arteries can also be used. Morbid obesity, severe debilitating back pain, peripheral claudication, previous femoral arterial grafting surgery, excessively tortuous aortic or iliac disease, femoral bruits, and absent lower extremity pulses are indications for selecting an alternative site for vascular access.[2] Radial artery access is more widely utilized outside of the United States for cardiac catheterization, but in light of studies demonstrating lower associated access site bleeding complications with radial compared to femoral access, there is increased interest in employing radial access in the United States.

Sones described the first cardiac catheterization using a brachial artery cutdown, but this technique is infrequently used today.[3] Rather, a percutaneous brachial artery technique is preferred without the need for cut down or repair.[3] The brachial artery should be cannulated several centimeters proximal to the elbow crease, because 10 percent of patients have a brachial bifurcation before the crease.[1] After a 4F to 6F sheath is introduced into the brachial artery, IV heparin should be given to prevent thrombus formation. Nitroglycerin is also recommended, because the brachial artery has the propensity for spasm. Advantages of using brachial over femoral arterial access include quicker time to ambulation and improved patient comfort.[3] Although it is easier to achieve hemostasis via the brachial approach, complication rates between brachial and femoral arterial access are indistinguishable.[3] Expanding hematomas and compression syndrome (forearm and hand) are more common after brachial access, because there is less space in the arm.[2] The brachial approach compromises image quality, increases radiation exposure, and impairs procedural efficiency as catheter manipulation can be quite challenging.[3] As a result, this technique should be reserved for patients who are not candidates for either femoral or radial access.[2]

Radial artery cannulation was first described by Campeau in 1989 and emerged as an alternative to the brachial approach in an effort to minimize vascular complications.[3,5] It has become increasingly popular to perform catheterization via the right radial artery secondary to markedly reduced time to ambulation and easier vessel compressibility, which controls bleeding.[1,2] In fact, patients may sit up and ambulate immediately after the procedure, facilitating outpatient cardiac catheterization.[3] Prior to cannulating the right radial artery, an Allen's test must be performed to verify dual circulation to the palmar arch. The left radial artery is frequently used as access for catheterization in the presence of a left internal mammary arterial (LIMA) graft. After the usual sterile prep and drape, the right radial site is locally anesthetized, and a 5F or 6F sheath is inserted into the radial artery using a micropuncture kit. Unfractionated heparin, intra-arterial nitroglycerin, and a nondihydropyridine calcium channel blocker should be administered to prevent thrombosis and vasospasm.

A recent meta-analysis of 12 randomized trials, including 3224 patients, showed that radial artery cannulation markedly decreased vascular complications, but it required greater technical skills and had slightly lower success rates.[5] Catheter manipulation from the wrist is more challenging than from the groin.[1] Other limitations of this approach include the small size of the radial artery, its increased likelihood for vasospasm, and the risk of radial artery occlusion from clot or dissection.[3] The radial approach increases the operator's exposure to radiation as the operator stands closer to the radiation source.[1] Radial artery access limits both guide selection and size if a complex percutaneous intervention is warranted, and an additional access site is often required if a right-heart catheterization is needed.[3] However, right-heart catheterization can be performed from the forearm with conversion of a peripheral IV catheter to a 6F sheath.

It is essential that the entire catheterization team be cognizant of the risks of radiation. Cumulative doses of radiation can result in skin erythema, hair loss, and necrosis, and these injuries occur in a dose dependent manner after a certain limit is exceeded (deterministic effects).[1,3] Radiation can also cause genetic defects and malignancies, and these feared complications of radiation are not dose dependent; rather, the probability of an effect is increased with radiation use (stochastic effects).[1,3] All catheterization personnel must understand the basic principles of minimizing radiation exposure. Radiation exposure is limited by the use of lead aprons, thyroid shields, and lead glasses. The catheterization table must have a lead shield to protect the operator's lower body and an adjustable glass lead shield for his or her upper torso and head. Radiation is also limited by reducing fluoroscopic and especially cineangiographic time, minimizing image magnification, and through the use of collimators (decrease field size) and less angled views.[6] Projections performed in the lateral, LAO, and steeply angulated caudal or cranial view increase radiation exposure to the patient and operator and are also associated with reduced image quality.[1] Minimizing distance between the patient and x-ray source reduces radiation exposure, and doubling the distance between the x-ray entrance and the operator decreases radiation dose to the operator by as much as 75 percent.[1] Catheterization personnel must wear radiation badges at all times; the maximum amount of whole body radiation dose per year and per lifetime is 5 and 50 rems, respectively.[3]

## CORONARY ANATOMY

The LM coronary artery arises from the left sinus of Valsava usually at an acute angle, and it travels between the left atrium and the pulmonary artery and is partially covered by the left atrial appendage.[7] The LM gives rise to the left anterior descending (LAD) artery, which supplies the anterior wall of the LV, and the left circumflex (LCx) artery, which supplies the lateral wall. In one-third of patients, the LM trifurcates into the LAD, ramus intermedius artery, and the LCx.[7] The ramus intermedius has a similar course as the first diagonal branch of the LAD and the first or high obtuse marginal branch of the LCx and provides blood supply to

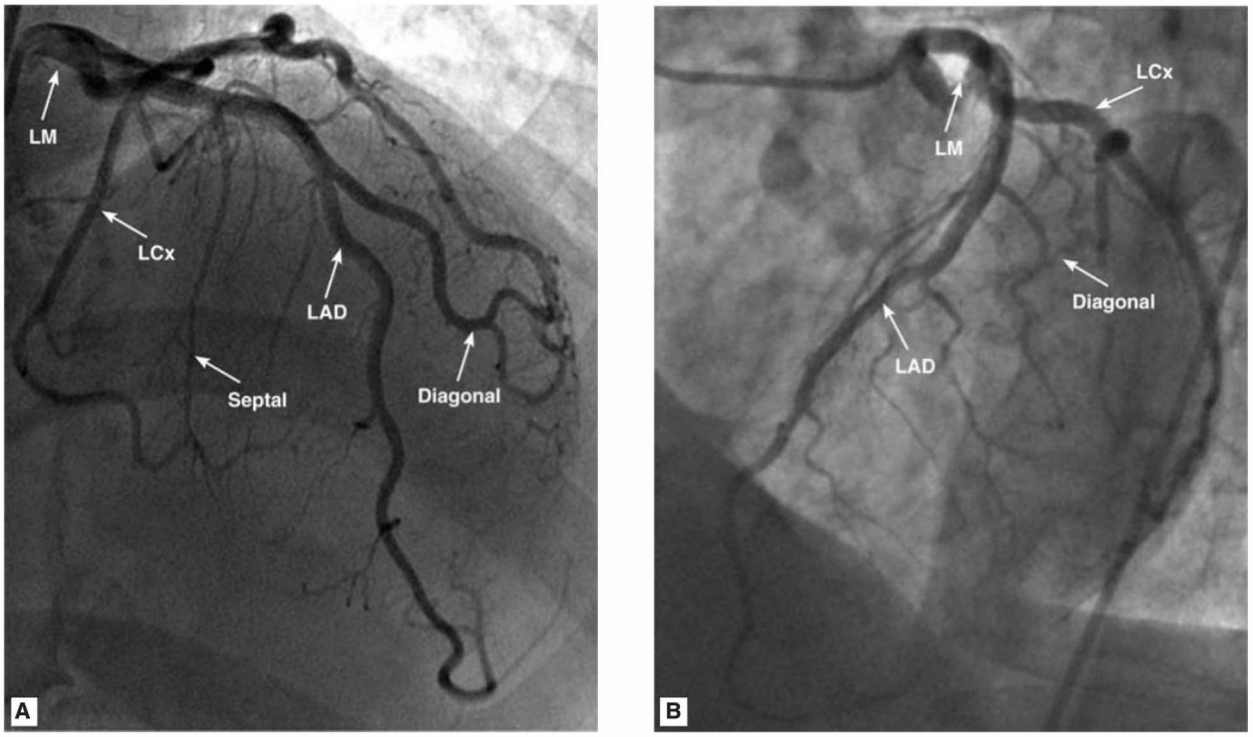

**FIGURE 55-2** **A.** The left system in the right anterior oblique cranial projection and the (**B**) left anterior oblique cranial view. LM, left main; LAD, left anterior descending; LCx, left circumflex.

the high lateral wall of the LV. The LAD gives off several diagonal and septal perforator branches as it courses along the anterior interventricular groove before either tapering into a small caliber vessel ending at the cardiac apex or wrapping around the apex to supply the distal one-third of the inferior wall (Fig. 55-2). The septal perforators supply two-thirds of the anterior portion of the interventricular septum and the majority of the conduction system including the His bundle.[8] The LAD diagonal branches supply the anterolateral aspect of the LV.[7]

The LAD takes an intramyocardial course in approximately 12 percent of patients,[7] and myocardial bridges almost always involve the mid-LAD but can infrequently affect a septal branch, the posterior descending artery (PDA), or an obtuse marginal branch. Bridging is easier to appreciate angiographically after administration of nitroglycerin.[1] Systolic narrowing of coronary arteries rarely causes ischemia as the majority of coronary flow occurs during diastole. Although myocardial bridging is benign in the majority of cases, it can result in critical luminal compression during systole in 2 percent of patients and also impair early diastolic coronary flow.[9] Myocardial bridging can make bypass surgery more challenging, especially during minimally invasive approaches.[1]

As the LCx courses along the left atrioventricular (AV) sulcus, it gives rise to small-caliber left atrial branches and several obtuse marginal branches, which supply the lateral wallbefore terminating in the AV groove (Fig. 55-3). The first obtuse marginal branch is frequently called the high lateral branch, and subsequent marginal branches may be referred to as left posterolateral branches.

The RCA originates from the right aortic sinus and supplies the inferior wall of the LV and right ventricle (RV). The first branch arising from the RCA is the conus branch. The proximal RCA then gives origin to small caliber right atrial branches and several acute marginal branches that supply the free wall of the RV.[7] In 85 percent of patients, the RCA is dominant and the distal RCA crosses the crux and bifurcates into the right posterior descending artery (RPDA) and right posterolateral ventricular (RPLV) branches distally (Fig. 55-4). The origin of the PDA defines coronary dominance as it determines the source of blood supply to the inferior wall of the LV, and it can arise from a dominant LCx in a minority of patients.[9] The length of the RCA along the inferior wall of the heart tends to be inversely related to the length of the LCx.[7] The inferior wall of the heart is supplied by both the RCA and the LCx in 20 percent of patients, and this is referred to as a mixed, shared, or codominant system.[7] The conus branch supplies the RV outflow tract and arises 50 percent of the time from a separate ostium in close proximity and anterior to the origin of the RCA.[1,9] Although the atrial branches of the RCA provide blood supply to the sinus

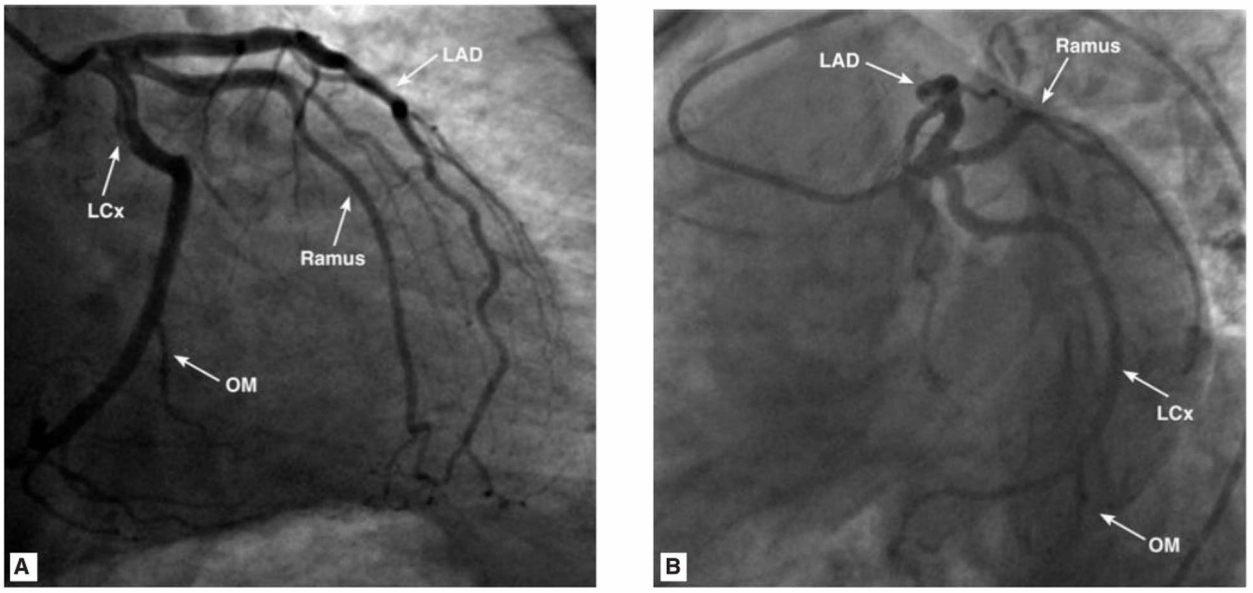

**FIGURE 55-3** **A.** The left system in the right anterior oblique caudal view and the (**B**) left anterior oblique caudal projection. LAD, left anterior descending; LCx, left circumflex; OM, obtuse marginal.

node 60 percent of the time, a minority of patients depend on an atrial branch of the LCx.[9] In approximately 90 percent of patients, the AV node receives blood supply from the AV nodal branch off of the distal RCA.[1]

The PDA courses along the posterior interventricular groove to supply the posterior and inferior free walls of the LV. The PDA gives off several small septal branches which supply the inferior portion of the interventricular septum, the posteromedial mitral papillary muscle, as well as the right and a portion of the left bundle branch.[7,8] The posteromedial muscle of the mitral valve is supplied by the PDA while the LAD and LCx provide dual supplies to the anterolateral

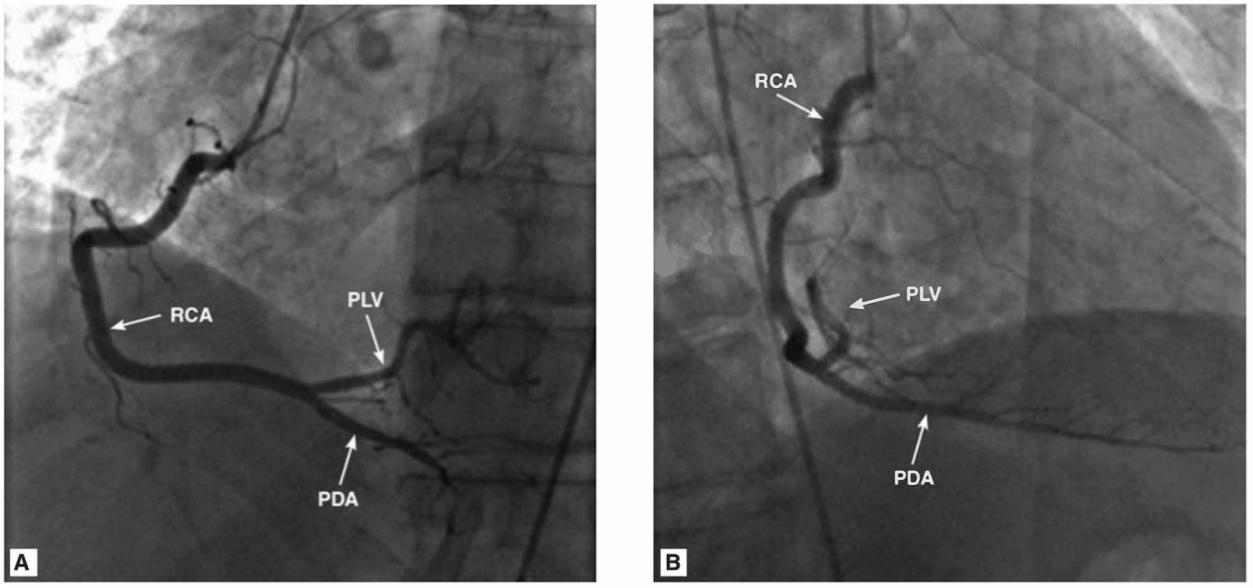

**FIGURE 55-4** **A.** The right coronary artery (RCA) in the left anterior oblique cranial projection. **B.** The RCA in the right anterior oblique view. PDA, posterior descending artery; PLV, posterior lateral ventricular branch.

mitral papillary muscle. As a result, an inferior wall MI involving the RCA or a dominant LCx is the most common cause of acute ischemic mitral regurgitation.

Coronary angiography was performed in 126,595 patients, and an anomalous coronary artery was present in 1.3 percent.[10] The most common coronary anomaly is the LAD and LCx arising from separate ostia (30.4 percent), and the second most common anomaly is the LCx originating from the right sinus or the proximal RCA (27.7 percent).[10] Although 81 percent of coronary anomalies are benign, there are several potentially serious anomalies such as the LM arising from the pulmonary artery (Bland–White–Garland Syndrome) and the LM originating from the right aortic sinus and taking an interarterial course (between the pulmonary artery and aorta).[1] This variant is considered benign if the LM arises from the right sinus and takes a septal, anterior, or retroaortic course. Coronary fistulas account for 10 percent of all coronary anomalies, and while small fistulas are relatively benign, patients with a large coronary fistula may present with angina or heart failure.[9] Patients with congenital heart disease, such as a bicuspid aortic valve or tetralogy of Fallot, frequently have an anomalous coronary artery.[1]

Coronary arteries communicate via anastomotic channels, and in patients with normal or minimal CAD, these collaterals are not usually seen due to their small size (50–200 μm in diameter).[7,11] However, collaterals gradually develop and enlarge when there is severe obstructive CAD secondary to a pressure gradient generated across the channel.[7,11] Collaterals provide approximately 50 percent of coronary flow in occluded vessels and are sufficient to protect the myocardium from infarction and ischemia at rest.[11] However, during provocative testing such as exercise stress testing, a collateral-dependent territory will generally show evidence of inducible ischemia.

## CORONARY ANGIOGRAPHY

When performing coronary angiography, at least two orthogonal views are needed for each vessel to properly assess the severity of eccentric lesions, and at least five views are recommended to adequately evaluate the left coronary system. Traditionally, images were acquired at 30 frames/s, but most labs today obtain images at 15 frames/s. Thirty frames/s is recommended if the patient is tachycardic or has a high-flow state.[1] Image quality in some projections, such as LAO cranial, is improved by acquiring images when the patient takes a deep breath, and vessel overlap is decreased by using angulated views.[1] Contrast injection by hand should start slowly with a gradual augmentation in force to prevent catheter disengagement, and the injection must be strong enough to cause a reflux of contrast into the sinus of Valsalva, enabling adequate visualization of the ostium.[1] Contrast injections should be sufficient to fully opacify the vessel lumen. Hand controlled automated injectors are becoming more popular in catheterization laboratories and facilitate adequate opacification of the coronary arteries especially when using 4F or 5F catheters. Extreme caution is required to avoid injecting air into the coronary circulation.

The LM is usually approached in the 30° LAO projection with a JL 4 catheter. Slight counterclockwise rotation might be warranted to move the catheter in an anterior direction to properly engage the LM. Conversely, clockwise rotation may be required to move the catheter in a posterior direction if it is not coaxial with the LM.[1] Clockwise rotation of a JL 5 or even JL 6 catheter may be required to engage the LM in the setting of a dilated aorta.[1] Forceful injection of contrast into the LM might result in dissection if there is damping or if the catheter is oriented upward against the roof of the LM and not coaxial with the LM.[1] Although the JL 4 normally engages the LM without manipulation, an Amplatz catheter might be necessary if the LM is anomalous or has an unusual orientation. Amplatz catheters are associated with a higher risk of catheter induced coronary dissection.[1]

Severe LM disease is extremely dangerous and suggested by damping or ventricularization of the pressure wave form upon catheter engagement. The best views to visualize the ostial LM are either the shallow LAO or the LAO cranial projections. A distal LM stenosis is best seen in an AP caudal or shallow RAO caudal view. RAO caudal and LAO cranial projections should be used to view the proximal LAD, and the AP, LAO, and RAO cranial views are recommended to visualize the mid and distal LAD as well as the diagonal branches (Fig. 55-2). Although the lateral view increases radiation exposure to the operator, it is helpful in evaluating mid LAD lesions. The LCx and obtuse marginal branches are best seen in the AP caudal and shallow RAO and LAO caudal projections (Fig. 55-3). The LAO caudal view is recommended for visualizing the origin of the ramus intermedius and the LAO cranial projection is the best for evaluating a left PDA.

The RCA is engaged in the 30° LAO projection with a JR 4 catheter. After advancing the JR 4 catheter to the aortic valve, the catheter is pulled back approximately 2 to 3 cm and turned clockwise in an anterior direction. The proximal and mid-RCA are best visualized in the LAO view (Fig. 55-4A). The 30° cranial AP projection is used for evaluating the distal RCA bifurcation and the origin of the RPDA and RPLV branches, and the midsegment of the RPDA is best seen using a shallow RAO view (Fig. 55-4B). The right lateral projection can help visualize the ostial and mid segments of the RCA and the origin of the acute marginal branches.

Coronary artery bypass grafts should be visualized in the same projections recommended for visualization of the native target vessels. The distal anastomosis of the bypass graft and the coronary artery is a frequent site of disease and must be evaluated carefully. Bypass grafts to the RCA should be engaged in the LAO projection and are usually more anterior and more caudal than grafts to the left coronaries. Left coronary bypass grafts should be engaged in the RAO view. Frequently, the sequence of the ostia of venous grafts in a cranial to a caudal direction is the second obtuse marginal branch, first obtuse marginal, ramus intermedius, diagonal, and then the LAD.[1] Most saphenous vein grafts can be

engaged with a JR 4 catheter and, if the graft is occluded, an injection is performed to verify the stump. An aortogram in the 30° LAO projection using approximately 40 to 50 mL of contrast might be necessary to locate grafts.[1]

Caution should be taken when engaging the RIMA and LIMA grafts due to the risk of dissection. The brachiocephalic or left subclavian artery should be cannulated by a JR 4 catheter, and then an exchange length J-tipped guide wire should be passed carefully into the respective distal subclavian artery. Catheters should not be advanced into the right or left subclavian artery unless over a guide wire. After the JR 4 catheter is removed, the IMA catheter is advanced slowly over the exchange guide wire. The IMA catheter is then slowly pulled back and torqued in the appropriate direction to engage the RIMA and LIMA grafts. The LIMA is generally engaged by pulling the IMA catheter back and by turning it counterclockwise or in an anterior direction. The catheter should be maintained in a coaxial orientation with the IMA during contrast injection to avoid causing a catheter-induced dissection.

## ISCHEMIC HEART DISEASE

The magnitude of the impact of CAD is extensive. Ischemic heart disease is the number one cause of death both in the United States and worldwide, and its incidence and prevalence continue to increase secondary to an aging population and an increase in obesity and diabetes.[12] Approximately 13 million Americans are affected by CAD, and slightly more than 50 percent of these patients have suffered from a MI.[12] The economic burden of CAD exceeded US$142.5 billion in the United States in 2006. After the age of 40, the lifetime risk for developing ischemic heart disease is 53 percent for men and 32 percent for women.[12]

The most common etiology of MI is plaque rupture and subsequent thrombus formation, but angina usually results from supply and demand mismatch. Supply is a function of coronary flow and arterial oxygen saturation, and demand is affected by heart rate, contractility, and LV wall stress. Classically, angina presents as substernal or left-sided crushing or squeezing chest pressure with radiation to the left arm and is frequently associated with dyspnea, diaphoresis, nausea, and vomiting. Angina is usually precipitated by exertion and relieved by rest and nitroglycerin. Ischemia can also manifest as dyspnea on exertion secondary to elevated left-sided filling pressures.

The initial evaluation of patients with chest pain includes a thorough history and physical exam, serum markers of myocardial necrosis, and a resting ECG. The resting ECG is normal in approximately 50 percent of patients with angina. Although cardiac enzymes such as troponin and creatine kinase rise within 3 h of myocardial injury and provide significant prognostic information, these biomarkers are usually normal in patients with angina.[12] Although a patient with ischemic ECG changes and/or elevated cardiac enzymes should be referred for cardiac catheterization, noninvasive stress testing is recommended in patients with an intermediate pretest probability of having CAD.[12] Exercise electrocardiography has a sensitivity and specificity of 68 and 77 percent, respectively.[12] The test is limited by the patient's ability to achieve their target heart rate and the requirement of a normal ECG at baseline. In patients who are unable to exercise and in those with abnormal resting ECGs, myocardial imaging is recommended, which markedly increases the prognostic power of the test. Myocardial perfusion imaging using adenosine has a sensitivity of 90 percent and a specificity of 82 percent.[12] Adenosine is very safe but contraindicated in patients with severe bronchospasm, high-grade heart block, and in those taking dipyridamole. Stress echocardiography using dobutamine has a sensitivity of 81 percent and a specificity of 79 percent, but its use is limited in patients with poor echocardiographic windows, ventricular arrhythmias, and left bundle branch block.[12]

Although noninvasive testing plays an integral role in diagnosing CAD, coronary angiography remains the gold standard. By coronary angiography, a lesion is considered to be severe if there is greater than a 70 percent narrowing of the luminal diameter, and a mild stenosis is defined as less than a 30 percent blockage. Results of coronary angiography in patients with stable angina are single-vessel disease in 25 percent, double-vessel disease in 25 percent, triple-vessel disease in 25 percent, significant LM disease (>50 percent stenosis) in 10 percent and 15 percent have nonobstructive CAD.[12] For intermediate lesions of uncertain significance, other techniques such intravascular ultrasound (IVUS) and fractional flow reserve (FFR) can be used to assess disease severity and to guide therapy. IVUS delineates and quantifies the atherosclerotic burden and consistently demonstrates that lesions are underestimated using angiography alone.[12] Although minimal luminal area and area stenosis as measured by IVUS provide additional information to angiography, FFR is probably the better test for determining both physiological ischemia (disease severity) and the need for revascularization.[13,14] However, IVUS might be preferable for evaluating LM disease and transplant vasculopathy.[15] FFR is performed by crossing the lesion of interest with a 0.014-in pressure wire and, after the administration of adenosine, the pressures distal and proximal to the stenosis are obtained. A ratio of distal pressure to proximal pressure of less than 0.75 to 0.80 is deemed abnormal. The sensitivity of FFR for detecting reversible ischemia is 88 percent, and the specificity is 100 percent.[14]

As compared to medical therapy, CABG has been shown to improve survival in patients with LM disease (>50 percent stenosis), triple-vessel CAD especially with LV dysfunction, and double-vessel CAD including severe proximal LAD disease. However, the survival benefit of CABG decreases over time due to eventual graft failure and emergence of new disease in ungrafted vessels. Although revascularization of single-vessel disease does not improve survival over optimal medical management, it does alleviate symptoms and improve quality of life.

CABG is preferred over percutaneous coronary intervention (PCI) in patients with unprotected LM involvement,

triple-vessel disease, diabetics with multivessel disease, and double-vessel CAD when it includes the proximal LAD. CABG is also preferable in patients requiring surgery for valvular disease.

## PERCUTANEOUS CORONARY INTERVENTIONS

Over the past 30 years, PCI has become the first line treatment of CAD, with approximately 500,000 interventions performed each year in the United States.[16] The first percutaneous transluminal coronary angioplasty (PTCA) was performed by Andreas Gruentzig in 1977. Since that time, numerous devices have emerged such as stents, atherectomy catheters, cutting balloons, thrombectomy catheters, radiation therapy, and lasers. As a result of decades of technical advances, the success of PCI is as high as 95 percent while the risk of death and emergent CABG is considerably less than 1 percent.[16]

PCI is generally performed through 6F guiding catheters but some specialized procedures such as large burr rotational atherectomy and bifurcational stenting require 7F or 8F catheters. The LM or RCA ostium is engaged with a guide catheter and, following the administration of adequate anticoagulation, the stenosis is crossed with a 0.014-in guide wire. A coronary angioplasty balloon is then advanced over the guide wire and after confirming proper placement with fluoroscopy, the balloon is inflated at the site of stenosis. Balloon angioplasty increases luminal diameter primarily by creating a dissection in the atherosclerotic plaque. In the process of enlarging the lumen, angioplasty also denudes endothelium and disrupts, cracks, and fissures atherosclerotic plaque resulting in accumulation of platelets and fibrin.[16] Balloon angioplasty is associated with a 5 percent risk of abrupt closure and a 50 percent risk of angiographic restenosis (>50 percent in-stent stenosis) within 6 months.[16] Nevertheless, balloon angioplasty was shown to improve outcomes compared to thrombolytic therapy in the setting of acute MI, and it was shown to alleviate angina better than optimal medical therapy alone.[16]

Bare metal intracoronary stents were first approved by the FDA in 1993 to treat acute or threatened closure and in 1994 to reduce restenosis compared to balloon angioplasty alone. The implantation of bare metal stents (BMS) became commonplace and markedly reduced complications such as abrupt closure and need for emergent bypass surgery. BMS decrease restenosis by nearly 50 percent compared to balloon angioplasty and, in general, there is a 20 to 30 percent risk of in-stent angiographic restenosis at 6 months following implantation of a BMS. BMS implantation requires aspirin indefinitely and clopidogrel for at least 1 month.

The first drug-eluting stent (DES) was approved by the FDA in 2003, and newer generation DES have been shown to reduce the risk of restenosis to as low as 5 percent at 12 months. DES implantation has been shown to be superior to BMS implantation in a wide range of patients including those with acute MI, acute coronary syndromes, stable CAD, diabetes, and renal insufficiency.[17–19] In the setting of acute MI, target lesion revascularization was decreased by one-third in patients receiving a DES[17] compared to BMS. In patients with either diabetes and/or chronic renal insufficiency, DES as compared to BMS had a lower incidence of major adverse cardiac events (death, nonfatal MI, or target vessel revascularization).[18,19] DES are also associated with better clinical outcomes than BMS in the treatment of unprotected LM disease and saphenous vein graft lesions.[20,21]

The enthusiasm and use of DES were drastically affected several years ago following preliminary reports suggesting an increased risk of late and very late stent thrombosis. This potentially catastrophic event is associated with major cardiac events including MI and death. After DES implantation, patients must take chronic aspirin and clopidogrel for at least 12 months to mitigate the risk of stent thrombosis. According to a recent study, the continuation of clopidogrel after 12 months failed to reduce the incidence of late stent thrombosis associated with DES.[22] However, a meta-analysis of 10 randomized studies that included 5030 patients demonstrated that stent thrombosis occurred at a similar rate after both DES (0.58 percent) and BMS (0.54 percent).[23] In fact, the incidence of stent thrombosis was indistinguishable (1.4 percent) after BMS and DES implantation in 3405 patient presenting with acute coronary syndromes (Fig. 55-5).[24]

Over the past 2 decades, the emergence of stents and the use of antiplatelet therapy have markedly decreased the incidence of severe periprocedural ischemic complications of PCI. Composite rates of Q wave MI, emergent CABG, and death are less than 1.0 percent. Higher volume centers (>400 cases annually) have lower complication rates than low-volume centers and high-volume operators (>75 cases annually) have lower complication rates than low-volume operators.[25] Other complications of PCI include distal embolization, coronary artery dissection, intramural hematoma, occlusion of side branches, and coronary artery perforation, which occur in 0.84 percent of cases.[26] Access site complications such as hematomas (major and minor), pseudoaneurysm formation, retroperitoneal bleeding, need for blood transfusion, arteriovenous fistula, and arterial occlusion are significant causes of morbidity associated with PCI and occur more frequently after PCI than diagnostic procedures, with an incidence as high as 6 percent.[27] Severe bleeding, minor bleeding, and surgical repair of the vascular access site occurs in 3, 10, and 1.4 percent of patients undergoing PCI from the femoral site and are related to the use of dual antiplatelet therapy and procedural anticoagulation.[27]

Other devices are also commonly used to increase immediate procedural success of PCI. The effect of these devices on long-term outcomes is less clear. Rotational atherectomy is performed to debulk heavily calcified lesions prior to stent deployment.[16] Cutting balloons have been shown to be superior to PTCA in the treatment of in-stent restenosis, and they may have an advantage during bifurcational interventions.[16] In the setting of acute MI, manual aspiration using a thombectomy catheter increases myocardial reperfusion and reduces myocardial necrosis.[8,28] Manual aspiration thrombectomy is

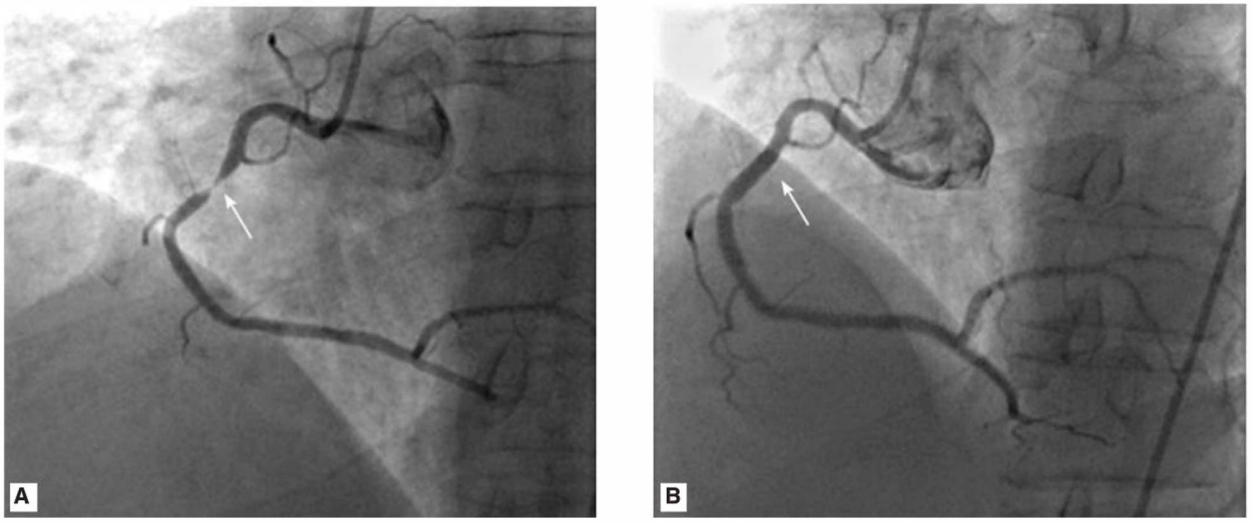

**FIGURE 55-5** **A.** This patient presented with an acute coronary syndrome and had a severe mid-RCA stenosis. **B.** Following placement of a drug-eluting stent, the patient had resolution of his chest pain and ST-segments.

also associated with a decreased risk of no reflow and distal embolization as compared to PTCA or stenting alone.[8,28]

PCI is indicated for the treatment of in-stent restenosis and severe single- or double-vessel CAD with demonstrable ischemia on stress testing. PCI is preferable over CABG in nondiabetic patients with preserved LV function, patients with a patent LIMA to the LAD, patients with multiple debilitating comorbidities who are high risk for CABG, elderly frail patients, patients with short life expectancies, and in those who need urgent noncardiac surgeries.

## INVASIVE HEMODYNAMICS

An essential part of cardiac catheterization is the acquisition and interpretation of hemodynamics. Cardiac output is a critical variable used to assess the systolic performance of the LV, and it is frequently obtained during right heart catheterization by the Fick and/or thermodilution method. Doppler flow velocity is also capable of measuring cardiac output, but this echocardiographic technique is more vulnerable to human error than invasive testing.[29] The most accurate measure of cardiac output at high-output states is thermodilution, while the Fick method is more accurate in patients with low-output conditions and atrial fibrillation.[29] The error in calculating cardiac output invasively is approximately 15 percent, and it might be slightly less for the Fick method.[29]

The Fick formula for cardiac output is:

$$\textit{Cardiac output} = O_2\ \textit{consumption}/(A\text{–}V)O_2 \times \textit{hemoglobin concentration} \times 1.36 \times 10$$

$O_2$ consumption is measured via a gas exchange face mask, but it can also be estimated using a patient's body weight. $(A\text{–}V)O_2$ is the arterial–venous oxygen difference.

Thermodilution cardiac output involves injection of a cold saline bolus into the right atrium, and changes in temperature are measured in the pulmonary artery after the cold saline mixes with the warm blood distally.[29] Cardiac output is dependent on a temperature or time intensity curve, where time is on the *x*-axis, and concentration is on the *y*-axis. Cardiac output is inversely related to the area under the curve. This method is inaccurate in patients with irregular heart rhythms, tricuspid regurgitation, and pulmonic regurgitation. In the absence of a cardiac output measurement, pulmonary artery saturation can be used to estimate LV function, and a saturation less than 65 percent is suggestive of low output.[29]

Cardiac catheterization is the only method capable of directly measuring pressures in the heart and great vessels. Pressure waveforms are passed from the cardiac chambers or great vessels to a pressure transducer via a fluid-filled catheter. The transducer produces an electrical potential that is proportional to variations in pressure, and these electrical potentials are displayed as intracardiac pressure tracings. Normal pressure of the right atrium and RV is 5 and 25/5 mm Hg, respectively. Pulmonary artery pressure, pulmonary capillary wedge pressure (PCWP), and LV pressures are normally 25/10, 10, and 120/10 mm Hg,[29] respectively.

Cardiac catheterization is also used to assess for intracardiac shunting. During a right-heart catheterization, a shunt should be suspected when there is a "step-up" on measurements of right-heart oxygen saturations, and the degree of shunting is reported as the $Q_p/Q_s$. $Q_p/Q_s$ is calculated using the following formula:

$$Q_p/Q_s = \textit{arterial } O_2 \textit{ sat} - \textit{mixed venous sat}/\textit{pulmonary vein sat} - \textit{pulmonary arterial sat}$$

$$\textit{Mixed venous sat} = 3\ \textit{SVC} + 1\ \textit{IVC}/4$$

Patients with valvular heart disease are frequently referred for left- and right catheterization. The severity of mitral stenosis is assessed by obtaining a gradient between the LV and the left atrium, which requires a transseptal puncture. As a result, it is simpler and faster to use the PCWP as an estimate of left atrial pressure.

Aortic valve gradients are used to determine the severity of aortic stenosis and can be obtained by a variety of methods. A peak-to-peak gradient is calculated by subtracting the peak aortic pressure from the peak LV pressure. An aortic valve gradient can also be obtained by the "pull-back method" in which a catheter is quickly pulled back from the LV and placed in the aorta. However, the best method for obtaining an aortic gradient is to perform simultaneous pressure measurements in the LV and aorta using a double-lumen catheter. The modified Hakki equation can be used to measure aortic valve area:

*Aortic valve area = cardiac output/square root of the peak-to-peak pressure gradient*

## VALVULAR HEART DISEASE

The most common valvular abnormalities encountered in clinical practice are aortic stenosis, aortic regurgitation, mitral stenosis, and mitral regurgitation. Aortic stenosis remains the most common acquired valvular abnormality and is frequently caused by progressive calcification of a trileaflet or congenitally bicuspid valve. Calcification extends from the base of the cusps to the leaflets, restricting leaflet motion and decreasing valve area without fusion of the commissures.[30] In contrast, rheumatic disease is characterized by commissural fusion and scarring, and is almost always accompanied by mitral valve disease.[30]

Aortic stenosis causes LV systolic pressure overload. The LV gradually adapts through a hypertrophic process characterized by an increase in wall thickness and maintenance of LV volume.[30] If increase in wall stress is out of proportion to the compensatory increase in concentric hypertrophy, the ejection fraction (EF) is reduced secondary to high afterload. Depressed contractility may also contribute to a low EF and, frequently, the etiology of the compromise in LV systolic function is unclear. Regardless, the distinction has important clinical implications as surgery is less advantageous when the reduction in EF is due to depressed contractility as opposed to an increase in afterload.[30] Although the progression of concentric hypertrophy is protective against high LV pressure, it limits coronary vasodilator reserve and reduces coronary flow per gram of muscle, resulting in subendocardial ischemia.[30]

Initially, there is a long latent period associated with minimal morbidity and mortality, but once aortic stenosis is considered to be moderate in severity (aortic valve area of 1.0–1.5 $cm^2$, mean gradient of 25–40 mm Hg, or jet velocity greater than 3.0 m/s), valve area decreases approximately 0.1 $cm^2$/year, jet velocity increases 0.3 m/s/year, and mean pressure gradient increases 7 mm Hg/year.[30] Sudden death is extremely rare (<1 percent) in asymptomatic patients with aortic stenosis, but after the onset of symptoms, which include angina, heart failure, and syncope, there is a marked increase in sudden cardiac death with an average survival without treatment of 2 to 3 years.[30] As a result, the management of patients with aortic stenosis is dictated by the presence of symptoms.

Cardiac catheterization serves an integral role in the evaluation and treatment of aortic stenosis and is indicated in patients at risk for CAD prior to surgery. If there is a discrepancy between clinical and echocardiographic findings or if the noninvasive tests are inconclusive, a hemodynamic evaluation is recommended to obtain both an aortic gradient and an aortic valve area.

Aortic valve replacement is indicated for symptomatic aortic stenosis and for severe aortic stenosis in patients with depressed LV function (EF less than 50 percent) or coexisting CAD requiring CABG. Valve replacement is also reasonable in asymptomatic patients with an abnormal response to exercise testing or if there is a critical stenosis (valve area less than 0.6 $cm^2$, mean gradient greater than 60 mm Hg, and jet velocity greater than 4.0 m/s) and the operative mortality is less than 1 percent.[30]

Prior to the first balloon aortic valvuloplasty (BAV) in 1985, observation was the only option for inoperable patients.[31] BAV has been shown to improve symptoms, LV function, and hemodynamics, and it enables much sicker and older patients to eventually undergo surgery.[31] BAV fractures valve leaflet calcification, stretches the annulus, and separates the commissures. This increases aortic valve area, reduces transvalvular pressure gradients, and mildly augments LV systolic function.[32] However, there is a limited role for percutaneous BAV secondary to short-term benefits, high rates of restenosis, and at least a 10 percent risk of severe complications.[31,32] The incidence of death, stroke, and vascular complications following BAV is 5, 2, and nearly 6 percent, respectively.[31,32] Other complications include LV perforation, MI, arrhythmias, and aortic regurgitation.[31,32]

BAV rarely increases aortic valve area greater than 1.0 $cm^2$ and, although it improves symptoms, clinical deterioration frequently occurs within 6 to 12 months.[32] BAV was performed in 144 patients who were not offered valve replacement secondary to high surgical risk.[32,33] Group 1 (57 percent) required no further treatment, group 2 (19 percent) needed a second valvuloplasty due to restenosis, and group 3 (24 percent) eventually underwent valve replacement.[32,33] At 36-month follow-up, survival was 13 and 20 percent for groups 1 and 2, respectively, and it was 75 percent for group 3.[32,33] In unstable patients who are too high risk for aortic valve replacement, BAV is a reasonable option as a bridge to surgery.[32,33] It is also appropriate to perform palliative BAV in an inoperable patient with severe symptomatic aortic stenosis and poor quality of life.[30,32]

Given the limitations of BAV, transcatheter aortic valve replacement (TAVR) of balloon expandable or self-expanding aortic valves has emerged as a viable option in both high risk and extreme risk, inoperable patients. The PARTNER Trial (Cohort B) compared the transcatheter Edwards Sapien aortic

valve to medical therapy in aortic stenosis patients deemed as extreme-risk or inoperable.[34–36] There was a marked decrease in all-cause mortality and cardiovascular mortality in the TAVR treated patients compared to the medically treated patients at 1 and 2 years of follow-up. Based on these results, the Edwards Sapien valve was approved by the FDA in November, 2011 for use in extreme risk or inoperable aortic valve patients. The PARTNER Trial (Cohort A) compared TAVR to surgical aortic valve replacement (SAVR) in high-risk patients. The all-cause mortality between TAVR and SAVR was comparable at 1 and 2 years, although the stroke rate was higher in the TAVR treated group.[37,38] Based on these data, the Edwards Sapien valve was also approved by the FDA for high risk (STS score >10%) patients. Similar clinical trials with the self-expanding Medtronic CoreValve are currently underway in the United States. It should be noted that the catheter systems for TAVR have been approved in many countries for several years and over 100,000 patients have been treated worldwide with TAVR. TAVR results in clinical and hemodynamic improvement and is associated with high procedural success, even in critically ill patients.[34] An aortic valve prosthesis can be successfully implanted percutaneously in 96.9 percent of patients.[39] The balloon expandable Edward SAPIEN valve can be delivered via a transfemoral or transapical approach. The self-expanding Medtronic CoreValve can be delivered via a transfemoral, subclavian or direct aortic approach. Major adverse cardiovascular complications occur in up to 10 percent of patients at 30 days and mortality, mostly secondary to severe comorbid conditions of these high-risk patients, is approximately 20 to 30 percent at 1 year.[34] Further studies of TAVR are warranted in intermediate risk patients and are in progress. As further technological improvements are made in percutaneous aortic valve delivery systems, this therapy will likely continue to expand to a greater subset of patients.

Common etiologies of aortic insufficiency include myxomatous degeneration, congenital abnormalities such as a bicuspid aortic valve, calcific degeneration, rheumatic heart disease, infectious endocarditis, hypertension, idiopathic dilatation of the aorta, ascending aortic dissection, and Marfan syndrome. Syphilis, rheumatoid arthritis, osteogenesis imperfecta, Ehlers–Danlos syndrome, Reiter syndrome, and anorectic drugs can rarely be the cause. Chronic aortic regurgitation results in volume overload and LV dilatation due to increased afterload. It progresses slowly over a long period of time in the absence of symptoms. In contrast, patients with acute regurgitation from endocarditis, dissection, or trauma present with cardiogenic shock or pulmonary edema secondary to abrupt elevation of left-sided filling pressures and a sudden drop in cardiac output. Acute aortic insufficiency can also lead to ischemia and sudden death.

Early in the disease process, LV dysfunction and dilation can be improved with aortic valve replacement. Left untreated, the LV eventually dilates further and adopts a more spherical geometry. At this point, LV systolic dysfunction is a product of reduced contractility and is irreversible with minimal if any survival benefit from surgery. This is why LV systolic function and LV end-systolic diameter are the most significant determinants of postoperative systolic function and survival.[30]

The rate of sudden death in asymptomatic aortic regurgitation is less than 0.2 percent per year, and asymptomatic patients with aortic insufficiency develop symptoms or LV dysfunction at a rate of 4.3 percent per year.[30] Asymptomatic patients with aortic insufficiency and depressed LV systolic function develop symptoms within 2 to 3 years, and rates of sudden death in patients with heart failure are as high as 20 percent per year.[30]

Aortic valve replacement is indicated in symptomatic patients with severe aortic regurgitation regardless of LV function. It is also recommended in asymptomatic patients with severe aortic regurgitation and depressed LV function (EF less than 50 percent) and in patients with severe aortic regurgitation who are undergoing CABG. Aortic valve replacement is reasonable in asymptomatic patients with severe regurgitation and normal LV function if there is severe LV dilatation (LV end-diastolic dimension greater than 75 mm or end-systolic dimension greater than 55 mm). Aortic valve replacement and aortic root reconstruction are recommended if there is aortic insufficiency and the aortic root exceeds 4.5 to 5.0 cm. Coronary angiography should be performed prior to surgery in patients at high-risk for CAD. Patients with discrepant clinical and echocardiographic findings should be referred for cardiac catheterization with an aortic root angiogram.

The most common etiology of mitral stenosis is rheumatic heart disease. Rheumatic mitral valve disease is characterized by leaflet thickening and calcification, commissural fusion, and chordal fusion. Isolated involvement of the mitral valve occurs in 40 percent of patients with rheumatic heart disease and is more common in women.[30] Mitral stenosis prevents adequate opening of the mitral valve during diastole, obstructing flow from the left atrium into the LV. A pressure gradient between the left atrium and LV is generated to open the mitral valve and drive blood into the LV. Chronic elevation of left atrial and pulmonary venous pressure causes pulmonary arteriolar vasoconstriction, intimal hyperplasia, and medial hypertrophy, eventually resulting in pulmonary arterial hypertension.

The mitral valve orifice is normally between 4.0 and 5.0 $cm^2$, and symptoms at rest may develop if the mitral valve area is less than 1.5 $cm^2$.[30] Symptoms may also occur with an area less than 2.5 $cm^2$ if there is an increase in left atrial pressure from either an augmentation in mitral flow or a reduction in diastolic filling secondary to atrial fibrillation, pregnancy, exercise, or stress.[30] Although mitral stenosis is initially a slow, stable, progressive disease with a latent period of 20 to 40 years from the time of rheumatic fever to the onset of symptoms, its course accelerates, and symptoms become disabling within a decade. Most patients in the United States present with mitral stenosis in their 50s to 60s, and greater than one-third of patients referred for valvotomy are older than 65. Ten-year survival of untreated patients presenting with mitral stenosis ranges from 50 to 60 percent, but depends on the severity of symptoms.

Survival is greater than 80 percent at 10 years in asymptomatic or mildly symptomatic patients, but the average survival is only 3 years in patients presenting with severe pulmonary hypertension.[30]

Doppler echocardiography is the preferred diagnostic tool for evaluating mitral stenosis, but cardiac catheterization is indicated when the echocardiogram is inconclusive or if there is discrepancy between clinical findings and noninvasive tests. Catheterization is also recommended if there is a discrepancy between the Doppler-derived valve area and mean gradient. It is reasonable to perform cardiac catheterization to assess hemodynamic response to exercise and to determine the etiology of severe pulmonary arterial hypertension when it is disproportionate to the magnitude of mitral stenosis as measured by noninvasive testing.[30]

Percutaneous mitral balloon valvotomy was introduced in the early 1980s and the Inoue valvuloplasty balloon was approved by FDA in 1994. Mitral valvuloplasty is preferred over surgery in appropriately selected patients who have noncalcified, pliable valves and minimal fusion of the subvalvular apparatus. Percutaneous mitral balloon valvuloplasty involves transseptal puncture and sequential inflation of the hourglass-shaped Inoue balloon across the mitral valve in an effort to open the fused commissures. Mitral valvuloplasty is successful in 80 to 95 percent of patients, and it has been shown to double the valve area, decrease the transmitral pressure gradient by 50 to 60 percent, and alleviate symptoms.[30]

Percutaneous mitral balloon valvotomy is recommended for symptomatic patients with moderate or severe mitral stenosis (valve area less than 1.0 $cm^2$, mean gradient greater than 10 mm Hg, or pulmonary artery systolic pressure greater than 50 mm Hg) and favorable valve morphology for percutaneous valvuloplasty in the absence of moderate-to-severe mitral regurgitation and left atrial thrombus.[30] It is indicated for asymptomatic patients with moderate or severe mitral stenosis and favorable valve morphology who have pulmonary hypertension (pulmonary artery systolic pressure greater than 50 mm Hg at rest and 60 mm Hg with exercise). Percutaneous mitral balloon valvulopasty is reasonable for asymptomatic patients with moderate or severe mitral stenosis if they have new onset atrial fibrillation. Percutaneous mitral balloon valvotomy should not be performed in patients with either mild mitral stenosis, left atrial thrombus, moderate-to-severe mitral regurgitation, or heavily calcified valve leaflets.[30]

Percutaneous mitral balloon valvuloplasty is associated with a mortality rate of less than 1 to 2 percent.[30] The most common complication is severe mitral regurgitation, and it occurs in 2 to 4 percent of cases.[30] Other complications include atrial septal defects (ASDs), embolization, LV perforation, and bleeding complications. At 3 to 7 years, freedom from repeat valvotomy, mitral valve surgery, or death is as high as 80 to 90 percent in patients with favorable mitral valve morphology.[30] Valvular calcification, thickened leaflets with impaired mobility, and subvalvular fusion increase risks for complications and rates of recurrent stenosis.[30] Randomized controlled trials comparing percutaneous balloon valvotomy with both open and closed surgical commissurotomy revealed comparable improvements in hemodynamics, exercise capacity, symptoms, and event-free survival.[30]

## HEART FAILURE

Heart failure is a growing epidemic due to an aging population, decreased mortality following MI, and improvements in therapies for CAD and cardiomyopathy. Five million Americans suffer from heart failure, and nearly 550,000 patients are diagnosed with new onset heart failure each year.[40] Approximately 80 percent of patients hospitalized with heart failure are more than 65 years of age, and after the age of 65, 10 per 1000 of the population are affected by this condition.[40] Annually, heart failure accounts for at least 1 million hospitalizations, 6.5 million hospital days, 15 million office visits, and approximately US$27.9 billion in direct and indirect costs.[40] Despite improvements in heart failure treatment, the number of deaths attributed to heart failure continues to rise.

Heart failure is not synonymous with LV dysfunction or cardiomyopathy; rather, it is a clinical syndrome associated with characteristic symptoms of shortness of breath and fatigue and various physical examination findings such as a third heart sound, jugular venous distension, crackles, and peripheral edema.[40] Heart failure is caused by either a structural or functional process that impairs diastolic or systolic LV function. This results in diminished exercise tolerance secondary to low cardiac output and pulmonary congestion with retention of fluid causing peripheral edema.[40] Using the old term "congestive heart failure" is now discouraged because not all patients presenting with heart failure have evidence of volume overload.[40]

Most common causes of heart failure are ischemic heart disease, hypertension, and dilated cardiomyopathy. Etiologies of dilated cardiomyopathy include idiopathic, genetic (30 percent), infectious (HIV), infiltrative diseases (hemachromatosis, sarcoid, amyloid), toxins (cocaine, alcohol, adriamycin), peripartum, nutritional deficiencies (thiamine), tachycardia, and endocrine disorders (hyperthyroidism and pheochromocytoma). Approximately, 50 percent of patients who present with symptoms and signs of heart failure have a normal or preserved LV EF, which is called diastolic dysfunction or heart failure with preserved LV systolic function. The incidence of diastolic dysfunction increases with age. Although the overall incidence of diastolic dysfunction is around 35 percent, nearly 50 percent of patients over the age of 70 are affected by this condition. Heart failure can also be caused by hypertrophic cardiomyopathy and restrictive cardiomyopathy.

Heart failure is a clinical diagnosis, and it cannot be confirmed by one diagnostic test. A thorough history and physical exam are essential to diagnosing and identifying the etiology of heart failure. A transthoracic echocardiogram evaluates LV function, valves, pericardium, pulmonary

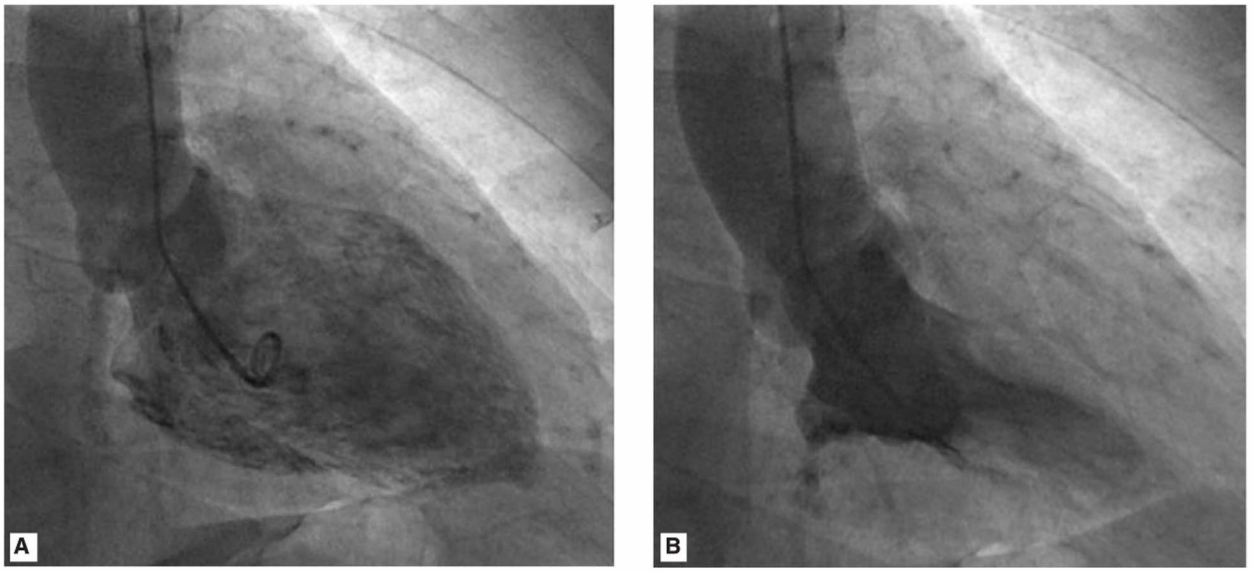

**FIGURE 55-6** Left ventriculography in the right anterior oblique projection shows the left ventricle in (**A**) end diastole and (**B**) end systole. This patient has normal LV systolic function without wall motion abnormalities.

pressures, and RV function. Certain laboratory tests such as natriuretic peptides (BNP and NT-proBNP) should be obtained, especially since elevated levels are associated with high left-sided filling pressures, reduced LV function, ischemia, infarction, and LV hypertrophy.[40] Cardiac catheterization plays an integral role in the evaluation and management of heart failure. A right-heart catheterization provides a measure of cardiac output, right- and left-sided filling pressures, and systemic peripheral resistance. These assessments help to guide the medical management of heart failure. Left-heart catheterization measures LV end-diastolic pressure and left ventriculography provides an assessment of LV systolic function, wall motion abnormalities, and the degree of mitral regurgitation (Figs. 55-6 and 55-7). Furthermore, two-thirds of patients with heart failure and depressed LV function have underlying CAD, and these patients must be evaluated for revascularizable disease. Patients with ischemic chest pain and depressed LV systolic function should be directly referred for coronary arteriography.[40] Surgical revascularization in properly selected patients prolongs survival, improves LV function, and alleviates symptoms.

Several heart failure therapies in addition to revascularization have been shown to improve survival, such as angiotensin converting enzyme inhibitors, β-blockers, aldosterone receptor blockers, and combinations of nitrates and hydralzine in African American patients. Diuretics and digoxin alleviate symptoms, but they do not enhance survival. Although inotropic agents might initially improve performance, they are associated with increased mortality.[40] Devices such as implantable cardioverter-defibrillators and biventricular pacemakers are now recommended to decrease mortality secondary to sudden cardiac death due to ventricular arrhythmias in patients with heart failure and severely depressed LV function.

Cardiac transplantation remains the best treatment for patients with end stage heart failure refractory to optimal medical therapy.[41] Given the limited number of heart donors, the goal is to select patients for transplantation with the greatest likelihood for benefit.[41] Criteria for transplantation include severe refractory heart failure despite maximal medical therapy, markedly impaired hemodynamics, impaired functional capacity (oxygen consumption less that 14 mL/kg/min), refractory angina not amenable to revascularization, congenital disease not suitable for repair, and intractable arrhythmias.[41] Cardiogenic shock, dependence on IV inotropes for adequate organ perfusion, and a peak oxygen consumption of less than 10 mL/kg/min are absolute indications for transplantation in appropriate patients.[40]

Advanced age, severe peripheral vascular disease, irreversible organ (kidney or liver) dysfunction, history of malignancy with likely recurrence, poor medical compliance, active drug abuse, systemic infections, and irreversible pulmonary hypertension are relative contraindications for cardiac transplantation.[41] Advanced age has been associated with worse outcomes following transplantation, and diabetic patients with evidence of neuropathy, nephropathy, and vascular disease are usually considered poor candidates.[41] Irreversible pulmonary hypertension is associated with an increased incidence of death and postoperative complications. In fact, pulmonary vascular resistance greater than 4 Wood units is a contraindication to transplantation, and

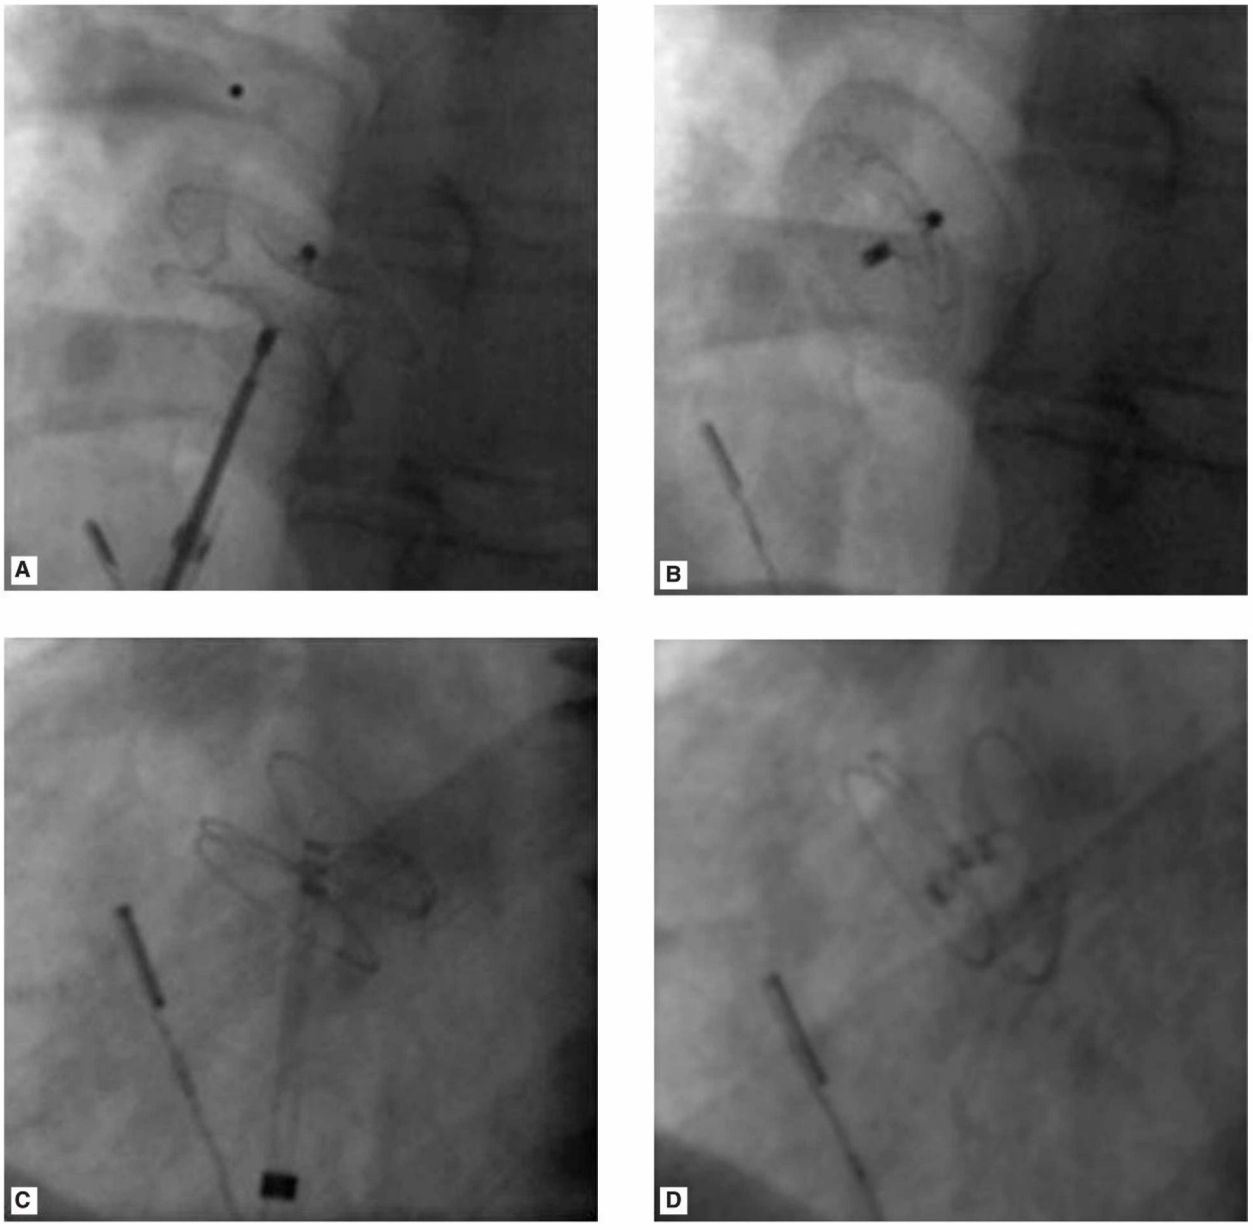

**FIGURE 55-7** **A.** Deployment of Amplatzer septal occluder. **B.** Once the device is stable, it is released by rotating a delivery cable. **C.** HELEX septal occluder prior to and (**D**) after deployment to close a PFO in a patient who suffered a cryptogenic stroke.

pulmonary vascular resistance as expressed in Wood units is calculated by the following formula:

*Pulmonary vascular resistance = (mean pulmonary pressure − PCWP)/cardiac output*

Although cardiac transplantation is available to less than 2500 patients in the United States each year, a left ventricular assist device (LVAD) is a reasonable option as either temporizing or destination therapy in patients with refractory heart failure and a 12-month mortality of 50 percent or less despite optimal medical management.[40]

## PERICARDIOCENTESIS

Pericardial effusions have been treated by percutaneous pericardiocentesis since the 18th century. Percutaneous pericardiocentesis is most commonly indicated for cardiac tamponade

and pericardial effusions greater than 2 cm in diastole.[42] They are also performed for smaller effusions in order to obtain fluid for cytology or culture. The only absolute contraindication for performing a pericardiocentesis is the presence of an aortic dissection, but pericardiocentesis should also not be performed for small, posterior, and/or loculated effusions. Other relative contraindications include traumatic hemopericardium, coagulopathy, and thrombyocytopenia (less than 50,000).[42] The etiologies of pericardial effusion include idiopathic (20 percent of cases), infectious, MI, cardiac surgery, trauma, malignancy, (lung breast cancer, lymphoma), radiation, autoimmune diseases, end stage renal disease, uremia, myxedema, heart failure, and severe pulmonary hypertension.

Percutaneous pericardiocentesis is usually performed in the catheterization lab with fluoroscopy, ECG, and echocardiographic guidance. After the patient is propped up so that the pericardial fluid drains inferiorly, the skin below the xiphoid process is sterilized and anesthetized with lidocaine. A long 18-gauge needle is inserted at a 30° angle to the skin from a subxiphoid approach and is directed toward the left shoulder, avoiding the pleura, coronary, pericardial, and internal mammary arteries. Other approaches may also be used with echocardiographic guidance. A soft J-wire is introduced through the needle, and its position is confirmed with fluoroscopy. Injection of agitated saline through the needle or small bore catheter can be performed with echocardiographic imaging to verify entry into the pericardial space prior to the insertion of a dilator and a multiholed pigtail catheter for drainage. Rapid removal of greater than 1 L of fluid is discouraged to prevent acute dilation of the RV, which is extremely rare.[42] The drainage catheter usually remains in place for 24 to 48 h under slight negative pressure or until the volume is less than 25 mL/day. A stopcock on the end of the catheter should be used for aspiration and flushing to prevent thrombus formation.

Percutaneous pericardiocentesis is associated with a major complication rate of less than 2 percent.[42] Complications include myocardial or coronary perforation (less than 1 percent), arrhythmias, bleeding, pneumothorax, and infection.[42] The most serious complication results from lacerating a coronary artery or from puncturing the LV or RV. Injuring the thin-walled RV is more common than injuring the LV, but it is less dangerous. Puncturing the right atrium is potentially catastrophic but extremely rare.[42] Although fluoroscopically guided pericardiocentesis using the subxiphoid approach remains the standard technique, an echocardiography-guided technique is gaining popularity as it allows for the shortest route to the fluid and has been shown to minimize adverse events.[42]

## ATRIAL SEPTAL DEFECT/PATENT FORAMEN OVALE CLOSURE

An ASD is one of the most common congenital heart anomalies. ASDs have been repaired surgically since 1952 with excellent results. The first attempt at percutaneous closure of an ASD was in the early 1980s, but initially these procedures were limited by high complications rates, a bulky delivery sheath system, and large catheters.[43] Technology has evolved tremendously over the past 2 decades, and newer devices have emerged that markedly improve accessibility and both short- and long-term outcomes. Percutaneous transcatheter closure of secundum ASDs is safe, effective, and reliable and is now preferable over surgical methods.[43] However, proper patient and device selection based on atrial septal anatomy and defect size is essential for successful closure.[43]

Indications for both surgical and percutaneous closure are the same and include a pulmonary-to-systemic shunt ratio ($Q_p/Q_s$) greater than 1.5:1. It is also reasonable to repair defects if the $Q_p/Q_s$ is less than 1.5:1 in the setting of paradoxical emboli, given the procedure's low morbidity and mortality. Closure of a secundum ASD is contraindicated in patients with severe pulmonary vascular disease ($Q_p/Q_s < 0.7:1$).[43]

Approximately 25 percent of adults have a patent foramen ovale (PFO), and the size of the defect increases with age. Although a PFO and secundum ASD are both abnormal communications involving the interatrial septum, they have different etiologies. A PFO is due to incomplete fusion of the septum primum and the septum secundum after birth, while a secundum ASD is the product of a missing segment of the atrial septum secondary to abnormal embryological development. Despite its association with cryptogenic strokes, paradoxical embolization, migraines, platypnea orthodeoxia syndrome, hypoxia with normal pulmonary pressures, and decompression sickness in divers and pilots, PFOs were rarely treated surgically in the past, but these interatrial defects are now being closed percutaneously with excellent procedural success, low complication rates, and low frequency of recurrent events.[43,44]

Although randomized clinical trials of PFO closure to prevent recurrent cryptogenic neurologic events are lacking, there are considerable registry data suggesting that PFO closure decreases recurrent neurologic events compared to medical management. In one study, 110 patients underwent percutaneous closure of a PFO as an alternative to surgery or long-term anticoagulation for prevention of recurrent stroke. Procedural success was 100 percent, and no deaths or strokes occurred during the procedure. The procedural complication rate was 5 percent and included device migration, pericardial tamponade, and arrhythmias.[44] At a mean follow-up of 2.3 years, the annual risk of recurrence was less than 1 percent, and freedom from recurrent cerebral ischemic events and reintervention was 96 and 90 percent at 1 and 5 years, respectively.[44] Although an earlier trial involving PFO closure in 80 patients was successful in 98 percent of the patients, they reported a 10 percent incidence of in-hospital complications.[44] Certainly, percutaneous transcatheter closure of interatrial septal defects involves a steep learning curve, but the complication rate by an experienced interventionalist is as low as 2 percent.[43] Procedural complications of percutaneous PFO and secundum ASD closure include vascular complications, strokes, air embolism, device migration, cardiac perforation, arrhythmias, endocarditis, device thombus, and device fracture.[43]

Percutaneous transcatheter closure of a PFO is an off label use of an FDA-approved device in the absence of randomized controlled trial data comparing medical therapy

to percutaneous closure. According to the American Heart Association, percutaneous closure of a PFO is a class IIB indication in patients with a PFO after a cryptogenic cerebrovascular stroke or after recurrent embolic events despite adequate medical therapy (anticoagulation and therapeutic INR).[43] Previously, the FDA permitted the use of these devices for the prevention of cryptogenic strokes under a Humanitarian Device Exemption based on evidence of device safety and not stroke prevention, but this expired in the end of 2006.[43] The Humanitarian Device Exemption still allows for percutaneous closure of a PFO in the setting of refractory hypoxemia due to right-to-left shunting, but there are no indications for PFO closure in patients with migraines.[43]

Available devices in the United States for percutaneous transcatheter closure of a secundum ASD or a PFO are the Amplatzer atrial septal occluder (ASO) device or cribiform ASD occluder (Amplatzer; AGA Medical, Golden Valley, MN), and the HELEX septal occluder (W.L. Gore and Associates, Flagstaff, AZ). The Amplatzer occluder is a self-expandable, double-disk device composed of nitinol wire and polyester mesh. The ASO device consists of a left atrial disk and a slightly smaller right atrial disk (Fig. 55-7A and B) with a waist that is selected based on balloon sizing of the defect. A cribiform ASO device has equal-sized left- and right atrial discs with a small connecting waist. The ASD closure devices are generally deployed with fluoroscopic and intracardiac echocardiographic guidance. The Amplatzer occluder device is easy to deploy and is self expanding.[43] The Gore HELEX Septal Occluder is made of an ePTFE patch material supported by a nitinol wire frame (Fig. 55-7C and D). Its preassembled delivery system permits deployment of the Helex though an 11F femoral venous sheath. Although the HELEX is approved by the FDA for closure of an ostium secundum ASD up to 18 mm in diameter, the company is presently conducting a randomized, multicenter trial designed to demonstrate the safety and efficacy of the HELEX device in patients with a PFO and a history of either a cryptogenic stroke or a transient ischemic attack. One additional device, the CardioSEAL-STARFlex occluder is an umbrella device supported by one nitinol microspring. The NMT sponsored CLOSURE-1 Study randomized 800 patients with crytogenic stroke to device closure or medical management. This study failed to demonstrate a significant reduction in recurrent neurologic events with PFO closure[45] and consequently PFO closure remains an off-label procedure in the United States. Similar randomized trials are being conducted with the Amplatzer and HELEX devices and hopefully results of these studies will be known in the very near future.

## CARDIAC CATHETERIZATION AND INTERVENTIONS BOARD REVIEW QUESTIONS (CHAPTER 55)

1. Which of the following statements is true?
   A. A malignancy can occur after a certain threshold of radiation is exceeded.
   B. If the operator stands twice as far away from the source of radiation, he or she decreases his exposure to radiation by half.
   C. Pregnant lab personnel must not be exposed to fluoroscopy.
   D. The maximum amount of whole body radiation dose per year is 5 rems.
   E. The maximum amount of whole body radiation dose per lifetime is 100 rems.

2. Which if the following statements is false?
   A. The ostium of the LM is best seen in the LAO or LAO cranial projection.
   B. The distal LM is best seen in an AP or shallow RAO caudal view.
   C. The LCx is best visualized in the RAO or LAO caudal projection.
   D. The mid-to-distal LAD is best visualized in the LAO caudal projection.
   E. The ostium of the RPDA is best seen using a shallow RAO view.

3. Which of the following is an indication for percutaneous balloon aortic valvulopasty?
   A. Bridge to surgery in an unstable patient with severe aortic stenosis and heart failure
   B. Octogenarians or nonagenarians who have severe aortic stenosis
   C. Palliation in a patient with critical aortic stenosis who is not a surgical candidate due to multiple comorbidities
   D. A and C
   E. All of the above

4. Which of the following treatments has not been shown to improve survival in patients with heart failure?
   A. Surgical revascularization
   B. Angiotensin converting enzyme inhibitors
   C. Dobutamine
   D. β-Blockers
   E. None of the above

5. Which of the following is an FDA-approved indication for percutaneous PFO closure?
   A. Cryptogenic strokes or paradoxical emboli
   B. $Q_P/Q_s$ >1.5:1
   C. Cryptogenic stroke and $Q_P/Q_s$ >1.5:1
   D. All of the above
   E. None of the above

## ANSWERS

1. **Answer: D.** The maximum amount of whole body radiation dose per year is 5 rems. The other statements are false.
2. **Answer: D.** The mid-to-distal LAD is best visualized in the RAO and LAO cranial projections. The other statements are true.
3. **Answer: D.** BAV is a reasonable option in unstable patients who are at too high risk for aortic valve replacement or as a bridge to surgery. Valvuolplasty should not be substituted for valve replacement in elderly patients if they are suitable surgical candidates and lack multiple comorbidities.
4. **Answer: C.** Inotropic agents such as milrinone and dobutamine have actually been shown to increase mortality.
5. **Answer: E.** Closing a PFO percutaneously is an off-label use of an FDA-approved device.

# Echocardiography in Cardiac Surgery

*Colleen Harrington*
*Samia Mora*
*Katherine C. Wu*

## PRINCIPLES OF ECHOCARDIOGRAPHY

Since 1976, echocardiography (echo) has been used to evaluate cardiac structure and function. Echo uses sound in the high-frequency range (2–10 MHz). Frequency ranges between 2 and 5 MHz are typically used for imaging adults, while frequencies of 7.5 to 10 MHz are used for children and specialized adult applications. The transducer contains a piezoelectric crystal that converts electrical to sound energy, producing sound waves that are transmitted in the form of a beam. A complete transthoracic echocardiogram (TTE) consists of a group of interrelated applications including two-dimensional (2D) anatomic imaging, M-mode, and three Doppler techniques: pulsed-wave (PW), continuous-wave (CW), and color-flow (CF) imaging.[1–7] In addition, the quantification of cardiac chamber dimensions, areas, and volumes is an important aspect of a complete examination. Using a combination of these ultrasound techniques, one can assess the anatomy and function of the cardiac valves, myocardium, and pericardium.

## TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Standard views are obtained along three orthogonal planes of the left ventricle (LV): long-axis, short-axis, and the four-chamber plane (Fig. 56-1A–C). The long axis is parallel to the long axis of the LV. The short axis cuts the LV cross-sectionally, similar to slices of bread in a loaf, and is orthogonal to the long axis. Four standard transducer locations are used to obtain complete visualization of the entire heart: parasternal, apical, subcostal, and suprasternal.

## M-MODE ECHOCARDIOGRAPHY

M-mode is a one-dimensional "ice pick" view of the heart (Fig. 56-1D) and is often used for measuring LV systolic and diastolic chamber dimensions and wall thickness.

## DOPPLER ECHOCARDIOGRAPHY

The Doppler effect is the phenomenon whereby the frequency of sound waves increases or decreases as the sound source moves toward or away from the observer. The resultant Doppler frequency shift can be detected and translated into blood-flow velocity. The velocity of blood can then be used to calculate valvular gradients and areas, intracardiac pressures, and volumetric flow.

### Pulsed-Wave Doppler

Pulsed-wave (PW) Doppler is obtained when a pulse of ultrasound is transmitted intermittently, allowing for estimation of blood-flow velocity at a specific region of interest. It is thus "site-specific." Its disadvantage is aliasing (or wrap-around) of the signal at velocities that are one-half of the pulse repetition frequency (Nyquist limit). This property limits the maximal velocity that can be accurately measured with PW.

### Continuous-Wave Doppler

Continuous-wave (CW) Doppler records all the velocities along the path of the ultrasound beam. Using CW, the magnitude of the blood-flow velocity and its direction can be accurately recorded. Its disadvantage is that it does not allow localization of the specific site of the velocity obtained along the beam path. CW is used to measure high-velocity jets associated with valvular dysfunction as well as intracardiac pressure gradients. The simplified Bernoulli equation can then be used to convert velocities into pressure gradients ($\Delta P = 4V^2$).

### Color-Flow Doppler

Color-flow (CF) Doppler transforms Doppler velocity information into a color-coded scheme. Red denotes flow

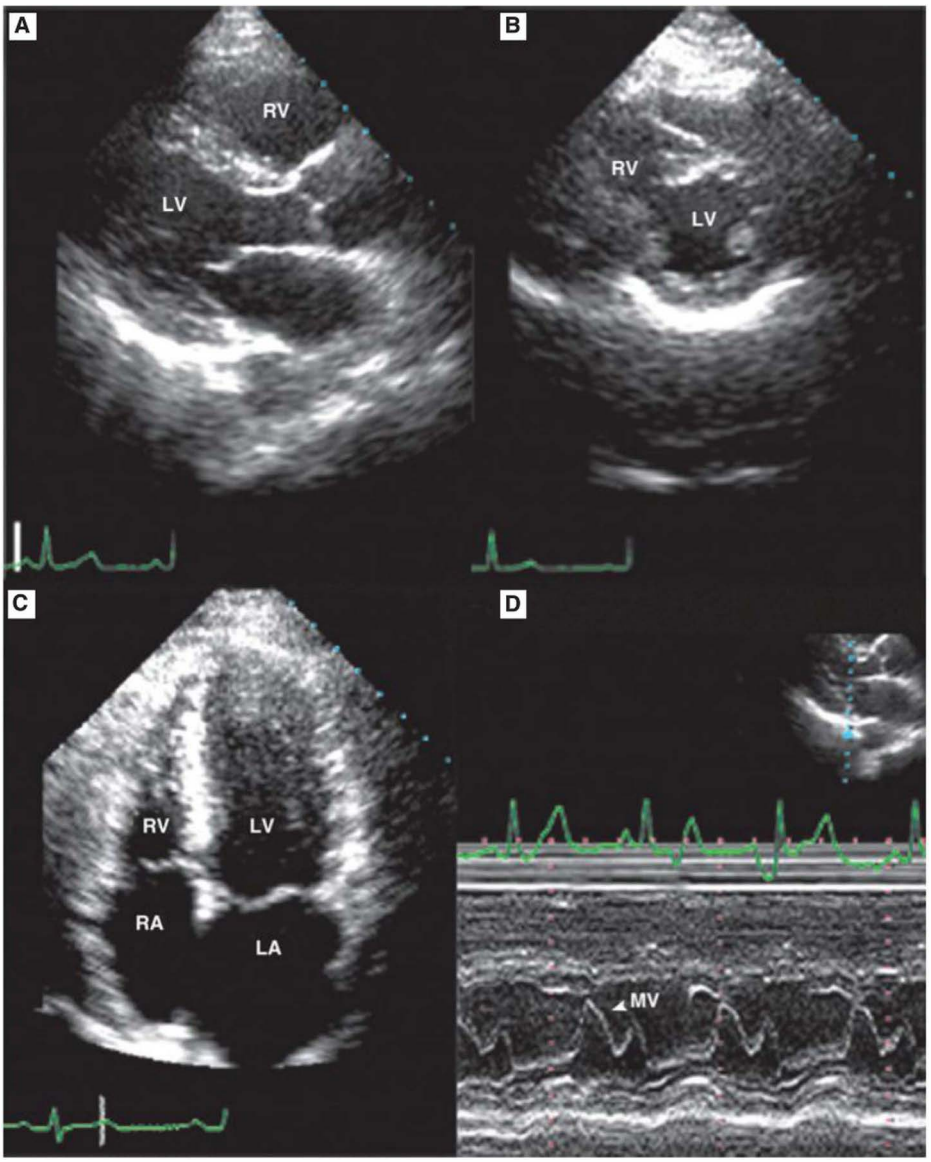

**FIGURE 56-1** Standard 2D TTE (**A–C**) and M-mode (panel **D**) views in a normal individual. **A.** Parasternal long-axis view of the right ventricle (RV), interventricular septum, left ventricle (LV) cavity and posterior wall, and both mitral and aortic valves. Since the RV is the most anterior structure, it will be located closest to the transducer beam and is seen at the top of the image display, while the LV and LA (both posterior structures) are farther away from the transducer and are seen at the bottom of the image. **B.** Parasternal short-axis view of the ventricles at the papillary muscle midventricular level obtained by rotating the transducer 90 degrees. **C.** Apical four-chamber view, important for evaluation of ventricular function, apical thrombus, mitral and tricuspid valve function. **D.** M-mode view through the RV and mitral leaflets. This view is useful for detecting RV diastolic collapse in tamponade.

toward the transducer, while blue represents flow away from the transducer. The relative velocity of blood flow is also depicted, with brighter shades of blue or red representing higher velocities. Turbulent flow is seen as multicolored jets (e.g., due to valvular disease or intracardiac shunts).

## TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) was first introduced clinically in the United States in the 1980s. By placing an echocardiographic probe in the esophagus, the

distance between the transducer and the structures of interest is decreased. This allows the use of higher frequency (5- and 7-MHz) transducers that further enhances image quality[39]. The development of transducer crystals that rotate from 0 to 180 degrees also allows for examination of each cardiac structure from different planes and angles. Acquisition of images is from two basic locations: midesophageal (30–35 cm from the incisors) and midgastric (40–45 cm from the incisors).

## Indications

Typically, a TEE examination provides additional information but does not replace a transthoracic examination. In the evaluation of the anterior structures, a TTE may in fact provide better image quality. A TEE is useful for the evaluation of patients with limiting body habitus, such as obesity or emphysema, who are not optimally imaged by the transthoracic approach. In addition, certain structures that are not well visualized by TTE [such as the left atrial (LA) appendage, thoracic aorta, and prosthetic valves] can be assessed by the transesophageal approach. A third common indication is to guide intraoperative management during cardiac surgery. Class I indications for perioperative TEE (conditions for which there is evidence and/or general agreement that TEE is useful and effective) are listed in Table 56-1.[8] There are other situations in which TEE may also be useful but is not required (i.e., class II indications: conditions in which there is a divergence of opinion about the usefulness/efficacy of a procedure but in which the weight of opinion is in favor of usefulness/efficacy). These include ongoing surgical procedures in patients at increased risk of myocardial ischemia or hemodynamic instability, minimally invasive surgery, or intracardiac mass resection. Examples include, the Cox-Maze procedure, cardiac tumor resection, aneurysmorrhaphy, intracardiac thrombectomy, and pulmonary embolectomy.

**TABLE 56-1: Class I Indications for Perioperative TEE**

| |
|---|
| Acute and life-threatening hemodynamic instability |
| Valve repair or complex valve replacements |
| Hypertrophic obstructive cardiomyopathy |
| Aortic dissection with possible aortic valve involvement |
| Endocarditis (perivalvular involvement) |
| Congenital heart surgery |
| Pericardial windows (posterior or loculated effusions) |
| Placement of intracardiac devices |

Data modified from Cheitlin MD, Armstrong WF, Aurigemma GP, et al. ACC/AHA/ASE 2003 guideline update for the clinical application of echocardiography: Summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/ASE Committee to Update the 1997 Guidelines for the Clinical Application of Echocardiography). *Circulation* 2003;108:1146–1162.

It is also particularly useful in detecting intracardiac air or aortic atheromatous disease and for selecting anastomotic sites during heart/lung transplantation.[8] Antibiotic prophylaxis for infective endocarditis is usually unnecessary but is optional in the high-risk patient (e.g., complex congenital heart disease, prosthetic valve, poor dentition, or prior history of endocarditis).[9]

## Contraindications and Complications

Relative contraindications for TEE include significant esophageal pathology (e.g., strictures, varices), history of radiation therapy to the mediastinum, and recent esophageal or gastric surgery. Serious complications of TEE are uncommon (<1 percent) but may include aspiration and other problems related to sedation, mucosal trauma, laryngospasm, esophageal or pharyngeal laceration or perforation, methemoglobinemia, and rarely death. Death occurs in less than 1 in 10,000 patients. The passage of the TEE probe is "blind" and is done without direct visualization. The severe complications of esophageal or pharyngeal trauma are signaled by patient complaints of severe pain and inability to swallow, which usually occur after the procedure has ended and sedation has worn off. Esophageal perforation during intraoperative TEE can go undetected for a period of time because of the use of anesthesia and paralytics that prevent patient feedback regarding pain during probe passage.

# THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Three-dimensional (3D) echocardiography has been one of the most important developments in cardiac ultrasound imaging during the last decade. Cardiac structures are seen in relation to each other in all three spatial dimensions[39]. Acquisition of data includes volumetric ultrasound imaging. It also includes 2D imaging in multiple planes with a known 3D location; as long as the images are linked. 3D echocardiography has been shown to be more accurate in the measurement of LV volumes and ejection fraction (EF) and has been validated against accepted reference techniques such as cardiac magnetic resonance[40]. 3D echocardiography is not widely available yet and it not part of the routine clinical examination.

# ASSESSMENT OF VENTRICULAR FUNCTION

Routinely, a qualitative visual estimate of global LV systolic function is obtained by examining LV wall thickening and motion in multiple topographic planes. It is imperative that the endocardium is visualized to make this assessment. In addition, LV systolic function can also be assessed semiquantitatively by using a grading scale (wall

motion score). On TEE, images obtained from the esophagus and transgastric orientations are used to assess LV systolic function.

## LEFT VENTRICULAR EJECTION FRACTION

EF is often reported qualitatively as increased (hyperdynamic), normal, mildly, moderately, or severely reduced.[8] In addition, the reader often assigns an estimated value to the qualitative assessment. Normal LV EF is 61 ± 10 percent.[10]

Visual estimation of EF by experienced readers is generally reliable but is limited by reader variability and depends on optimal echocardiographic delineation of the endocardium.

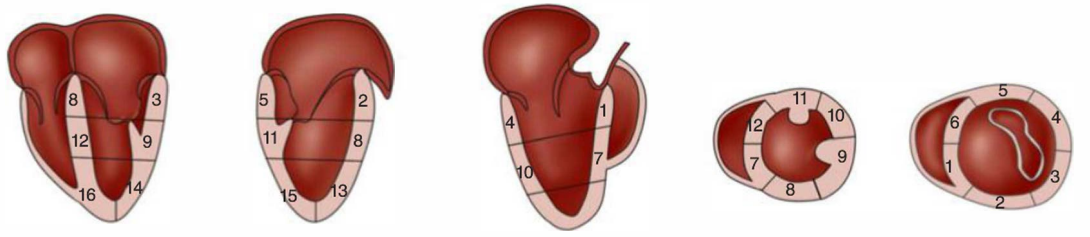
EF can also be quantified from the equation below after determining end-diastolic volume (EDV) and end-systolic volume (ESV):

$$EF = SV/EDV = (EDV - ESV)/EDV$$

where SV, stroke volume; EDV, end-diastolic volume; and ESV, end-systolic volume.

Volumes can be obtained by the modified Simpson's rule or method of disks. This calculates ventricular volume as the sum of parallel slices from the apex to the base. Further details of the technique can be found in several of the references.[1,2,11]

## LEFT VENTRICULAR FRACTIONAL SHORTENING (PERCENT FRACTIONAL SHORTENING)



Percent FS is another method for estimating LV systolic function and reflects a percent change in LV dimension with systolic contraction. It is calculated from LV end-diastolic and end-systolic dimensions measured by M-mode. The normal range for FS is between 25 and 45 percent. For ventricles that are roughly symmetrical without regional wall motion abnormalities, EF is approximately 2 (percent FS).

$$\text{Percent FS} = (EDD - ESD) / EDD \times 100$$

where EDD, end-diastolic dimension and ESD, end-systolic dimension.

## LEFT VENTRICULAR REGIONAL WALL MOTION

For the assessment of LV regional wall motion, the LV is divided into 16 segments (Fig. 56-2), each of which is given a score from 1 to 5 (1, normal or hyperkinetic; 2, hypokinetic; 3, akinetic; 4, dyskinetic; 5, aneurysmal or diastolically deformed). This grading system differs from the 1-to-5 grading system of TEE often used by cardiac anesthesiologists [1, normal (>30 percent thickening); 2, mildly hypokinetic (10–30 percent thickening); 3, severely hypokinetic (<10 percent thickening);

Four-chamber view | Two-chamber view | Long-axis view | Mid-short-axis view | Basal short-axis view

| Basal segments | Mid segments | Apical segments |
|---|---|---|
| 1 = Basal anteroseptal | 7 = Mid anteroseptal | 13 = Apical anterior |
| 2 = Basal anterior | 8 = Mid anterior | 14 = Apical lateral |
| 3 = Basal lateral | 9 = Mid lateral | 15 = Apical inferior |
| 4 = Basal posterior | 10 = Mid posterior | 16 = Apical septal |
| 5 = Basal inferior | 11 = Mid inferior | |
| 6 = Basal septal | 12 = Mid septal | |

**FIGURE 56-2** Sixteen-segment model of the left ventricle. According to guidelines of the American Society of Echocardiography and the Society of Cardiac Anesthesia, the left ventricle is divided into 16 segments (6 basal, 6 midventricular, and 4 apical segments) for evaluation of wall motion and calculation of the wall motion score. (From Shanewise JS, Cheung AT, Aronson S, et al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *J Am Soc Echocardiogr* 1999;12:884–900. With permission. Copyright Elsevier.)

4, akinetic (no thickening); 5, dyskinetic (paradoxical systolic motion)].[12] The wall motion score index is calculated as the sum of segmental wall motion scores divided by the number of segments seen. A score of 1 is normal, and higher wall motion scores indicate more extensive ventricular dysfunction. However, this grading system is more useful for research databases than for clinical use.

## LEFT VENTRICULAR FILLING

LV preload is the LV volume at end-diastole. Normal LV end-diastolic size is 3.5 to 5.7 cm in the parasternal long-axis view. The size of the ventricles and atria may be used for the qualitative evaluation of filling pressures and assessment of hyper- or hypovolemia, particularly intraoperatively with TEE.[13] Small LA size and near cavity obliteration of the LV can indicate hypovolemia.[14] On the other hand, ventricular and atrial enlargement may indicate hypervolemia or an underlying cardiomyopathy. Doming of the interatrial septum toward the right suggests elevated LA pressure and increased LV preload. One limitation to using TEE for indirect measurement of volume status is that the LV may be foreshortened; it is therefore recommended that the LV be imaged from several different planes to get a more accurate estimate of LV volume.[14]

## LEFT VENTRICULAR DIASTOLIC FUNCTION

Doppler echo is the most common diagnostic tool for assessing diastolic function. Indices of transmitral and pulmonary venous Doppler flows are commonly used to identify patterns of diastolic dysfunction.[11]

### Mitral Valve Inflow

When sinus rhythm is present, PW Doppler at the level of the mitral valve (MV) leaflets records two velocities separated by a period of diastasis (no flow), as shown in Fig. 56-3. After the MV opens, early rapid diastolic filling of the LV occurs (E wave), followed by a period of diastasis, after which late filling occurs due to atrial contraction (A wave). Normally, in individuals less than 60 years old, the peak *E*:*A* wave velocity ratio is greater than 1. When there is impaired relaxation without elevated filling pressures, the peak E decreases; hence, the *E*:*A* ratio becomes less than 1. In contrast, a "restrictive" filling pattern is seen when both impaired relaxation and elevated filling pressures are present, resulting in a smaller contribution of atrial contraction and an increased *E*:*A* ratio (>1.5–2).

### Pulmonary Vein Flow

Four velocities are seen in PW Doppler of the pulmonary veins (Fig. 56-4). Occurring in early systole, the first systolic forward flow velocity ($PV_{S1}$) is due to the relaxation of the LA,

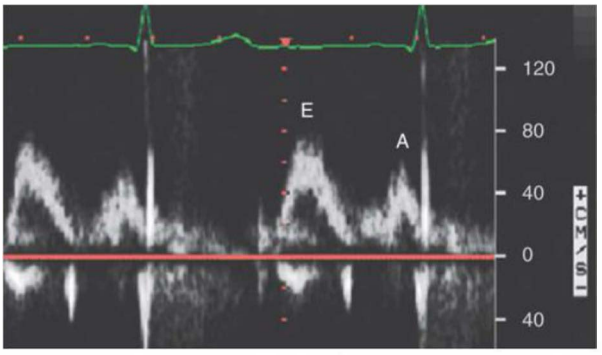


**FIGURE 56-3** Pulsed-wave (PW) Doppler of the mitral valve inflow. This figure shows a normal pattern of blood flow through the mitral valve in diastole. The two peaks indicate early (E wave) and late (A wave) diastolic filling separated by a brief period of diastasis (no flow). In individuals less than 65 years old, a normal *E*:*A* ratio is 2:1. Deceleration time is the time interval from peak E velocity to baseline.

which promotes pulmonary venous flow into the LA. In mid-to-late systole, a second systolic forward flow ($PV_{S2}$) occurs that is produced by the increase in pulmonary venous pressure occurring after right ventricular (RV) systole. In diastole, a third pulmonary vein velocity is seen ($PV_D$). This is related to the decrease in LA pressure seen after MV opening. The fourth velocity is the atrial flow reversal velocity ($PV_a$) that is related to LA contraction. A pulmonary vein systolic velocity peak less than the diastolic velocity peak is suggestive of elevated LA pressures. Restrictive filling indicative of very high filling pressures is seen when $PV_{S2}$ is much less than $PV_D$. When higher filling pressures are present, both the duration and peak velocity of $PV_a$ are increased. Another sign of elevated LA pressure is when the duration of $PV_a$ is longer than the duration of the mitral inflow A wave (by >0.03 s).

## RIGHT VENTRICULAR SIZE, FUNCTION AND FILLING PRESSURES

Qualitative evaluation of RV size, wall thickening, and motion is done visually. The subcostal and apical four-chamber views provide the most accurate assessment of RV size. Normal RV size is less than two-thirds of LV size (see Fig. 56-1) and wraps around the LV in a U-shaped manner. The RV size is described as normal if it smaller than the LV and its apex is more basally located than the LV apex; mildly dilated if it is enlarged but to a lesser extent than the LV area; moderately dilated if the RV area is the same as the LV area; and severely dilated if the RV area is larger than the LV. RV hypertrophy is present when the RV free wall thickness is >0.5 cm.

Assessment of RV function is also done visually as is estimation of LV function; however, it is much more difficult to estimate RV function. The function is compared to the function of the LV and is described as normal, mildy reduced, moderately reduced, and severely reduced. It can also be assessed by the amount of displacement of the tricuspid valve

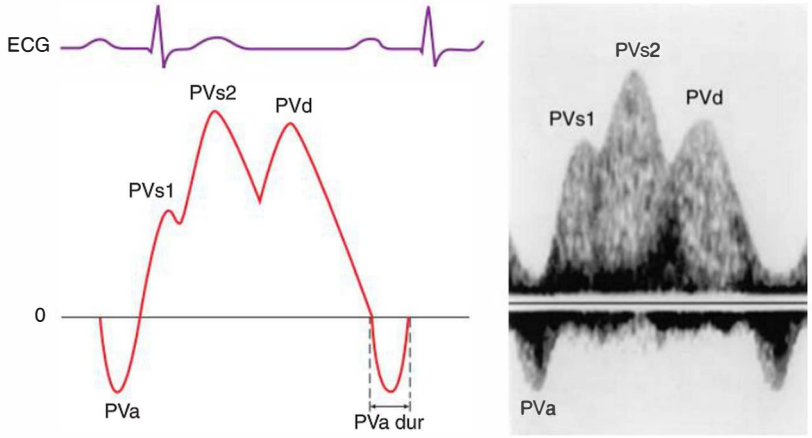

**FIGURE 56-4** Pulsed-wave (PW) Doppler of the pulmonary vein. This figure shows a normal pattern of blood flow through the pulmonary veins with four velocities seen ($PV_{S1}$, $PV_{S2}$, $PV_{D}$, $PV_{a}$). Duration of peak reverse flow velocity during atrial contraction ($PV_{a}$ dur) is also measured. (From Oh JK, Appleton CP, Hatle LK, et al. The noninvasive assessment of left ventricular diastolic function with two-dimensional and Doppler echocardiography. *J Am Soc Echocardiogr* 1997;10:246–270. With permission. Copyright Elsevier.)

annulus toward the apex in systole. A reduction of motion of less than 1.5 cm indicates a significant reduction in RV function. Normal tricuspid annular motion is 1.5 to 2.0 cm.

Septal wall flattening (resulting in a D-shaped LV in the short-axis view) or septal deviation into the LV can be seen in both pressure- and volume-overload conditions of the RV.[12] With elevated RV pressure, the septum moves toward the LV with maximum reversed curvature in midsystole. In RV volume overload, the reversed curvature of the septum is seen in middiastole with normalization during systole.

When tricuspid regurgitation (TR) is present, the RV systolic pressure (RVSP) can be estimated (see also "Pulmonary Hypertension," below). TTE is preferred to TEE for measuring RVSP because of better alignment of the transducer beam with the direction of the regurgitant jet.

Examination of the size and respiratory changes of the venae cavae and hepatic veins can give helpful clues to the patient's volume status and is also used in the evaluation of pericardial disease. Although TTE is preferred for examination of the respiratory variation of the inferior vena cava (IVC), TEE provides better visualization of the superior vena cava. Dilatation of the superior vena cava (greater than one-half the aortic dimension in the short-axis view) is suggestive of hypervolemia.[14]

# VALVULAR DISEASE

## Mitral Valve

### MITRAL VALVE MORPHOLOGY

Normal MV function depends on the normal function of all its component parts, including the mitral leaflets, annulus, chordae tendineae, and papillary muscles. Not only is LV function important for normal MV function but also the cavity size, since LV dilation will prevent or limit leaflet coaptation in systole, causing mitral regurgitation (MR). The rectangular posterior leaflet is composed of three scallops (P1, P2, P3), while the semicircular anterior leaflet is divided into thirds for descriptive purposes (Fig. 56-5). Normal MV area is 4 to 6 $cm^2$.

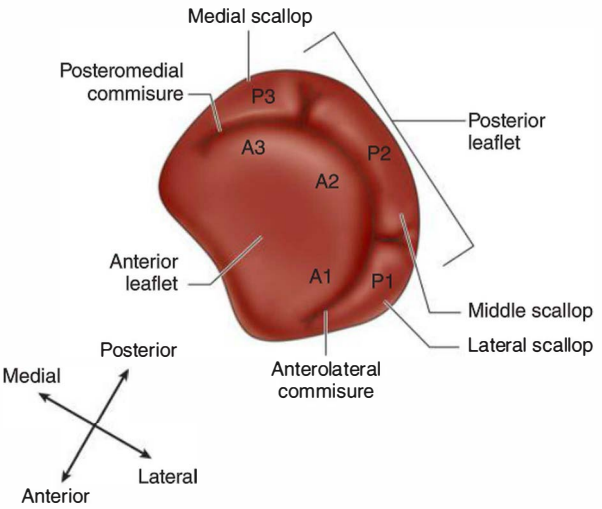

**FIGURE 56-5** Mitral valve structure. The mitral valve consists of two leaflets, the anterior and posterior leaflets, which are separated at the annulus by the posteromedial and anterolateral commissures. The posterior leaflet is rectangular and composed of three scallops (P1, P2, P3). The anterior leaflet is semicircular and is divided into three segments for descriptive purposes (A1, A2, A3). (From Shanewise JS, Cheung AT, Aronson S, et al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *J Am Soc Echocardiogr* 1999;12:884–900. With permission. Copyright Elsevier.)

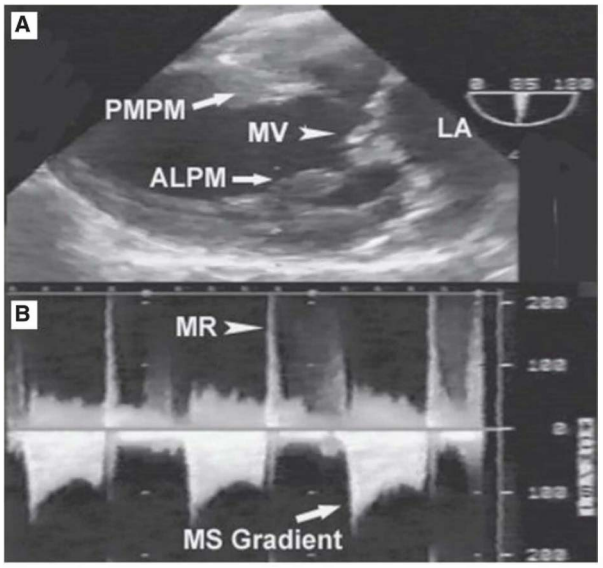

**FIGURE 56-6** Rheumatic mitral stenosis. **A**. Transesophageal transgastric long-axis view of the left ventricle, the anterolateral papillary muscle (ALPM), the posteromedial papillary muscle (PMPM), mitral valve (MV) leaflets, and left atrium (LA). Note the thickened and partially calcified subvalvular and valvular structures (short arrow). The patient had severe three-vessel coronary artery disease in addition to rheumatic aortic stenosis and atrial fibrillation and underwent successful mitral and aortic valve replacements and coronary artery bypass grafting. **B**. Continuous-wave (CW) Doppler of the mitral valve intraoperatively. MR, mitral regurgitation; MS, mitral stenosis.

## MITRAL STENOSIS

Rheumatic heart disease is the most common cause of mitral stenotic lesions (Fig. 56-6), with leaflet thickening and fusion of the commissures. Subvalvular involvement is also common, which causes chordal thickening, shortening, calcification, and fibrosis. This creates the characteristic fish-mouth valve that is best seen in the short-axis view. Commissural fusion results in bowing of the leaflets in diastole causing a hockey-stick appearance in the long-axis view.

2D echo is the "gold standard" for evaluating mitral stenosis (MS) and allows assessment of the structure and function of the mitral annulus, leaflets, chordae, papillary muscles, LV size and function, LA size, and pulmonary hypertension (RVSP). 2D short axis imaging during diastole allows assessment of the valve area that has been well validated with measurements obtained intraoperatively. The Wilkins echo score[15] for rheumatic MS is based on four variables (leaflet mobility, leaflet thickening, subvalvular thickening, and calcifications). Each variable receives a score of 1 to 4 and the individual scores are summed up. A total score equal to or greater than 8 is associated with better outcomes for mitral balloon valvuloplasty. For valves with less favorable scores (>8), cardiac surgery with valve replacement may be the preferred treatment option.

***Mitral Valve Area.*** As mentioned above, the 2D short axis imaging on TTE allows direct planimetry of valve area. With this approach, it is important to scan completely above and below the MV plane in order to identify the smallest orifice. Direct planimetry is difficult if image quality is poor.

Calculation of MV area can be done by using the pressure half-time (PHT) method. PHT is the time (milliseconds) for the maximal pressure gradient to decrease by half and is usually equal to the deceleration time multiplied by 0.29.

$$\text{MV area (cm}^2\text{)} = 220/\text{PHT (ms)}$$

Accurate assessment of MV area requires a near-parallel orientation between directions of blood flow and the Doppler beam. The PHT method has several important shortcomings. It is affected by concomitant aortic regurgitation (AR) or decreased LV compliance.[4] Rapid increase in LV diastolic pressure associated with either of these conditions may shorten the PHT and underestimate the extent of stenosis. Severe AR can actually lead to restricted opening of MV leaflet causing functional MS and lengthening of the PHT measurement in addition to anatomic stenosis. Another technique to estimate valve area includes the continuity equation.[1,4] The latter approach is also less reliable in the presence of significant aortic and MR. Details of this approach are outlined in references 1 through 11.

***Mitral Valve Pressure Gradients.*** As the degree of obstruction to blood flow caused by a stenotic valve increases, the velocity of the blood flow also increases in order to maintain constant flow (conservation of mass or flow). Velocities can then be transformed into pressures with the simplified Bernoulli equation:

$$\Delta P = 4V^2$$

where $\Delta P$, MV pressure gradient (mm Hg) and $V$, velocity of blood flow across the MV (ms).

***Severity of Mitral Stenosis.*** The mean MV pressure gradient and MV area are used to estimate the severity of MS and the need for intervention (Table 56-2).

**TABLE 56-2: Severity of Mitral Stenosis**

| Severity | Mitral Valve Area (cm²) | Mean Gradient[a] (mm Hg) |
|---|---|---|
| None | 4–6 | – |
| Mild | 1.6–2.0 | <5 |
| Moderate | 1.1–1.5 | 5–10 |
| Severe | ≤1 | >10 |

## MITRAL REGURGITATION

There are three basic mechanisms of MR: primary abnormalities of the mitral leaflets, commissures, or annulus; malfunctioning of the subvalvular structures (chordae tendineae and papillary muscles); and alterations in LV and LA dimensions and function.

The most common cause of isolated severe MR is myxomatous degeneration (Fig. 56-7). The valve itself can also be deformed from rheumatic fever, mitral annular calcification, infective endocarditis, and congenital lesions (cleft MV). Myxomatous degeneration is appreciated by thickened, redundant leaflets and chordae that exhibit excessive motion. The leaflets prolapse into the left atrium in systole. The severity ranges from mild prolapse to severe prolapse or a flail leaflet. Mitral annular calcification is seen more commonly in elderly patients and in patients with renal disease

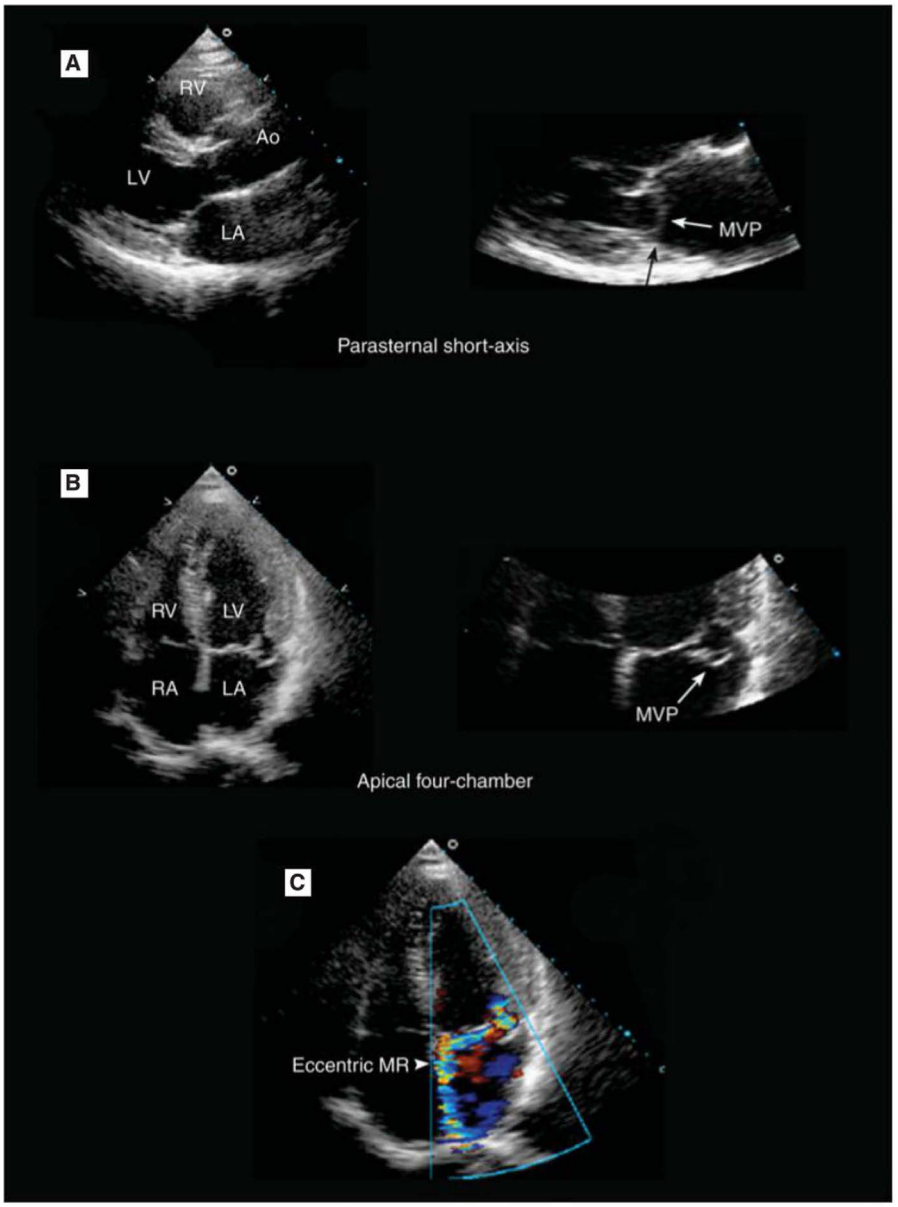

**FIGURE 56-7** Myxomatous mitral valve prolapse and mitral regurgitation. **A.** Transthoracic parasternal long-axis view of the mitral valve with a greater than 2-mm prolapse of the posterior leaflet (MVP) beyond the plane of the annulus. **B.** Apical four-chamber view shows biatrial enlargement. **C.** Color-flow Doppler shows severe mitral regurgitation (MR) with an eccentric jet that is "wall hugging" and anteriorly directed (opposite the side of leaflet prolapse).

and more commonly affects the posterior annulus. It is exhibited by increased echogenicity and subsequent acoustic shadowing.

Other less common causes of leaflet abnormalities include endomyocardial fibrosis, carcinoid disease, drugs (e.g., fenfluramine hydrochloride and phentermine, or Fen-Phen), radiation therapy, trauma, Marfan disease and collagen vascular disease.

Abnormalities in the subvalvular structures include dysfunctional and/or ruptured chordae tendineae and papillary muscles. Ruptured chordae tendineae accounts for a large proportion of MR lesions. Etiologies include idiopathic causes, MV prolapse, infective endocarditis, and thoracic trauma. Papillary muscle dysfunction (with or without frank rupture) is most often seen in the setting of myocardial ischemia or infarction. The posteromedial head of the papillary muscle is most vulnerable to ischemia because of its end-artery vascular supply. Ischemic MR causes restricted leaflet motion resulting in the tenting of the MV in systole. Other causes of dysfunction include dilated cardiomyopathy, myocarditis, hypertension, and chest trauma. Papillary muscle partial or complete rupture is a known potential complication of a myocardial infarction. The ruptured papillary muscle head is visualized in the left atrium in systole and in the LV in diastole.[40]

Global or regional LV enlargement may dilate the mitral annulus and change the position and axis of contraction of the papillary muscles, leading to dysfunction. This is often called functional MR. Progressive LA and LV enlargement associated with chronic MR further exacerbate the extent of MR because of continued changes in chamber geometry.

***Two-Dimensional Echocardiography.*** Unlike the case in MS, where echo is the accepted gold standard for diagnosis, there is no gold standard for the assessment of MR; therefore, multiple parameters are used in estimating the severity of MR.[16] The purpose of echo in MR is to determine the etiology, mechanism, and severity of regurgitation; determine the need and type of surgery; and evaluate other valves, RV and LV function, and the presence of pulmonary hypertension. The most important aspect is to determine the hemodynamic significance of the regurgitation based on LV size (particularly end-systolic dimension), LV systolic function (EF), and the presence and degree of LA enlargement and pulmonary hypertension (RVSP). Regurgitant jet size and area may contribute to the assessment of MR but often correlate poorly with MR severity.[16] The degree of MR intraoperatively may appear less or more severe compared to the degree preoperatively, because of different hemodynamic and ischemic conditions (e.g., lower blood pressure or relief of ischemia will reduce the amount of regurgitation).[17]

***Echocardiographic Findings in MR.*** MR results in LV volume overload. Acutely, the LV is able to empty more efficiently, such that forward cardiac output is maintained. Chronic MR leads to LV dilation and eventual decrease in contractility. The LA also increases in size to accommodate the regurgitant volume. Pulmonary artery pressures increase both in acute MR as well as in chronic MR due to elevated LA pressures. This can subsequently lead to pulmonary hypertension. The direction and shape of the regurgitant jet may aid in assessment of valve pathology and severity. Anterior leaflet pathology produces a posteriorly directed jet and posterior leaflet pathology causes an anterior directed jet. A central jet is often seen in dilated cardiomyopathy as mentioned earlier due to a dilated LV and/or valve annulus.[40]

***Severity of Mitral Regurgitation.*** Echo findings in severe MR[4,16] include the following:

- Large regurgitant jet: >40 percent of LA area.
- Wide vena contracta (the narrowest part of the regurgitant color jet at its origin): ≥7 mm.
- Eccentric wall-impinging regurgitant jet (Fig. 56-7B).
- Dilated LV: end-systolic dimension ≥45 mm or end-diastolic dimension ≥70 mm.
- LV EF <55 to 60 percent.
- Dilated LA (≥5.5 cm), although the LA may not be dilated in acute MR.
- Pulmonary hypertension: resting RVSP >50 mm Hg.
- Restrictive mitral filling pattern: high peak early transmitral velocity (E wave) >1.5 ms.
- Pulmonary vein systolic flow reversal: A normal pulmonary vein Doppler pattern has a systolic (S) wave larger than the diastolic (D) wave. As the MR progresses, the S wave decreases until it may become reversed. While a reduced S wave is a nonspecific finding,[18] the presence of a reversed S wave has high specificity for significant MR. The absence of a reversed S wave does not exclude significant MR.
- Effective orifice area (ERO) ≥0.4 $cm^2$.

Table 56-3 summarizes the important echo features of MV stenosis and regurgitation.

**TABLE 56-3: Echocardiographic Assessment of the Mitral Valve**

| | |
|---|---|
| Morphology | Mitral annulus, leaflets, chordae, papillary muscles, LV size and function, LA size, pulmonary hypertension (RVSP) |
| Stenosis | Often rheumatic<br>*ECHO score:* Leaflet mobility, thickening, subvalvular thickening, calcifications, <8 favors valvuloplasty<br>*Severe MS:* Area ≤1 $cm^2$ or mean gradient >10 mm Hg |
| Regurgitation | Regurgitant jet size does not correlate well with severity<br>*Severe MR:* Dilated LV (ESD >45 mm), ↓ LV systolic function (EF <55–60%), dilated LA, pulmonary hypertension (RVSP >50) |

EF, ejection fraction; ESD, end-systolic dimension; LA, left atrium; LV, left ventricle; MR, mitral regurgitation; MS, mitral stenosis; RVSP, right ventricular systolic pressure.

***Mitral Valve Prolapse.*** Mitral valve prolapse (MVP) is the most common cause of MR in patients undergoing cardiac surgery in the United States.[19] MVP is the systolic billowing or displacement of at least 2 mm of either mitral leaflet into the LA beyond the plane of the mitral annulus in the parasternal or apical long-axis views (see Fig. 56-7). Recent criteria for echo diagnosis of MVP have become more stringent,[20] leading to increased specificity of the criteria for MVP while at the same time preserving sensitivity for the detection of MVP complications. Classic MVP is defined as equal to or greater than 5 mm of leaflet thickening (myxomatous changes) of the prolapsing leaflet, while nonclassic prolapse is leaflet thickening less than 5 mm. Compared to nonclassic MVP, classic MVP has a worse prognosis, with most complications of MVP (significant MR and congestive heart failure, MV surgery, infectious endocarditis) arising in patients with classic MVP.[19] Asymmetrical prolapse of the leaflets is associated with progression to more significant disease (flail leaflet and severe MR).

Determining which segment of the mitral leaflet tissue is prolapsing is essential for proper MV repair. MR associated with MVP often has an eccentric jet directed opposite to the prolapsing leaflet (e.g., anteriorly directed jet if posterior leaflet prolapse is present). In contrast, in MR associated with rheumatic MS, the regurgitant jet is directed toward the affected leaflet due to restricted leaflet motion (e.g., anteriorly directed jet if the anterior leaflet is calcified). MR associated with MVP may be due to flail leaflet or chordal rupture resulting from myxomatous involvement of the chordae or leaflet. Chordal rupture is diagnosed when the chords are seen as mobile echodensities attached to a flail or partially flail leaflet (Fig. 56-8).[21] Chordal rupture may be difficult to distinguish from vegetations of infective endocarditis. Mitral annulus calcification (MAC) may also be seen in patients who have MVP.

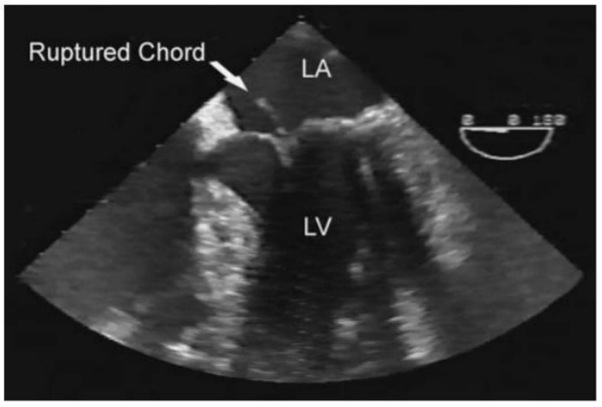

**FIGURE 56-8** Ruptured chord attached to a flail segment of the posterior mitral leaflet due to myxomatous disease. Intraoperative transesophageal echocardiogram showing the ruptured chord as an echodense linear filament attached to the flail leaflet, prolapsing into the left atrium during systole. LA, left atrium; LV, left ventricle.

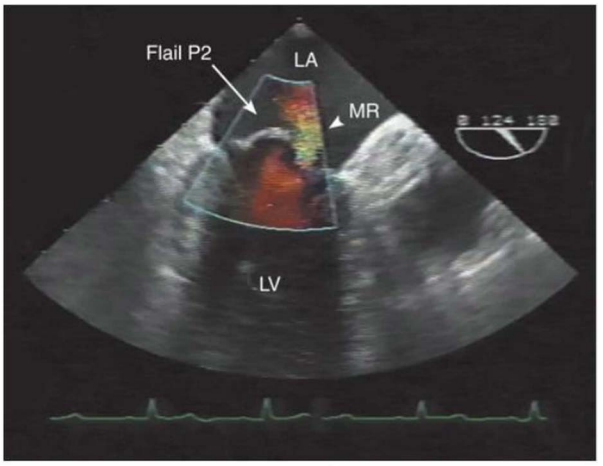

**FIGURE 56-9** Flail mitral leaflet with severe mitral regurgitation. Intraoperative transesophageal echocardiogram with color-flow Doppler consistent with severe mitral regurgitation. This patient underwent successful mitral valve repair with posterior leaflet quadrangular resection and an annuloplasty band. LA, left atrium; LV, left ventricle; MR, mitral regurgitation.

***Flail Leaflet.*** Flail leaflet encompasses a spectrum of disease severity from partially to completely flail leaflets, resulting in excessive motion of the mitral leaflets and various degrees of MR (Fig. 56-9). Flail mitral leaflet is diagnosed when the leaflet tip is "upturned" toward the LA during MV closure (due to loss of coaptation). Most commonly, it is caused by MVP or endocarditis resulting in chordal rupture, but it may also be caused by ischemia or infarction of the papillary muscle. A partially flail leaflet (due to chordal rupture) is usually associated with moderate to severe MR, while a completely flail mitral leaflet is almost always associated with severe MR necessitating surgery.[21]

***Ruptured Papillary Muscle.*** Dysfunction of the papillary muscle results in severe MR and is most often due to acute myocardial infarction. Papillary muscle dysfunction should be differentiated from acute chordal rupture. Papillary muscle rupture is diagnosed in the appropriate clinical context when a triangular mass or balled up mass (the head of the papillary muscle), is seen attached to the anterior or posterior leaflets. The ruptured papillary muscle may prolapse into the LA during systole and in the LV in diastole. Papillary muscle rupture is accompanied by severe MR.[17]

***Leaflet Perforation.*** This is most commonly caused by valvular endocarditis, while less common etiologies include congenital (cleft MV) or iatrogenic causes. With leaflet perforation, the regurgitant jet is often eccentric and originates at the site of perforation.

***Mitral Valve Repair.*** TEE is essential in determining the suitability of a valve for repair. It can assess the mechanism

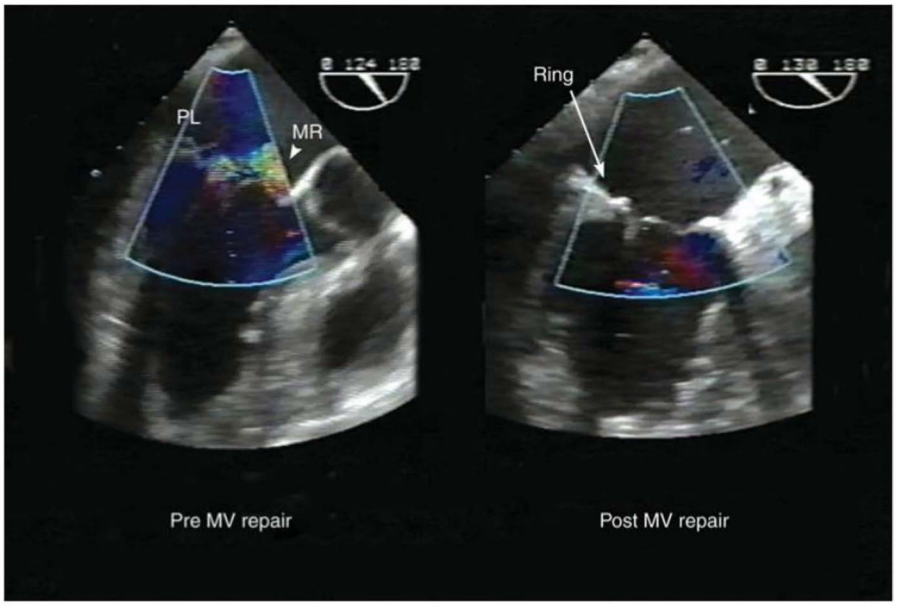

**FIGURE 56-10** Posterior leaflet prolapse and dilated mitral annulus. Note the anteriorly directed eccentric jet of mitral regurgitation seen on transesophageal echocardiography. Following the repair (posterior leaflet quadrangular resection and annuloplasty ring), the patient had good ventricular function and no residual mitral regurgitation. PL, posterior leaflet.

and severity of MR, identify the affected leaflets, determine the presence of coexisting valvular lesions, and estimate RV and LV function. The prognosis of MV repair differs based on the mechanism of MR (organic/primary vs functional/secondary) and is strongly influenced by the preoperative EF. The most common indication for MV repair is myxomatous disease. Determining which leaflet or segment is involved is important in deciding on the suitability of the repair, the likelihood of successful repair (better with posterior leaflet prolapse), and the method of repair. This is done by analyzing the motion of the leaflets and the direction of the regurgitant jet.

TEE is also helpful intraoperatively to assess the success of the repair. Immediately postrepair (Fig. 56-10), the competency of the valve can be assessed for residual MR (1+, mild; 2+, moderate; 3+, moderate to severe; 4+, severe). Phenylephrine and volume may be administered in order to assess the effect of increased afterload and preload on the degree of residual MR. If there is MR postrepair equal to or greater than 2+, further surgery is indicated. Repeat imaging is also done after the patient is off cardiopulmonary bypass. Other findings that may be detected on TEE include residual MS, global or regional LV systolic dysfunction, suture dehiscence or leaflet perforation, and LV outflow obstruction from systolic anterior motion (SAM) of the MV. Limitations to intraoperative TEE include the effect of changing hemodynamics, which may significantly affect the appearance and severity of valvular lesions. Hence, it is important that loading conditions be similar in comparing the severity of MR.

## Aortic Valve

### AORTIC VALVE MORPHOLOGY

Normally, the aortic valve (AV) is composed of three semilunar leaflets (cusps) that open and close passively due to pressure differences between the LV and the aorta. They consist of the right, left, and non coronary cusps. Small strands may be seen on the cusps (Lambl excrescences), particularly on TEE, and represent a normal variant. Bicuspid and rarely unicuspid or quadricuspid valves may be seen on echo (Fig. 56-11). The normal valve area is 3 to 4 $cm^2$ with a 2-cm leaflet separation during systole.

A bicuspid AV is the most common congenital heart defect and occurs in about 1 to 2 percent of the US population. The morphologic features of a bicuspid AV are somewhat variable. The anterior–posterior configuration arises when the right and left coronary cusps are fused and this orientation is seen more commonly. The right–left configuration occurs when the right and noncoronary cusps are fused. In most patients, the two cusps are unequal in size with larger right or anterior leaflets. A well-defined raphe is sometimes present that may give the appearance of a trileaflet valve. In many others, the cusps may be unequal in size with an eccentric commissure, with the larger of the two cusps containing a raphe.[1,22] The M-mode may help in diagnosis in that the closure line of the AV leaflets are eccentric[40]. In the parasternal long-axis views, bicuspid valves are characterized by systolic doming. In the short-axis views, the hallmark is an elliptical "football"-shaped systolic orifice. The valve leaflets themselves may be

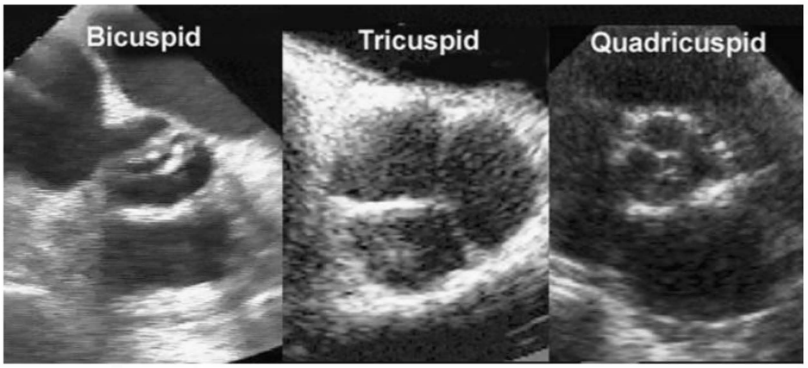

**FIGURE 56-11** Bicuspid, tricuspid, and quadricuspid aortic valves. The normal aortic valve is trileaflet (central panel). Bicuspid valve is the most common congenital anomaly of the aortic valve (left panel), with quadricuspid (right panel) aortic valves being much less common.

thickened and fibrotic, particularly with increasing patient age. A bicuspid valve may be functionally normal with no significant stenosis or regurgitation, particularly in adolescents and young adults, among whom up to one-third have no significant valvular dysfunction.[23] However, over time, fibrosis and valve calcification leads to functional abnormalities. By the age of 60 years, over 50 percent of bicuspid valves are significantly stenotic. Valve regurgitation is frequently present as well and may be the predominant functional abnormality in younger patients. Etiology of the regurgitation may be retraction and fibrosis of the commissures or leaflets, cusp prolapse, dilatation of the aortic root or valve annulus, or damage from infective endocarditis.

It is important to recognize that bicuspid AVs are often associated with abnormalities of the aorta. Concomitant aortic coarctation occurs in a minority. Aortic dissection is another known association, with 5 to 9 percent of patients with dissecting aortic aneurysms having bicuspid valves. Aortic root dilatation may be due to a common developmental defect that affects both the aorta and the valve.[24] Poststenotic dilatation of the ascending aorta can also occur.

## AORTIC STENOSIS

Degenerative calcific disease is the most common cause of aortic stenosis (AS) in the United States. It is often associated with MAC and coronary artery disease. Nodular calcification is often present on the aortic aspect of the valve along the bases of the cusps and may protrude into the sinuses of Valsalva (Fig. 56-12B and C). In contrast to rheumatic AS, there is no commissural fusion in degenerative AS, hence AR is rare. Rheumatic AS (Fig. 56-12A) is usually associated with MV disease. Calcium deposits may be present on both sides of the aortic cusps, resulting in commissural fusion and AR. In younger patients, congenital bicuspid AV accounts for two-thirds of cases of severe AS.[40]

***Two-Dimensional Echocardiography.*** A thorough echo evaluation includes assessing the thickness and calcification of the leaflets, their mobility, looking for the etiology of stenosis (e.g., bicuspid, rheumatic, degenerative calcific) and its extent, the presence of other valvular lesions, and assessing LV size and function. TTE is often superior to TEE in assessing the severity of AS because obtaining maximal velocity jets (i.e., absolutely parallel to flow) is often difficult with TEE.

***Aortic Valve Area.*** In aortic stenotic lesions, the AV area decreases by approximately 0.1 $cm^2$/year, although large variations from patient to patient exist.[25] The AV area is usually determined using the continuity equation. Direct planimetry (visualization of the orifice area) is less reliable for patients with heavily calcified valves (due to shadowing of the valve) and for critical ("pinhole") stenoses.[22] The continuity equation is based on the principle of conservation of flow (or mass), whereby flow before the valve must equal flow across the valve. Since the area of the LV outflow tract (LVOT) can be directly measured, as can velocities in the LVOT and across the valve, the AV area can then be calculated:

$$A_1 V_1 = A_2 V_2$$

where $A$, area or $\pi r^2$; $V$, velocity; $A_1 V_1$ flow proximal to the valve (LVOT); $A_2 V_2$, flow across the valve.

The major limitation to the continuity equation is that small errors in the LVOT diameter become magnified in estimating the AV area (since the radius is squared in the equation). As a general rule, one may assume that the LVOT diameter is 2 cm ($r_1 = 1$ cm) with generally good estimates of the AV area. LVOT is measured in midsystole and the parasternal view provides the most accurate assessment[39]. Another limitation to the continuity equation is in obtaining the maximal aortic jet velocity, which requires that the echocardiographic Doppler beam be exactly parallel to the direction of blood flow.

***Aortic Valve Pressure Gradients.*** Like pressure gradients obtained for MS, the simplified Bernoulli equation is used for estimating AV pressure gradients:

$$\Delta P = 4V^2$$

where $\Delta P$, AV pressure gradient (mm Hg) and $V$, velocity of blood flow across the AV (ms).

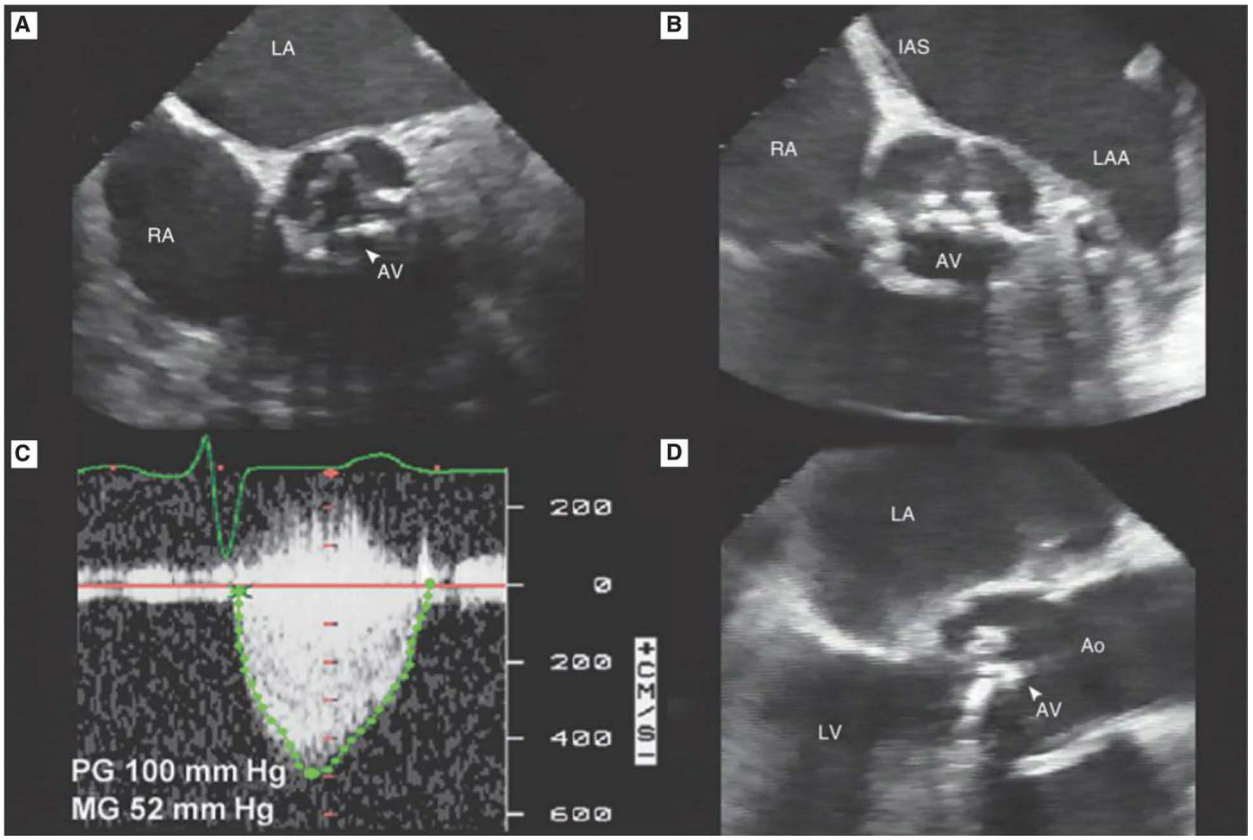

**FIGURE 56-12** Rheumatic and calcific aortic stenosis. **A.** Rheumatic aortic stenosis with calcium deposits in the commissures resulting in commissural fusion. **B** and **D.** Short- and long-axis views: Calcific aortic stenosis, with calcium deposits on the aortic aspect of the valve on the bases of the cusps and no commissural fusion. **C.** Continuous-wave (CW) Doppler of the aortic valve (shown in B and C) is consistent with severe aortic stenosis (aortic velocity >4 ms, mean gradient >50 mm Hg). RA, right atrium; LA, left atrium; AV, aortic valve; LAA, left atrial appendage; IAS, interatrial septum; Ao, aorta; PG, peak gradient; MG, mean gradient.

AV pressure gradients may be significantly underestimated because of inadequate envelopes (because the Doppler beam is not parallel to the blood flow) or an inadequate number of measurements from different locations. Maximal velocities may be present or obtainable from only certain locations in an individual patient. Hence, complete assessment from all images is required. In addition, the velocity of flow is highly dependent on overall LV function. Pressure gradients may significantly underestimate the severity of AS in the presence of severe LV dysfunction ("low-gradient AS"). The opposite is also true, whereby increased flow velocity across the valve is seen in situations of increased cardiac output (i.e., anemia, AR, hyperthyroidism) and may not reflect true AS. In such situations, valve area calculations may be more accurate, and correlation with valve morphology and visual assessment of leaflet mobility is important.

***Severity of Aortic Stenosis.*** The mean AV pressure gradient and the AV area are used to estimate severity of AS and the need for surgical intervention (Table 56-4). If there is a significant discrepancy between the pre- and intraoperative grading of the severity of AS, the following should be considered:

1. Change in hemodynamic conditions: Changes in heart rate or rhythm, contractility, and hemodynamics influence the gradients across the AV. The AV area is usually less affected by loading conditions. The pressure gradient will rise with an increase in stroke volume such as exercise and coexisting AR and decrease with sedation and hypovolemia when stroke volume decreases.[39]
2. Measurement variability in data recording: Measurement errors in the LVOT diameter lead to large errors in calculating the AV area, since the LVOT radius is squared in the continuity equation.

## AORTIC REGURGITATION

AR can result either from valve pathology or from conditions that affect the aortic root. Echo assessment of AR includes a

**TABLE 56-4: Severity of Aortic Stenosis**

| Severity | Velocity (m/s) | Area ($cm^2$) | Mean Gradient[a] (mm Hg) |
|---|---|---|---|
| None | 1 | 3–4 | – |
| Mild | 2.5–2.9 | >1.5 | <25 |
| Moderate | 3–4 | 1–1.5 | 25–50 |
| Severe | >4 | <1 | >50 |

[a]Assumes normal cardiac output.

Reproduced from: ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease. A report of the American College of Cardiology/American Heart Association. Task Force on Practice Guidelines (Committee on Management of Patients with Valvular Heart Disease). *J Am Coll Cardiol* 1998;32:1486–1588. Copyright Elsevier.

comprehensive examination of AV morphology, aortic root dimensions, and LV size and function.[16] TTE is generally the initial diagnostic test used for evaluating the severity of AR. However, TEE is also helpful particularly for patients with poor transthoracic windows, if prosthetic valves are present, and intraoperatively to guide surgical repair. TEE is particularly useful for determining the mechanism of regurgitation by distinguishing valvular from nonvalvular causes of AR. Common etiologies for AR include those that cause AS with subsequent AR. Common causes include congenital malformations (bicuspid valves); degenerative calcific, myxomatous, rheumatic, and infective endocarditis; aortic aneurysm (Fig. 56-13) or dissection; Marfan syndrome; drug-induced AR; and prosthetic valve dysfunction.[9] Common etiologies for aortic root dilation include hypertension, aortic dissection, cystic medical necrosis, Marfan syndrome, bicuspid AV, and autoimmune diseases.

Acute and chronic AR differ in both their pathophysiology and echo findings. Many of the echo findings in chronic AR (e.g., LV dilatation and systolic dysfunction) may not be present in acute AR. Chronic AR is a state of both pressure and volume overload of the LV, resulting in LV hypertrophy and dilatation and increased chamber sphericity. Initially LV end-diastolic pressure is preserved, but over time, EF declines

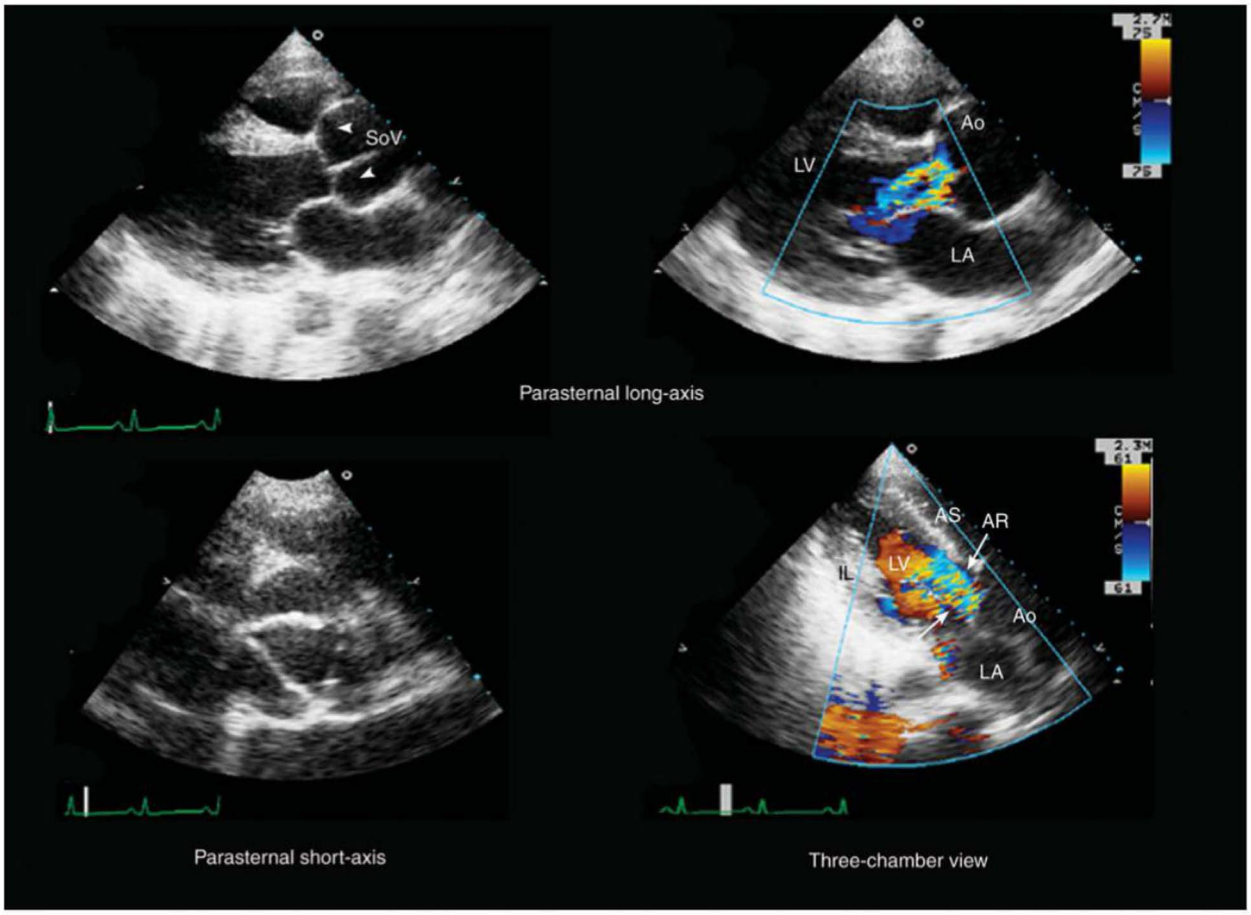

**FIGURE 56-13** Aortic aneurysm of the sinuses of Valsalva and secondary aortic regurgitation. The aortic wall is thin at the sinuses of Valsalva and aneurysmal dilatation results in aortic regurgitation. Note the wide base of the regurgitant jet (vena contracta) consistent with severe aortic regurgitation (arrow). Ao, aorta; AR, aortic regurgitation; LA, left atrium; LV, left ventricle; SoV, sinuses of Valsalva.

due to chronic volume overload and decreased compliance. Acute AR is characterized by normal LV size, elevated EDP, and steep CW Doppler slope.

***Two-Dimensional Echocardiography.*** This is helpful for evaluating LV size and function, AV structure and leaflet mobility, aortic root dilatation, aortic dissection, associated vegetations, diastolic fluttering motion of MV leaflets, and premature MV closure (indicative of significant AR).

***Severity of Aortic Regurgitation.*** In assessing the severity of chronic AR, it is essential to combine data on LV size and function with Doppler data and not to rely solely on color Doppler, since it is often misleading. No study has yet demonstrated that quantification of the severity of AR by Doppler criteria alone is predictive of outcome. Instead, LV size and function are used for risk stratification of asymptomatic patients with chronic AR. Echo findings in severe AR include:

- Dilated LV: minor-axis dimension >50 to 55 mm in systole or >70 to 75 mm in diastole
- LV EF <55 percent
- PHT <200 ms
- Proximal regurgitant color jet width/LVOT diameter ≥65 percent
- Vena contracta >6 mm
- Holodiastolic flow reversal in the thoracic aorta (100 percent sensitive and 97 percent specific for severe AR).
- Restrictive filling pattern to the MV inflow

In comparison to men, women with AR should be considered for surgery before severe symptoms have developed and for smaller LV dimensions. In a recent study, intraoperative mortality was similar for men and women, but 10-year survival was significantly worse for women than for men (39 vs 72 percent, respectively).[26]

In acute AR, many of the features of chronic volume overload will not be present. The severity will be need to be assessed by evaluation of CF Doppler jet width, presence of significant pulmonary hypertension, and evidence by Doppler of rapid equilibration of aortic and LV diastolic pressure (short diastolic half-time <200 ms, short mitral deceleration time <150 ms, or premature closure of the MV). Echo assessment of the AV is summarized in Table 56-5.

**TABLE 56-5: Echocardiographic Assessment of the Aortic Valve**

| | |
|---|---|
| Morphology | Three semilunar leaflets/cusps, LV size and function |
| Stenosis | Often degenerative/calcific<br>*Severe AS:* Area <1 $cm^2$ or mean gradient >50 mm Hg |
| Regurgitation | Regurgitant jet size does not correlate well with severity<br>*Severe AR:* Dilated LV (ESD >50–55 mm), LVH, ↓ LV systolic function (EF <55%)<br>*Acute AR:* LV dilatation/systolic dysfunction may be absent |

AR, aortic regurgitation; AS, aortic stenosis; ESD, end-systolic dimension; LV, left ventricle; LVH, left ventricular hypertrophy.

## Tricuspid Valve

### TRICUSPID VALVE MORPHOLOGY

Normal function of the TV depends on the normal function of its components: annulus, leaflets, chordae, papillary muscles, right atrium, and ventricle.

### TRICUSPID STENOSIS

Tricuspid stenosis (TS) is not common in adults. The most common cause of TS is rheumatic, which results in both stenosis and regurgitation of the TV and is often associated with concomitant mitral or AV disease. Carcinoid heart disease tends to involve the valves on the right side of the heart as well. Echo assessment of TS is similar to that of MS. The valve leaflets are thickened and shortened. The mean gradient across the TV is normally <2 mm Hg. TS is considered severe when the mean gradient is ≥7 mm Hg and the PHT is ≥190 ms.

### TRICUSPID REGURGITATION

As in the case of the AV and MV, TTE or TEE evaluation of TR focuses on the identification of the etiology or mechanism of TR as well as its hemodynamic severity. TR is the most common abnormality of the TV. Mild TR is a normal finding in 90 percent of individuals (38). Pathologic TR is often secondary to RV dysfunction, RV dilatation causing annular dilation, or significant systolic pulmonary hypertension (systolic pulmonary artery pressures >55 mm Hg). Primary causes of TR are less common (Ebstein anomaly, endocarditis, trauma, anorectic drugs, carcinoid, myxomatous or rheumatic valvular disease, radiation). The tricuspid valve is affected in 20 to 30 percent of patients with rheumatic disease and usually occurs with concomitant mitral or AV involvement.

Patients with severe TR of any cause have poor long-term outcomes because of RV dysfunction and/or systemic venous congestion. TV reconstruction, annuloplasty, or valve replacement is indicated in some cases of severe TR.

TEE is useful intraoperatively to assess the need for TV surgery when TR is secondary to annular dilatation and/or elevated pulmonary artery pressures, particularly during MV surgery. After correction of MV disease, TV surgery may be required if persistent severe TR or annular dilatation (≥30 mm) is still present (Fig. 56-14).[27]

***Severity of Tricuspid Regurgitation.*** Using color Doppler, mild TR is characterized by a jet area in the right atrium of <5 $cm^2$, moderate regurgitation has a jet area of 5 to 10 $cm^2$ of the RA, and severe TR has a jet area of >10 $cm^2$.

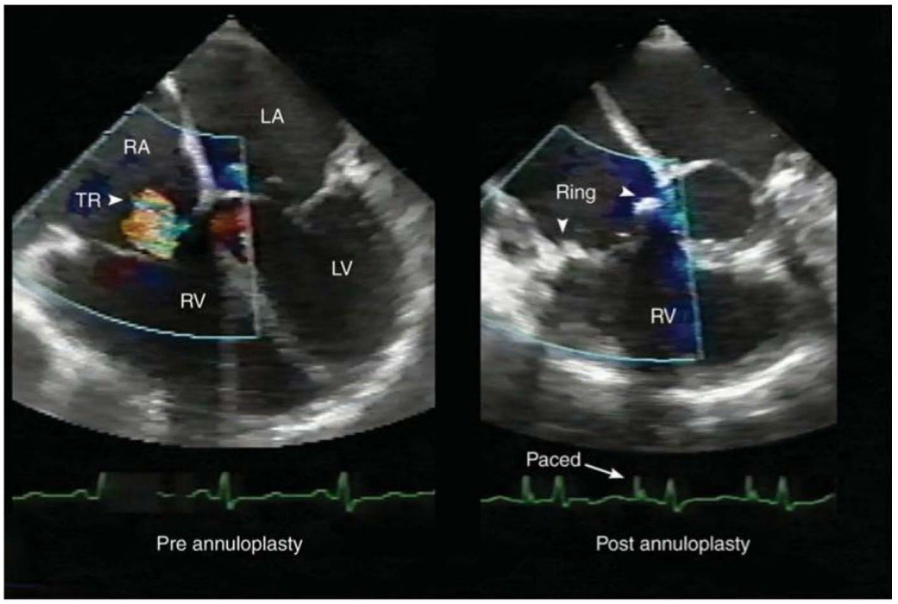

**FIGURE 56-14** Tricuspid valve annuloplasty. This patient had infective endocarditis r esulting in flail posterior mitral valve leaflet and tricuspid regurgitation. He underwent mitral valve repair and tricuspid valve annuloplasty. Note the dilated atria and tricuspid annulus preprocedure and the pacer spikes on the rhythm strip postprocedure. RA, right atrium; TR, tricuspid regurgitation; RV, right ventricle; LA, left atrium; LV, left ventricle.

Echo findings in severe TR include the following[16]:

- A large regurgitant (color) jet (area >10 $cm^2$), vena contracta >7 mm, or eccentric jet. Vena contracta is the most accurate approach; when >7 mm it is 89 percent sensitive and 93 percent specific for severe TR.
- Annular dilatation (≥30 mm), leaflet coaptation, anatomic clues (e.g., vegetations, myxomatous disease)
- Dilated right atrial (RA)
- Dilated RV and paradoxical interventricular septal wall motion
- Pulmonary hypertension
- Dilated venae cavae and hepatic veins with minimal respiratory flow variation and systolic flow reversal

**Estimation of Right Atrial Pressure**

| IVC Diameter | Change with Respiration or Sniff | Estimated RA Pressure |
|---|---|---|
| Small (<1.2 cm) | Spontaneous collapse | Volume depletion |
| Normal (<1.7 cm) | Decrease by ≥50% | 0–5 mm Hg |
| Dilated (>1.7 cm) | Decrease by ≥50% | 5–10 mm Hg |
| Dilated (>1.7 cm) | Decrease by <50% | 10–15 mm Hg |
| Dilated (>1.7 cm) | No change | 15–20 mm Hg |
| Dilated with dilated hepatic vein | No change | >20 mm Hg |

Data from Kircher BH, Himelmann RB, Schiller NJ. *Am J Cardiol* 1990;66:493, and from Lang RM, Bierig M, Devereux RB, et al. *J Am Soc Echocardiog* 2005;18:1440.

### PULMONARY HYPERTENSION

The velocity of the tricuspid regurgitant jet is an accurate measure used to estimate the pulmonary artery systolic pressure. In the absence of pulmonary stenosis, pulmonary artery systolic pressure is equal to RVSP. RVSP is estimated using the simplified Bernoulli equation ($\Delta P = 4V^2$) from the peak TR velocity ($V$). $\Delta P$ is then the pressure gradient across the TV, or the pressure difference between the RA and RV ($\Delta P = P_{RV} - P_{RA}$). In the absence of elevated RA pressures, the RA pressure ($P_{RA}$) is estimated at 10 mm Hg. Therefore,

$$RVSP = P_{RA} + \Delta P = 10 + 4V^2$$

where RVSP, RV systolic pressure and $V$, peak TR velocity (ms).

RA pressure can be estimated by respiratory variation in the IVC. This is best assessed in the subcostal view.

***Severity of Pulmonary Hypertension.*** Normal pulmonary artery systolic values are 18 to 25 mm Hg with a mean of 12 to 16 mm Hg.[2] Pulmonary hypertension is defined as systolic pulmonary artery pressure greater than 30 mm Hg or mean pulmonary artery pressure less than 20 mm Hg at rest.[2] Commonly used values using RVSP to estimate the severity of pulmonary hypertension are shown in Table 56-6.

## Prosthetic Valves

Any evaluation of prosthetic valve function should include an assessment of transvalvular pressure gradients and valve area, similar to the evaluation of native valve function.

**TABLE 56-6: Severity of Pulmonary Hypertension**

| | RVSP (mm Hg) |
|---|---|
| Normal | 18–25 |
| Mild | 30–40 |
| Moderate | 40–70 |
| Severe | >70 |

RVSP, right ventricular systolic pressure.

Structural or mechanical failure is usually a disease process unique to prosthetic valves causing failure of the device to open or close properly. This usually occurs over a period of time and can involve tissue degeneration or fibrocalcific changes of the valve leaflets. Acute stenosis is rare but may be caused by acute valve thrombosis. Prosthetic valves can also develop paravalvular leaks, chronic thrombus, or pannus formation as well as endocarditis.[39] TTE is helpful in the initial assessment of prosthetic valve dysfunction. However, its sensitivity is impaired by difficulty in visualizing structures around and behind the prosthesis, particularly for mechanical valves. Prosthetic material attenuates the ultrasound beam and causes multiple reverberations and acoustic shadowing, thus hampering interpretation. TEE is often required for the complete evaluation of prosthetic valve structure and function. Cinefluoroscopy may also be a relatively quick and useful method for determining leaflet mobility in mechanical valves and is indicated when mechanical valve thrombosis is suspected. When valve dysfunction is suspected, 2D echo with Doppler and color flow in addition to TEE may be necessary for a comprehensive evaluation of valve function. Such an evaluation of valve function is summarized in Table 56-7.[28] TEE findings in common complications of prosthetic valves are shown in Table 56-8.[28]

**TABLE 56-7: Evaluation of Prosthetic Valves**

| | |
|---|---|
| Pressure gradients | $\Delta P = 4V^2$ |
| Valve area | *MV prostheses:* Area = 220/PHT<br>*AV or MV prostheses:* $A_1V_1 = A_2V_2$ |
| Regurgitation/leaks | Size, symmetry, velocity, eccentricity |
| Leaflet mobility/restriction | Degree of leaflet excursion |
| LV size/function | LV dimensions, EF |
| Pulmonary hypertension | RVSP = $4V^2 + 10$ |
| Compare with prior ECHO | Change in gradients, area, leaks |

$\Delta P$, pressure gradient; $V$, velocity; MV, mitral valve; AV, aortic valve; $A_1V_1$, flow (area$_1$ × velocity$_1$) proximal to the valve prosthesis; $A_2V_2$, flow (area$_2$ × velocity$_2$) across the valve prosthesis; RVSP, right ventricular systolic pressure.

## PROSTHETIC VALVE PRESSURE GRADIENTS

Like native valve gradients, prosthetic valve pressure gradients can be obtained using the simplified Bernoulli equation ($\Delta P = 4V^2$). Compared to normal native valves, homografts and the newer nonstented bioprostheses have similar velocities and pressure gradients, while mechanical valves have higher flow velocities. Prosthetic valves except ball–cage valves normally have pressure gradients since they are by design obstructive, with gradients increasing as valve size decreases. High gradients are often seen with 19-mm AV prostheses. High gradients in prosthetic valves may be seen for other reasons as well, such as high cardiac output, valve obstruction, or significant valvular regurgitation (due to increased flow).

## PROSTHETIC VALVE AREA

As in the case of native valves, prosthetic valve area can be calculated using the continuity equation or PHT method. For AV prostheses, the continuity equation ($A_1V_1 = A_2V_2$) is usually used. The LVOT diameter or outer diameter of the sewing ring (not its internal diameter) should be measured for accurate estimation of $A_1$. For MV prostheses, use of the continuity equation is preferred, since the PHT equation may overestimate the true prosthetic MV area. The continuity equation should not be used if there is significant AR or MR. The same equations may be used for the calculation of prosthetic TV areas.

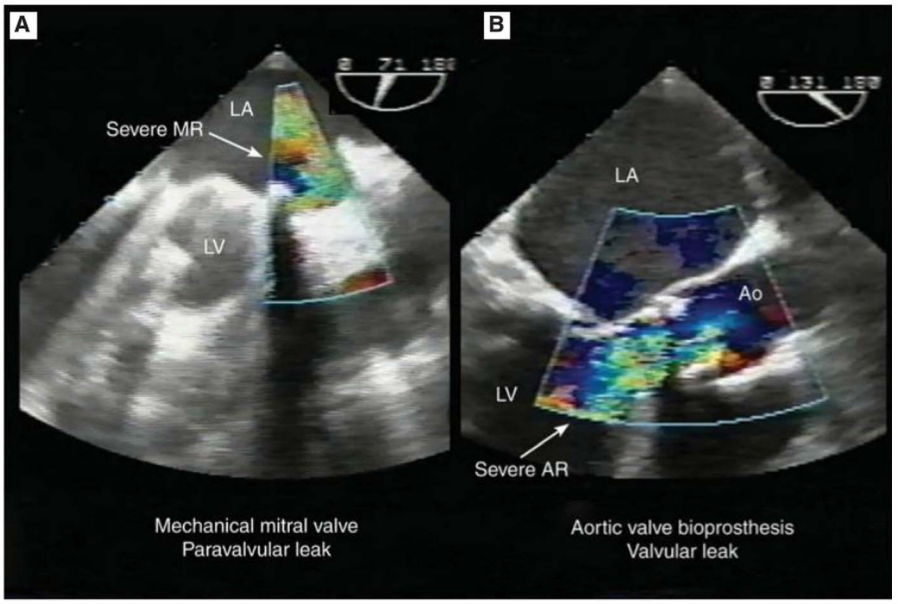

**FIGURE 56-15** Paravalvular and valvular leaks. **A.** Bileaflet mechanical mitral prosthesis with severe paravalvular regurgitation secondary to endocarditis and partial valve dehiscence, requiring valve replacement. **B.** Aortic bioprosthesis with severe aortic regurgitation due to calcific degeneration and a torn leaflet. LA, left atrium; LV, left ventricle; MR, mitral regurgitation; Ao, aorta.

### PARAVALVULAR LEAKS

Normal amounts of regurgitation are expected with prosthetic valves owing to the built-in transvalvular regurgitation ("closing volume"). The amount of regurgitation increases with valve size, the size of the gap between the occluder and the rim, and lower heart rates. Echo findings[4] of normal prosthetic valve regurgitation include:

1. AV: regurgitant area <1 $cm^2$ and length of jet 1.5 cm
2. MV: regurgitant area <2 $cm^2$ and length of jet 2.5 cm
3. Characteristic flow patterns (Medtronic-Hall, one central jet; Star–Edwards, two curved side jets; Bjork–Shiley, two unequal side jets; St. Jude Medical, two side jets and one central jet)

Larger leaks in other locations (Fig. 56-15) are abnormal and may be associated with significant hemodynamic compromise, hemolysis, or valve dehiscence.[28] TEE is often required to fully assess prosthetic valve regurgitation because of the limited sensitivity of TTE. Echo characteristics that differentiate physiologic from nonphysiologic regurgitation are summarized in Table 56-9.[28]

## INFECTIVE ENDOCARDITIS

TEE is the procedure of choice for the detection of vegetations in infective endocarditis, with better sensitivity (50 percent for TTE vs 90 percent for TEE) and specificity (95 percent for TTE vs >95 percent for TEE) for native valve endocarditis compared to TTE.[29,30] Characteristics of valvular vegetations are listed in Table 56-10.[29] However, early in the course of infective endocarditis, vegetations may not have these typical characteristics and TEE should be repeated if the clinical suspicion is high. It may be difficult to identify a vegetation involving a native valve that is calcified or structurally abnormal. Compared with native valve endocarditis, it is more difficult to identify vegetations on prosthetic valves because of artifact from the prosthetic materials. Often both TTE and TEE are useful to detect vegetations, although TTE has lower sensitivity compared with TEE for prosthetic valve endocarditis.[8] TEE is particularly sensitive for identifying ring abscesses.

AV vegetations usually develop on the ventricular side of the leaflet. They exhibit rapid independent motion and may prolapse into the LVOT during diastole. Rapid oscillating

**TABLE 56-9: Physiologic and Nonphysiologic Valvular Regurgitation**

| Regurgitant Jet | Physiologic | Nonphysiologic |
|---|---|---|
| Size | Small, narrow | Large, wide |
| Symmetric | Yes | No |
| Velocity | Low | High |
| Eccentric | No | Yes |

**TABLE 56-10: Echocardiographic Characteristics of Vegetative and Nonvegetative Valvular Masses**

| Characteristic | Vegetation | Not Vegetation |
|---|---|---|
| Echogenicity | Similar to myocardium<br>Low echogenicity/gray | Similar to pericardium<br>High echogenicity/white |
| Location | Upstream surface of valve near the regurgitant jet | Downstream surface of valve |
| Motion | Mobile, prolapses | Less mobile |
| Shape | Amorphous, lobulated wide base of attachment<br>Severe regurgitant jet | Filamentous, strand-like narrow base of attachment<br>Mild or no regurgitant jet |
| Regurgitation | Vegetation located near jet | |
| Other | Paravalvular abscess/leak<br>Fistula<br>Valve dehiscence | None |

Data from Schiller NB. Clinical decision making in endocarditis. In: Otto CM (ed). *The Practice of Clinical Echocardiography*. Philadelphia: Saunders, 2002:451–468. With permission. Copyright Elsevier.

motion is also seen on M-mode imaging. MV vegetations typically occur on the atrial side of the leaflets. They also exhibit rapid independent motion and may prolapse in the LA during systole[39].

It is important to differentiate infective vegetations from other intracardiac masses, which include papillary fibroelastoma, nonbacterial thrombotic endocarditis, thrombus, Lambl excrescence or nodule of Arantis, and myxomatous valve disease. Lambl excrescences are thin, strand-like fibroelastic projections. The incidence of these masses increases with advancing age.

Complications of infective endocarditis (Fig. 56-16) include the following:

1. Paravalvular abscesses
2. Valve destruction or perforation, leaflet rupture, or dehiscence of prosthetic valves
3. Fistulas
4. Pseudoaneurysms
5. Emboli

## EVALUATION OF SPECIFIC DISORDERS

### Coronary Artery Disease

#### MYOCARDIAL ISCHEMIA/INFARCTION

The echo manifestation of myocardial ischemia is a decrease in contractility or systolic wall thickening of the ischemic territory that is manifest within seconds of the onset of ischemia, prior to evidence of electrocardiographic ischemia.[4] Decreased or absent wall thickening

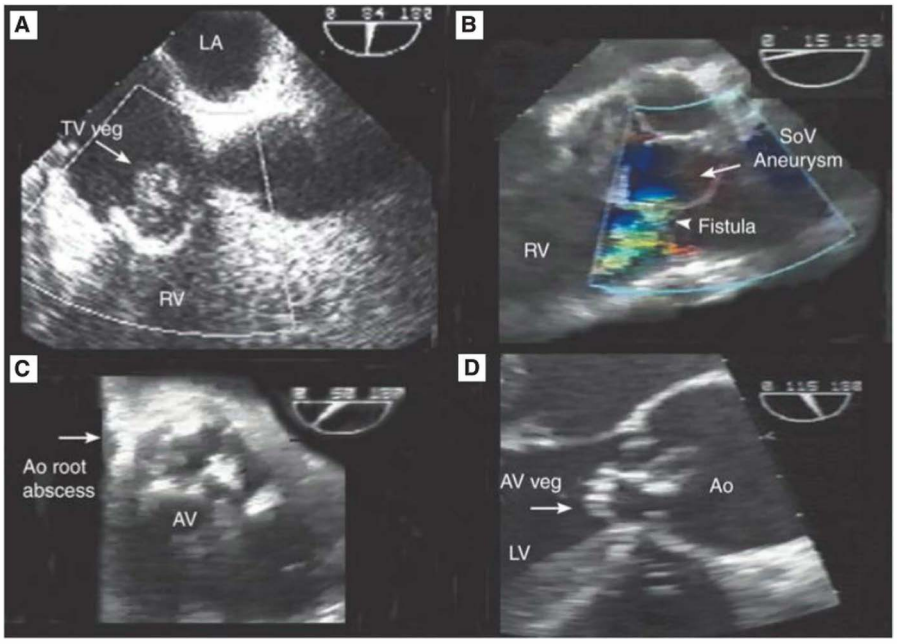

**FIGURE 56-16** Complications of infective endocarditis. **A.** Large vegetation on bioprosthetic tricuspid valve seen on transesophageal echocardiogram. **B.** Sinus of Valsalva aneurysm and aortic–right ventricular fistula. **C.** Bicuspid aortic valve with bacterial endocarditis complicated by large aortic root (annular) abscess (note the thickened perivalvular tissue) and complete heart block requiring emergent surgery. **D.** Large aortic valve vegetation prolapsing into the left ventricular outflow tract during systole. Ao, aorta; AV, aortic valve; LA, left atrium; LV, left ventricle; RV, right ventricle; SoV, sinus of Valsalva; TV, tricuspid valve.

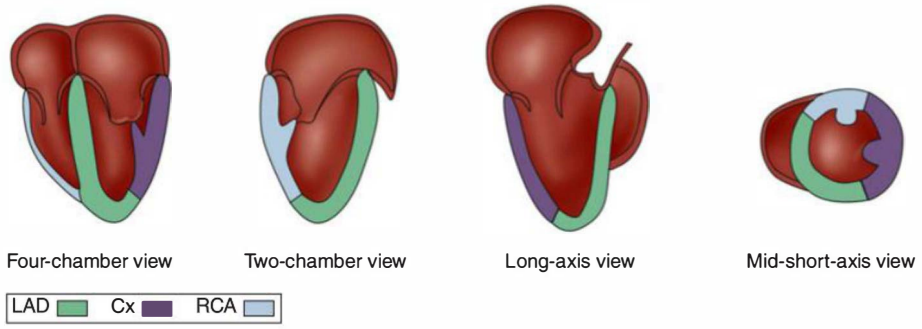

**FIGURE 56-17** Common myocardial perfusion patterns by each of the three major coronary arteries. LAD, left anterior descending; Cx, left circumflex; RCA, right coronary artery. (From Shanewise JS, Cheung AT, Aronson S, et al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *J Am Soc Echocardiogr* 1999;12:884–900. With permission. Copyright Elsevier.)

is a better indicator of ischemia than wall motion, since infarcted myocardium may be passively pulled or tethered by adjacent normal myocardium, resulting in apparent wall motion without active contraction. Ancillary signs of ischemia include an increase in end-systolic LV volume and a decrease in global contractility or EF.[4] Hypokinesis is decreased contractility (<30 percent wall thickening); akinesis is the absence of contractility (<10 percent wall thickening); and dyskinesis is outward motion during systole. Echo is accurate at localizing the site of coronary obstruction (Fig. 56-17). However, it usually overestimates infarct size due to myocardial stunning, which has resulted in a lack of correlation between wall motion abnormalities detected on echo in the setting of an acute myocardial infarction and infarct extent.[31]

## ISCHEMIC, INFARCTED, STUNNED, OR HIBERNATING MYOCARDIUM?

Myocardial segments may be dysfunctional secondary to ischemia, infarction/scar, or stunned or hibernating myocardium. Stunned myocardium is postischemic ventricular dysfunction that occurs when reperfusion of the occluded artery has been achieved but the wall motion and thickening of the corresponding myocardial segment remain abnormal—a condition that may last for days to weeks. Hibernating myocardium results from chronic ischemic dysfunction when the myocardial tissue is chronically hypoperfused owing to inadequate blood flow, resulting in abnormal wall motion and thickening, but it usually recovers after successful revascularization. Resting echo may help differentiate viable (stunned or hibernating) myocardium from nonviable (infarcted or scarred) myocardium based on wall thickness. Thicker myocardium is more likely to be viable, while thinned and fibrotic myocardium most likely represents scar.[4] The specificity of these criteria is quite low; however, viability assessment can be significantly improved with dobutamine or stress echocardiography.[8] A biphasic response on dobutamine echo is the most sensitive parameter for viable myocardium and is associated with improved survival after revascularization. This is evidenced by an improvement in wall motion and thickening or recruitment at low-dose dobutamine (10 to 20 μg/kg/min) followed by worsening of wall motion and thickening at higher doses (30 to 40 μg/kg/min) when the ischemic threshold is reached.

## LEFT VENTRICULAR ANEURYSM AND MURAL THROMBUS

A true ventricular aneurysm consists of a thin myocardial wall (<7 mm) that is echogenic (and sometimes calcified) and has outward motion in both systole and diastole.[31] Most aneurysms occur apically, with inferobasal aneurysms being the second most common. Aneurysms are complications of adverse remodeling following transmural myocardial infarcts. Spontaneous echo contrast (SEC) or mural thrombus may be present within an LV aneurysm and is associated with an increased risk of embolic events. The appearance of an acute mural thrombus (same echogenicity as myocardium) generally differs from that of a chronic thrombus, which tends to be layered with areas of calcification.[31] Compared to TTE, TEE may be limited in detecting apical thrombi because of the often suboptimal visualization of the true LV apex with TEE.

LV pseudoaneurysms can also be complications of acute myocardial infarction and are characterized by the lack of a true myocardial wall. They result from contained free wall myocardial rupture in which a portion of the pericardial space limits frank rupture. Pseudoaneurysms can generally be differentiated from true aneurysms by the presence of a narrow neck (less than half of the maximum diameter) compared to the wider base of a true aneurysm.[31] Flow can be occasionally seen in and out of the pseudoaneurysm.

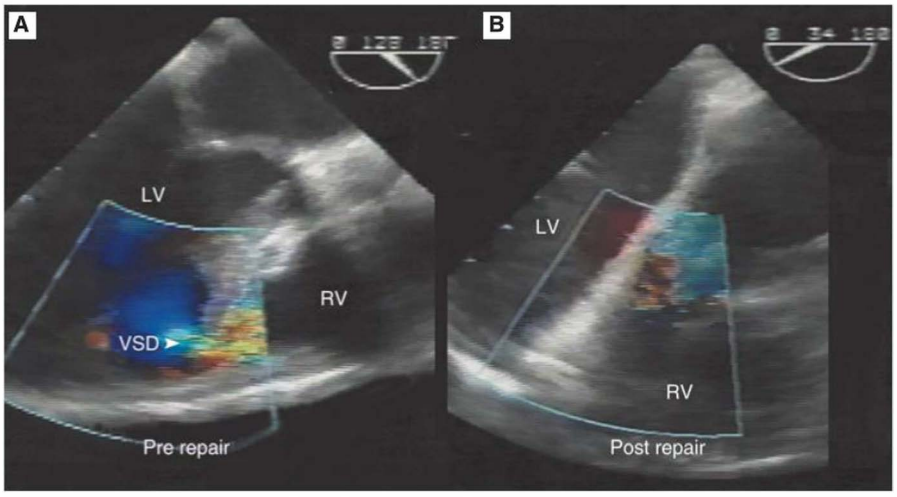

**FIGURE 56-18** Postinfarct ventricular septal defect (VSD). This patient had suffered an acute anterior myocardial infarction that was treated with thrombolytics but subsequently developed a high septal VSD. **A.** Intraoperative transesophageal echocardiogram with color-flow Doppler diagnostic of VSD with high-velocity turbulent flow across the septum. **B.** Surgical repair with a pericardial patch and coronary artery bypass grafting to the ostial left anterior descending artery was successful. Color-flow Doppler shows no flow across the septum. LV, left ventricle; RV, right ventricle.

### POSTINFARCT VENTRICULAR SEPTAL DEFECT

Life-threatening mechanical complications after acute myocardial infarction include free wall rupture, papillary muscle dysfunction/rupture, and ventricular septal defect (VSD) (Fig. 56-18). TTE is usually sufficient for the diagnosis of mechanical complications, although TEE may be used as an adjunct. Postinfarct VSD is uncommon (less than 1 percent of total infarcts), although it is associated with the worst outcome of mechanical complications in patients with cardiogenic shock. Unlike postinfarct papillary muscle rupture, VSD occurs with approximately equal frequency after anterior and inferior infarcts. The posteroapical septum is the most common site to undergo necrosis and rupture. TTE using CF Doppler has a sensitivity of 85 to 95 percent, while TEE has a sensitivity and specificity of 100 percent.[31] A high-velocity left-to-right systolic jet is seen on CW Doppler. Echo characteristics of postinfarct VSD, in addition to the septal defect, include the presence of a small pericardial effusion (PE) with possible intrapericardial thrombus (echogenic mobile mass in the pericardial space) and echo evidence of tamponade.[31]

## THORACIC AORTIC ANEURYSM AND DISSECTION

TTE may diagnose aortic dissection by detecting an intimal flap in the aorta (specificity 95 percent), but it has low sensitivity (80 percent) for ascending aortic dissection and even lower sensitivity for distal thoracic aortic dissection (70 percent).[32] TEE is one of three imaging modalities used for the diagnosis of acute aortic dissection—TEE, computed tomography (CT), and magnetic resonance imaging (MRI)[33,34]—and for the diagnosis of perioperative aortic dissections (Table 56-11). The choice of imaging modality depends primarily on the availability of the imaging procedure and patient characteristics (e.g., hemodynamic instability, presence of a pacemaker, or contrast allergy), since the overall diagnostic accuracy for TEE, CT, and MRI is comparable.[32] TEE is the imaging procedure of choice for patients who are hemodynamically unstable. Compared to CT or MRI, one limitation of TEE is that it cannot image the aortic segment located between the distal ascending aorta and the proximal arch, which may decrease its sensitivity for detection of aortic dissection, hematoma, or atheroma in this region.

The main criterion for TEE diagnosis of suspected acute aortic dissection is the presence of two lumina (false and true) separated by an intimal flap (Table 56-12 and Fig. 56-19). Other findings for diagnosing aortic dissection by TEE[32] include the following:

1. Tear or disruption of the flap continuity or jets seen with color Doppler across the flap
2. Complete obstruction of the false lumen; presence of thrombus
3. Central displacement of intimal calcification or separation of intimal layers from thrombus
4. Periaortic hematoma (echo-free spaces around the aorta)
5. Intramural hematoma (crescent-shaped echodensity with vacuolization within it on the aortic short-axis view)
6. Pericardial or pleural effusion
7. AR

**TABLE 56-11: Diagnostic Tests for Acute Aortic Dissection**

| Test | Sensitivity (%) | Specificity (%) | Advantages and Disadvantages |
|---|---|---|---|
| TEE | 99–100 | >89 | *Advantage*: Quick, semi-invasive, assess AR, coronaries, pericardial effusion, may assess IH.<br>*Disadvantage*: Limited assessment of IH, "blind spot" of distal ascending aorta and anterior aortic arch, reverberation artifact |
| CT | >90 | >85 | *Advantage*: Quick, noninvasive<br>*Disadvantage*: Cannot assess branch vessels or IH, dye load/allergy |
| MRI | 98–100 | 100 | *Advantage*: Noninvasive, assess branch vessels, IH<br>*Disadvantage*: Slow, may not be available, pacemakers/device, breath-hold necessary |
| Angiography | 88–91 | >95 | *Advantage*: Assess coronaries, AR, branch vessels<br>*Disadvantage*: Slow, invasive, dye load, may miss dissection if completely thrombosed lumen, does not detect IH |

IH, intramural hematoma; AR, aortic regurgitation.

It is important to define the anatomic site and extension of the dissection, the degree of AR, involvement of the coronary arteries, LV dysfunction, and the presence of PE or tamponade.

Intraoperatively, TEE is used during reconstructive surgery for hemodynamic status, entry/exit sites, evaluation of decompression of the false lumen, and assessment of concomitant valve surgery.[13] Postoperatively, TEE is used for the detection of residual regurgitation and LV dysfunction. TEE is also indicated for defining the anatomic site and size of aortic aneurysms.

## PERICARDIAL DISEASE

### Pericardial Effusion and Tamponade

Echo is the diagnostic test of choice for detection of PE and assessing its hemodynamic significance. TEE is usually superior to TTE for evaluating pericardial thickness and adjacent structures, although CT and/or MRI are preferred for evaluating the pericardium. Normally, the pericardial space contains 10 to 50 mL of fluid and the pericardium measures 1 to 3 mm in thickness. An increase in the volume of the pericardial fluid results in elevated pericardial pressures, leading to reduced RV filling, followed by reduced LV filling (Fig. 56-20). PE usually appears as an echo-free space surrounding the myocardium, although as protein or cellular debris increases in the fluid, it becomes increasingly echogenic.[35] PE is differentiated from pleural effusion by the anterior location of PE relative to the proximal descending thoracic aorta, while pleural effusion is located posterior to the aorta. Epicardial fat may be confused with PE, since it is also echolucent, although epicardial fat is usually more echogenic than pericardial fluid and is usually located anteriorly.[35] TEE is useful in the postoperative patient with tamponade and a small loculated PE that may be difficult to visualize on TTE. Loculated PE in postoperative cardiac surgery patients may cause tamponade in the absence of typical echo signs (Table 56-13). In these patients, any evidence of LA or LV collapse or other localized chamber compression may be indicative of hemodynamically significant elevated intrapericardial pressures.

**TABLE 56-12: True Versus False Lumen in Aortic Dissection**

| | True Lumen | False Lumen |
|---|---|---|
| Systole | Expansion | Collapse |
| Diastole | Collapse | Expansion |
| SEC/thrombus | Absent or minimal | Present |
| Blood flow | Systolic forward flow | Reversed or absent flow |

SEC, spontaneous echo contrast.

### Constrictive Pericardial Disease

In constrictive pericardial disease, the visceral and parietal pericardium are adherent, thickened (>3 mm) and often calcified, which reduces ventricular filling in diastole and causes diastolic heart failure. However, the absence of pericardial calcification does not rule out the diagnosis of constriction. There are a number of causes of constrictive pericarditis and include repeated episodes of pericarditis, prior cardiac surgery, and radiation to the chest. The LV size, thickness, and function are typically normal. Multiple images should be taken in order to evaluate the thickness of the pericardium because it can be asymmetric. The IVC and hepatic veins will be dilated on subcostal views due to elevated RA pressure. Although echo signs of constriction (Table 56-14) are not very sensitive or specific, a completely

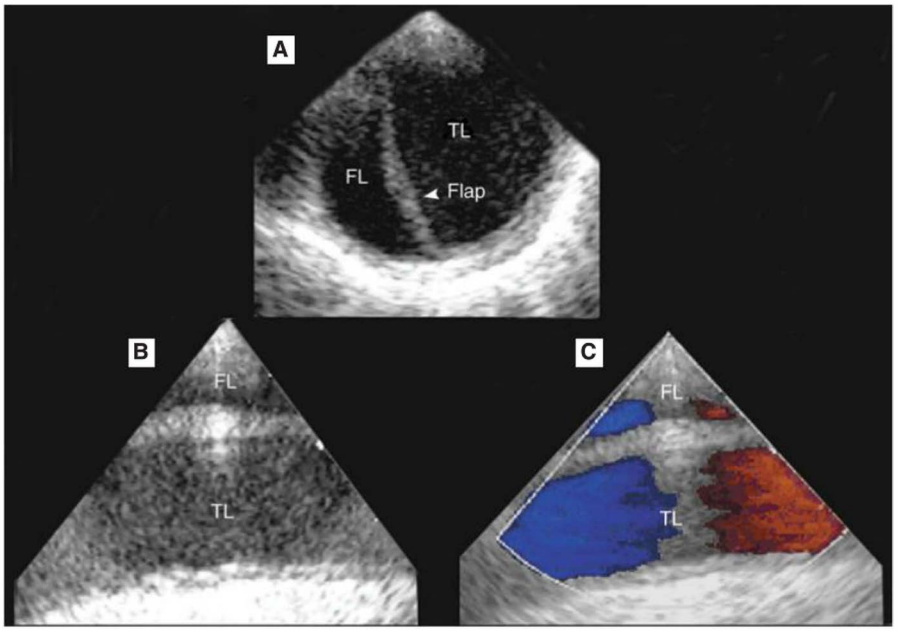

**FIGURE 56-19** Dissection of the descending thoracic aorta. Transesophageal echocardio-gram showing a large aortic dissection with t he diagnostic flap separating the true (TL) and false lumen (FL). **A.** Short-axis view. **B.** Long-axis view. **C.** Long-axis with color-flow Doppler shows flow in both the true and false lumens.

normal echo study usually rules out constriction.[36] Other imaging modalities, such as CT or MRI, may be necessary to further evaluate the pericardium and distinguish constriction from restriction.

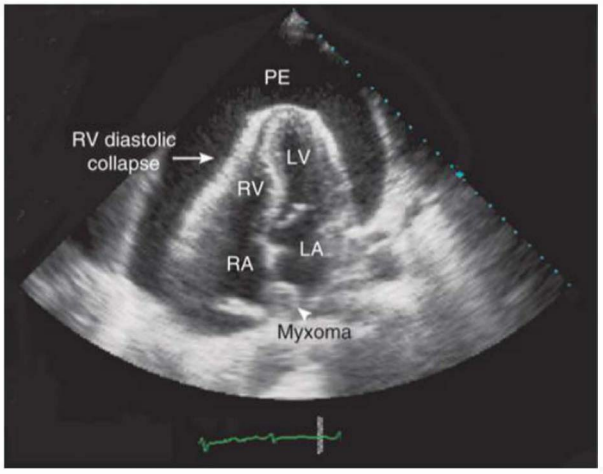

**FIGURE 56-20** Large pericardial effusion and cardiac tamponade. Transthoracic echocardiogram of the apical four-chamber view reveals an atrial myxoma attached to the interatrial septal with a large echolucent circumferential pericardial effusion (PE) and evidence of elevated intrapericardial pressure. Classic features of tamponade are shown with right ventricular (RV) diastolic collapse and abnormal interventricular septal motion (shifted toward the left during inspiration). RA, r ight atrium; LA, left atrium; LV, left ventricle.

## CARDIAC SOURCES OF EMBOLI

One of the most common indications for TEE includes the evaluation of cardiac sources of emboli, since TTE does not visualize well the potential sources of emboli (LA appendage thrombus, aortic atheroma, patent foramen ovale or atrial septal defect (ASD), LV thrombus, valvular lesions, intracardiac tumors). Small thrombi in the LA or LA appendage can be detected using TEE. In addition, factors that may contribute to or accompany atrial thrombi are often seen in the absence of an obvious thrombus: LA or LA appendage enlargement, SEC consistent with blood stasis, and decreased LA appendage contraction with low PW Doppler velocities (<20 mm/s). Aortic atheromas are evaluated for mobile components, plaque rupture, and ulceration and are graded as mild (<1 mm), moderate (1–3.9 mm), and severe (≥4 mm).

## ATRIAL SEPTAL DEFECTS

TEE is superior to TTE for visualizing ASDs. The anatomic defect is visualized using 2D echo and confirmed with Doppler and contrast (bubble study) using maneuvers that increase RA pressure, such as Valsalva or cough. The hemodynamic significance of the shunt is assessed using Doppler by quantifying the shunt size and determining the presence of pulmonary hypertension. Shunt quantification is obtained as the ratio of pulmonary-to-systemic flow ($Q_p$:$Q_s$) using Doppler cardiac outputs across the pulmonary valve and AV.[4] All four pulmonary veins should be visualized and

## TABLE 56-13: Echocardiographic Signs of Cardiac Tamponade

| RA Collapse | Sensitive But Not Specific |
|---|---|
| RV diastolic collapse | Ranges from inward dip to complete collapse of RV-free wall in diastole; specific sign but may be absent if elevated RV pressures or adhesions tether RV |
| LA, LV collapse | May be the only sign of tamponade in postoperative cardiac surgery patients |
| Abnormal interventricular septal motion | Inspiration: Septum shifts to the left |
| Respiratory variation in ventricular size | Inspiration: LV becomes smaller, RV larger |
| Respiratory variation in transvalvular inflow velocities | Inspiration: Mitral inflow E velocity decreases, tricuspid inflow velocity increases |
| Respiratory variation in PV and HV velocities | *Inspiration*: PV velocities decrease and HV velocities increase |
| Dilated IVC and blunted respiratory changes | Not very specific |

HV, hepatic vein; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RV, right ventricle.

## TABLE 56-14: Echocardiographic Signs of Constriction

| | |
|---|---|
| Pericardial thickening and calcification | TEE better than TTE, but additional imaging with CT or MRI may be necessary |
| Dilated RA, LA, IVC | Nonspecific findings |
| Diastolic flattening of the LV posterior wall | Secondary to reduced filling in mid–late diastole, sensitive but not specific |
| Abnormal interventricular septal motion | *Inspiration*: Septum shifts to the left |
| Premature pulmonary valve opening | RV diastolic pressure > PA diastolic pressure in middiastole |
| Respiratory variation in ventricular size | Inspiration: LV becomes smaller, RV larger |
| Respiratory variation in transvalvular and venous (pulmonary/hepatic) flow velocities | Similar to tamponade, respiratory variation may be more prominent in constriction |

IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Reproduced from: Oh JK. *The Echo Manual*. Philadelphia: Lippincott Williams & Wilkins, 1999:278. With permission.

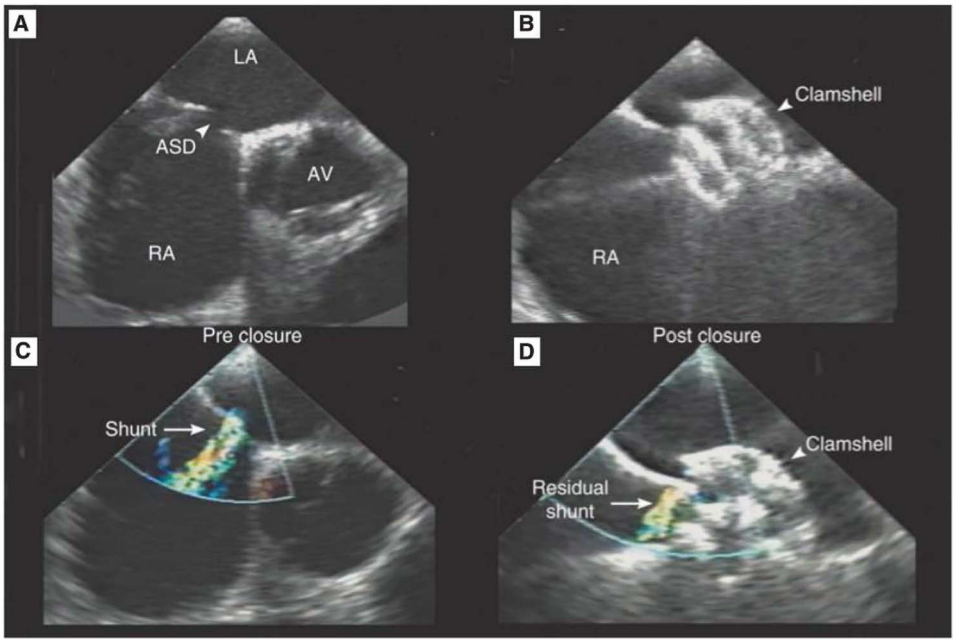

**FIGURE 56-21** Secundum atrial septal defect (ASD) and clamshell closure. **A.** Secundum ASD seen as a defect in the midinteratrial septum along with a dilated right atrium (RA) on transesophageal echocardiography. The size of the rim of tissue between the ASD and the aortic valve is critical in determining likelihood of success with device closure. **C.** Color-flow Doppler of the ASD shows a high-turbulence jet consistent with shunt (arrow). **B.** The clamshell has been deployed across the ASD. **D.** Postprocedure color-flow Doppler with small residual shunt that usually resolves spontaneously after a period of several weeks to months. AV, aortic valve.

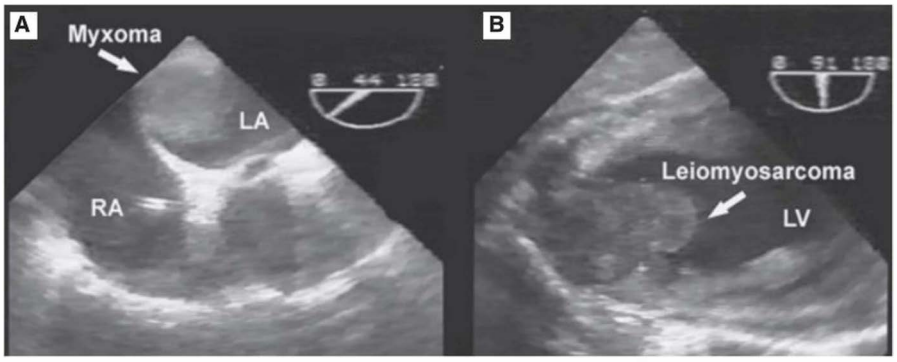

**FIGURE 56-22** Cardiac tumors. **A.** Large atrial myxoma attached to the interatrial septum, seen as a spherical mass with a speckled appearance. **B.** Metastatic leiomyosarcoma of genitourinary tract origin with myocardial invasion of the left ventricular (LV) apex.

the presence of associated anomalies excluded. TEE plays an important role in determining the suitability of ASDs for device closure versus cardiac surgery based on the size of the ASD and the rim of tissue surrounding it as well as the degree of septal tissue redundancy.[23] TEE has become essential for guiding placement of catheter-deployed closure devices and in assessing residual shunts (Fig. 56-21).

## CARDIAC TUMORS

TEE, because of its high sensitivity, is the imaging modality of choice and is superior to TTE, CT, MRI, and angiography for detecting cardiac tumors.[1,4] Although MRI may not detect small cardiac tumors, it is usually performed after TEE for further differentiation of thrombus (presence of methemoglobin or hemosiderin) from neoplasm, since it is superior to TEE for tissue characterization. MRI examinations are multiplanar and typically include fast T1- and T2-weighted techniques with administration of gadolinium (a paramagnetic contrast agent) and a technique for imaging moving structures with single-slice breath-hold, such as fast gradient-echo sequences (e.g., FLASH). Primary tumors are more likely to affect the myocardium, while secondary tumors usually involve the pericardium with secondary intramyocardial infiltation.[37] Atrial myxomas are the most common (up to 25 percent) primary cardiac tumors. Atrial myxomas as seen on TEE or TTE show several typical features[37] (Fig. 56-22A):

- Ninety percent originate in the interatrial septum, near the fossa ovalis.
- A spherical mass with a speckled appearance is often seen in RA myxomas, while a villous amorphous mass may be seen in LA myxomas.
- Ninety percent attach to the wall of the atrium via a stalk, which may allow prolapse through the MV.
- Intramural hemorrhage (cysts) and necrosis result in a heterogeneous appearance of echodensity; calcifications are uncommon but may be seen.
- They may be highly mobile and a cardiac source of embolus.

Metastatic tumors to the heart most commonly arise from the breast or lung but may include leiomyosarcoma (Fig. 56-22B). Metastatic tumors usually affect the pericardium and result in PE. In addition, some tumors metastasize through the IVC (renal cell, hepatoma), affecting the right heart more than the left; TEE allows for visualization of the route of extension.[37] Tumors involving the cardiac valves are rare (often fibroelastomas) and may affect valve competence and global LV function. MRI and ultrafast CT may be a useful adjunct in delineating tumors of the cardiac valves.[38]

## LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

TEE is used intraoperatively for septal myectomy for treatment of obstruction of the LVOT due to hypertrophic cardiomyopathy. SAM of the MV may cause LVOT obstruction; TEE is used to define the structures involved in the SAM (e.g., chordae, anterior leaflet). As in AV, LVOT gradients may differ intraoperatively versus preoperatively owing to different hemodynamics. CF Doppler typically demonstrates turbulent blood flow (mosaic pattern) at the site of LVOT obstruction. An eccentric jet of MR may also be seen if there is abnormal coaptation of the mitral leaflets (usually a posteriorly directed jet owing to abnormal coaptation of the anterior mitral leaflet).

TEE is also helpful during resection of lesions causing subaortic stenosis. It can determine the location and severity of obstruction. It is also useful for evaluating the success of the surgery in relieving the obstruction and in detecting MR that may result from the surgery.[22]

## ECHOCARDIOGRAPHY IN CARDIAC SURGERY BOARD REVIEW QUESTIONS (CHAPTER 56)

1. Which is correct for assessment of LV regional wall motion by anesthesia?
   A. Normal ≥40 percent thickening
   B. Mild hypokinesis = 25 to 40 percent thickening
   C. Severe hypokinesis = 20 percent thickening
   D. Dyskinesis = paradoxical systolic motion
   E. Akinetic ≤10 percent thickening

2. Which is true regarding pulmonary vein flow on echocardiography?
   A. There are five velocities.
   B. $PV_a$ is related to left atrial contraction.
   C. Pulmonary vein systolic velocity peak greater than diastolic velocity peak suggests elevated left atrial pressures.
   D. Duration and peak $PV_a$ velocity are decreased in the setting of high filling pressures.
   E. Mitral inflow A wave duration greater than $PV_a$ duration indicates high left atrial pressures.

3. Which is an echo finding of severe MR?
   A. Regurgitant jet >20 percent of LA area
   B. Vena contracta >4 mm
   C. Eccentric wall-impinging jet
   D. LV end-diastolic dimension >60 mm
   E. LA dimension >4.5 cm

4. Which is an echocardiographic finding of severe AR?
   A. LV end-systolic dimension >50 mm
   B. Pressure half-time <300 ms
   C. Vena contracta >4 mm
   D. Systolic flow reversal in thoracic aorta
   E. Proximal regurgitant color jet/LVOT diameter >50 percent

5. Which is not an normal echocardiographic fining on a prosthetic valve?
   A. Regurgitant area of 1.5 $cm^2$ on aortic prosthesis
   B. Regurgitant jet length of 2.0 cm on mitral prosthesis
   C. Single central jet on Medtronic-Hall valve
   D. Four jets on St. Jude Medical valve
   E. Unequal jets on Bjork–Shiley valve

## ANSWERS

1. **Answer: D.** Dyskinesis is defined as paradoxical systolic motion. Normal function is >30 percent thickening, mild hypokinesis is 10 to 30 percent thickening, severe hypokinesis is <10 percent thickening, and akinesis is no thickening.

2. **Answer: B.** $PV_a$ (atrial flow reversal velocity) is related to left atrial contraction. There are four velocities measured on echocardiography—$PV_{S1}$, $PV_{S2}$, $PV_D$, and $PV_a$. Pulmonary vein systolic velocity peak less than diastolic velocity peak suggests elevated left atrial pressures. Duration and peak $PV_a$ velocity are increased in the setting of high filling pressures. $PV_a$ duration longer than the mitral inflow A wave duration indicates high LA pressures.

3. **Answer: C.** The echocardiographic findings of severe MR are regurgitant jet >40 percent of LA area, vena contracta >7 mm, eccentric wall-impinging jet, LVESD >45 mm, LVEDD >70 mm, LVEF <55 to 60 percent, dilated LA >5.5 cm, resting RVSP >50 mm Hg, restrictive mitral filling pattern, pulmonary vein systolic flow reversal, and ERO >0.4 $cm^2$.

4. **Answer: A.** The echocardiographic findings of severe AR are LVESD >50 to 55 mm, LVEDD >70 to 75 mm, LVEF <55 percent, pressure half-time <200 ms, proximal regurgitant jet width/LVOT diameter >65 percent, vena contracta >6 mm, holodiastolic flow reversal in thoracic aorta, and restrictive mitral filling pattern.

5. **Answer: A.** Normal amounts of regurgitation are found with most prosthetic valves. For an aortic prosthesis, the regurgitation area should be less than 1 $cm^2$ and length of the jet <1.5 cm. For a mitral prosthesis, the regurgitant area should be less than 2 $cm^2$ and length of the jet <2.5 cm. Characteristic flow patterns of specific valve types include one central jet for a Medtronic-Hall valve, two side jets and a central jet for a St. Jude medical valve, and two unequal side jets for a Bjork–Shiley valve.

# Cardiac Magnetic Resonance Imaging

*Jens Vogel-Claussen*
*David A. Bluemke*

## INTRODUCTION

The availability of high-field-strength magnets, high-performance-gradient hardware, and ultrafast sequence technology in recent years has transformed cardiac magnetic resonance imaging (MRI) into a multifunctional tool. Cardiac MRI can provide three-dimensional analysis of cardiac anatomy, viability, motion, and function with high accuracy and reproducibility.[1,2] Because of the complexity of cardiac anatomy and motion, cardiac MRI can be challenging and previously had been performed primarily at specialized centers. More recently, a comprehensive cardiac MRI exam has become a reliable clinical tool in a wide range of healthcare centers. In this article, we briefly outline imaging techniques and illustrate the various applications of cardiac MRI.

## GENERAL PRINCIPLES

Communication between the surgeon and the MRI center is essential for efficient and accurate diagnosis. The examination will then be tailored to the specific clinical question. Instructing patients as to the nature of the examination will likely significantly improve the quality of the test. During the MRI examination, patients will need to perform multiple breath-holds of about 10- to 20-s duration. Patients with severe shortness of breath or who cannot lie flat on the MRI table are often poor candidates for cardiac MRI. Such patients should be discussed with the MRI center prior to referral. Overall, a directed examination requires about 20 to 30 min, whereas a comprehensive examination will require 45 to 60 min. There are no restrictions on eating or drinking before the MRI examination except if stress examinations are performed (see below).

### Contraindications

Compatibility of a patient's devices with the MRI scanner is a frequent issue and changes frequently with technology development. In general, all prosthetic cardiac valves are MRI compatible. Pacemakers and implantable cardioverters/defibrillators (ICDs) have previously been considered as strict contraindications to MRI. However, there have been recent reports at our institution and others of patients who have safely undergone MRI at 1.5 T magnetic field strength with certain types of these devices in place.[3,4] In these instances, imaging information from other techniques, such as computed tomography or echocardiography, was incomplete. Currently, MRI scanning with pacemakers or ICDs in place remains investigational. Older devices manufactured before the year 2000 and certain manufacturers' devices are less likely to be MRI compatible. Lower magnetic field strength (i.e., 1.5 T instead of 3 T) should also improve safety in conjunction with implanted devices. Thus, consultation with the MRI center should be performed when an MRI examination is deemed essential to patient care.

Coronary and other vascular stents are increasingly common. Most stents have not been explicitly tested by the manufacturer for MRI compatibility. Package labels from the manufacturer may indicate that MRI may be performed 6 weeks after implantation, with the rationale that the stent is endothelialized at that time and less likely to move in the magnetic field. Our approach is to evaluate these devices on a case-by-case basis. In many instances, the risk of performing the MRI examination with such a device may be outweighed by the benefit of performing the examination. Lists of devices that have been tested for MRI compatibility have been published in the literature as well as listed on websites, such as www.MRIsafety.com.

There is no known adverse effect of MRI on the fetus; MRI examination is frequently preferred compared to imaging examinations using x-rays. The decision to scan during pregnancy should be made on an individual basis. The gadolinium-based contrast agents used for MRI cross the placenta, so deferring the examination to a later trimester or after the pregnancy would also reduce any potential risk.[5] If an MRI exam has to be performed during pregnancy, we usually can avoid giving MRI contrast agents to answer a specific clinical question in most patients at our center.

Patients with renal failure should not undergo gadolinium-enhanced MRI, because they are at risk of developing nephrogenic systemic sclerosis (NSF). NSF is a rare but potentially debilitating or fatal fibrosing condition that has recently been linked to gadolinium-based contrast agents. For patients with chronic renal failure, the FDA has determined that the risk is greatest when the estimated glomerular filtration rate (GFR) is less than 30 mL/min/1.73 $m^2$. The policy at our institution is therefore generally not to administer intravenous gadolinium-based contrast agents in patients with chronic severe renal failure (GFR less than 30 mL/min/1.73 $m^2$), acute renal failure or in patients on dialysis.[6]

If cardiac stress imaging is performed with dobutamine, adenosine, or dipyridamole, the patient should be questioned about relative contraindications to these agents and specifically counseled to avoid theophylline-containing drugs or foods for at least 24 h prior to the exam. A gadolinium-based contrast agent is frequently used in association with cardiac MRI. Reactions to the MRI contrast agent are very rare, but a prior severe reaction would constitute a contraindication to another contrast injection.

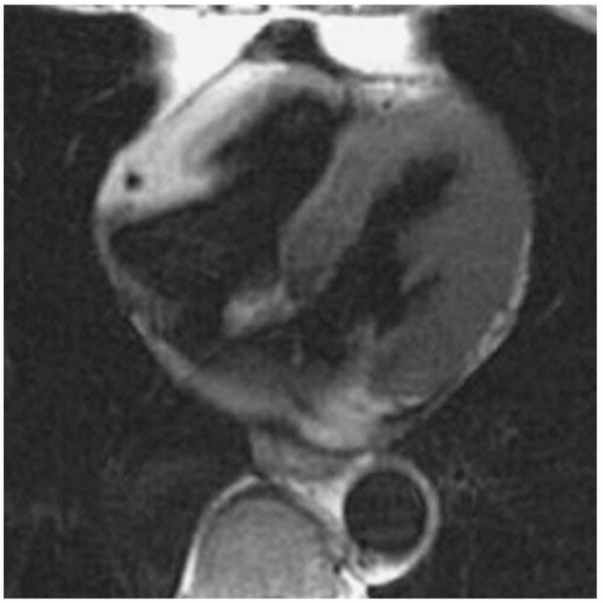

**FIGURE 57-1** Transverse black-blood MRI of the heart and descending thoracic aorta. Because of the double-inversion technique, the blood in the cardiac chambers and descending aorta appears black.

## Cardiac Gating

Cardiac MRI makes use of electrocardiographic (ECG) gating to suppress cardiac motion artifacts and arterial pulsation. The objective of cardiac gating is to acquire an R wave that is taller than the S or T wave. Even after obtaining a strong ECG signal initially, the signal may become obscured by additional noise from the magnetic field or regurgitant fraction (RF) pulses. Therefore optimal electrode-to-skin contact is necessary and skin shaving and cleansing is often necessary at the electrode placement sites. Nevertheless, imaging with an impaired ECG signal (i.e., pericardial effusion) or cardiac arrhythmias can be challenging.[7] For patients with arrhythmias who can tolerate β-blockade, a short-acting agent (e.g., metoprolol) may be administered 30 min before the MRI examination.

## Understanding Cardiac Magnetic Resonance Images

Terminology in MRI can be quite confusing to both the cardiovascular imager and the cardiovascular surgeon. The method of creating the images is termed the "pulse sequence," and pulse sequence names often change in order to give a manufacturer a perceived marketing advantage over competitors. Therefore a brief review of some principles underlying the terminology is worthwhile.

Images may be rather simply classified by the relative brightness of blood in the vessels or in the ventricular chambers. The blood can be made to be dark ("black-blood images") when the ventricular or arterial walls are the primary focus of the examination (Fig. 57-1). For example, to visualize a myocardial infarction, it is useful to make the blood in the ventricle very dark so as not to obscure the ventricular wall. Although it is entirely acceptable to refer to such images as "black-blood images," more specific terminology can be used to indicate how the image was generated. Thus, the term *black-blood image* is a very generic way of describing more specific terminology such as fast spin-echo or turbo spin-echo images.

The most important type of black-blood image generation for the cardiovascular system is termed a double-inversion recovery fast spin-echo sequence. These images are acquired in a breath-hold and are used to image myocardial edema, tumors, or complex anatomic regions. The method involves a specific pulse ("inversion pulse") that is used to make the blood dark relative to the myocardium. Advantages of the method include very high soft tissue contrast images, similar to those seen in brain or musculoskeletal imaging. Spatial resolution is usually quite good, between 0.5 and 2 mm. The disadvantage is a relatively long imaging time. In addition, the images are static rather than cine images.[8]

Black-blood magnetic resonance (MR) images can be further categorized. "T1-weighted" MR images display myocardium and fluid as intermediate signals and fat as bright signals. T1-weighted MR images are also used to show enhancement of abnormal tissues after intravenous administration of a gadolinium-based MR contrast agent (discussed further below). "T2-weighted" MR images show fluid and edema as bright signals. These are most commonly used to depict inflammation, tumor edema, or edema from myocardial infarction.

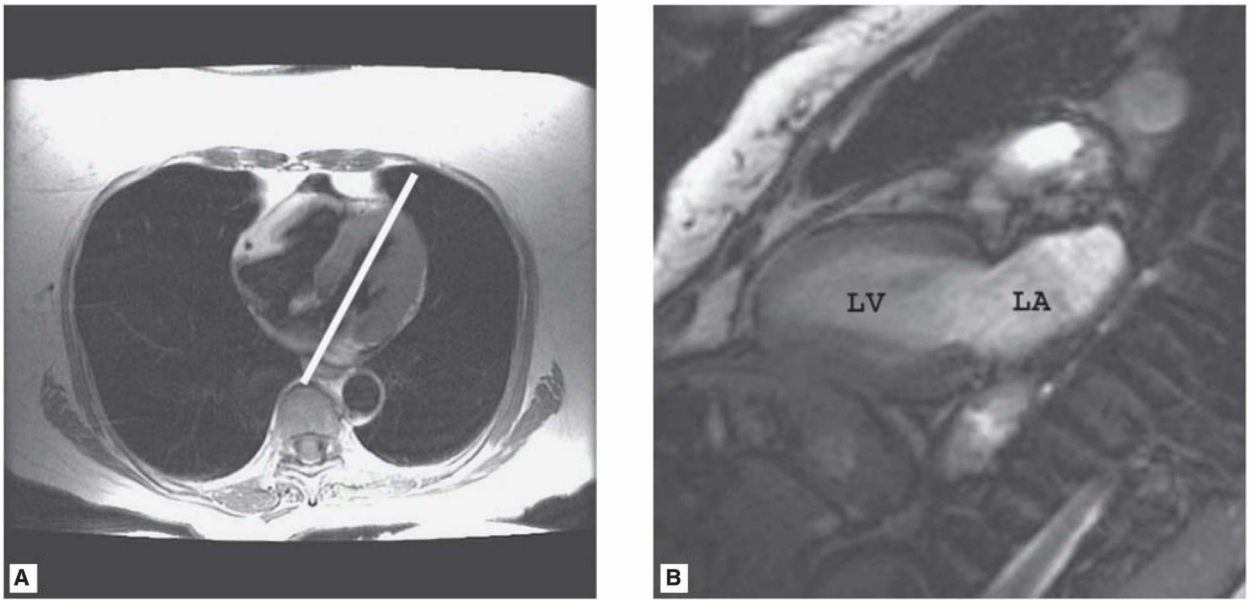

**FIGURE 57-2** By imaging in the plane through the left ventricle and left atrium prescribed by the white bar on the transverse view (**A**), an oblique vertical long-axis two-chamber view of the left ventricle and left atrium is obtained (**B**). The long-axis view is acquired with the bright-blood (FIESTA) MRI technique (B). LA, left atrium; LV, left ventricle.

Besides black-blood images, the most commonly used MR images are "bright-blood images" (Fig. 57-2). Typically, these are viewed as cine images of the ventricular or valvular planes. These methods have the advantage of taking less time to acquire than the black-blood images; thus visualization of motion is possible. The temporal resolution of these images is 25 to 50 ms or less if needed.

The bright-blood cine images are generated using a method generally known as gradient echo (GRE) imaging. The newest GRE methods have trade names such as balanced fast-field echo, FIESTA, or TrueFISP, depending on the vendor of the MR scanner. These sequences carry specific advantages for cardiac MR and represent a substantial improvement in image quality compared to older methods of cardiac cine imaging.[9] The spatial resolution of the images is about 2 mm, which is substantially greater than the resolution possible with nuclear techniques (6 mm). The blood pool in the ventricle has a very bright signal, so that the border between the ventricle and blood pool is easily distinguished. Turbulent jets at sites of stenosis or regurgitation are dark and readily distinguished using the newest sequences. GRE images are also used for imaging myocardial infarctions.

Disadvantages of bright-blood GRE images include large amounts of image distortion around metal, including sternal wire implants, stents, and embolization coils. The most frequent problem we have observed arose in patients with congenital heart disease who had embolization coils placed and required later evaluation with MRI. These coils distort large areas of anatomy, with the area of distortion centered on the device.

Other techniques—such as flow-sensitive MRI, myocardial viability techniques, and vascular imaging—are discussed later in this chapter.

## Cardiac Imaging Planes

Since the cardiac axes differ significantly from the axial, sagittal, and coronal planes of the body, specific imaging planes are necessary for adequate cardiac visualization and evaluation. Recently, three-dimensional acquisitions have been developed, so that the heart can be sliced and viewed from any desirable angle at postprocessing. This further shortens the acquisition time. A brief illustration of key imaging planes and how these images are derived is provided below.

### AXIAL, SAGITTAL, AND CORONAL PLANES

The first imaging plane is usually a transverse image of the chest with black-blood techniques (Fig. 57-1). Radiologists and surgeons are most familiar with this plane; it not only permits evaluation of the anatomic position of the cardiac chambers, coronary artery origins, and great vessels, but also detects extracardial intrathoracic pathology. Further sagittal and coronal planes can be obtained. The coronal plane is useful in evaluating the left ventricular outflow tract, aortic valve anatomy, diaphragmatic portion of the left ventricular wall, and the extension of the pericardium over the proximal portion of the great vessels. The plane parallel to the aortic arch on axial images is called the double-oblique or oblique sagittal plane. This plane is used to evaluate the aortic arch and aortic dissection.

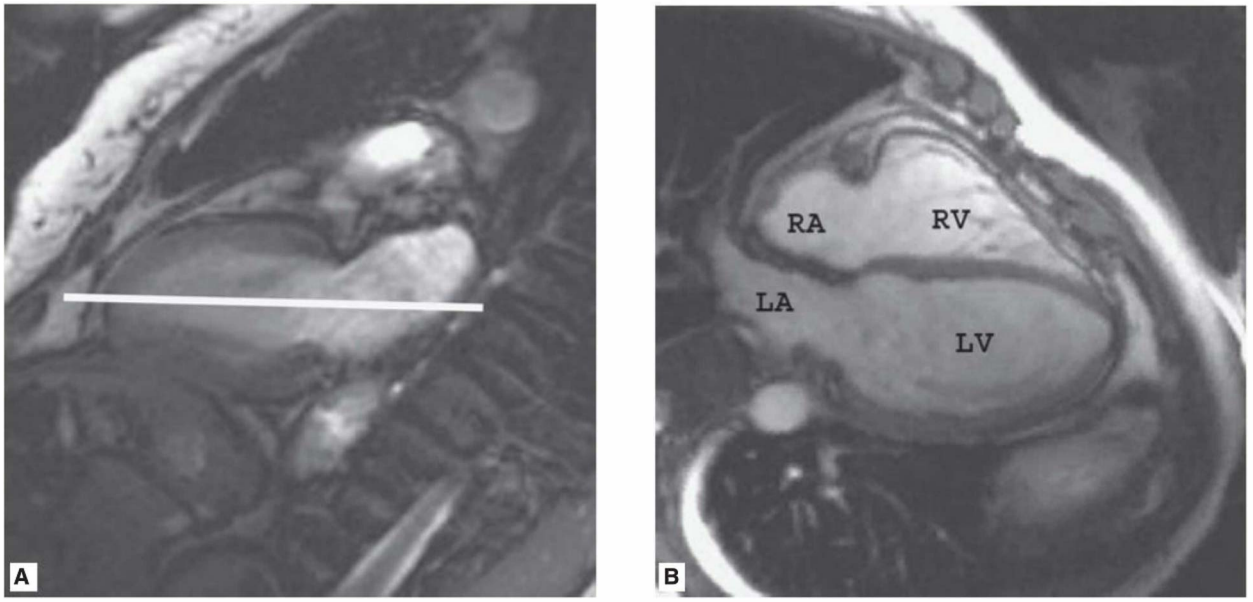

**FIGURE 57-3** By imaging along the axis prescribed by the white bar on the long-axis view (**A**), the horizontal long-axis view is obtained (**B**). The horizontal long-axis view is acquired with the FIESTA MRI technique. RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

### VERTICAL LONG-AXIS VIEW

The vertical long-axis plane, sometimes referred to as a two-chamber view, is named based on visualization of the left ventricle and left atrium (Fig. 57-2A and B). The mitral valve is readily depicted in this plane.

### HORIZONTAL LONG-AXIS VIEW

The horizontal long-axis plane, sometimes referred to as a four-chamber view, is oriented 90 degrees to the vertical long-axis view. This view is obtained from a line drawn through the posterior wall of the left atrium, the middle of the mitral valve, and the left apex on the two-chamber view (Fig. 57-3A and B). The horizontal long-axis view depicts the right and left atria, both ventricles, and the mitral and tricuspid valves. This view also displays the relationship of the four chambers on a single image. Cine GRE images in this plane can evaluate mitral and tricuspid valve function, atrial or ventricular septal defects (VSDs), and bilateral ventricular contractions.

### SHORT-AXIS VIEW

Images in the short-axis plane are perpendicular to the left ventricular long axis seen on the horizontal or vertical long-axis views (Fig. 57-4A and B). The short-axis images show the cross-sectional anatomy of the right and left ventricle. Short-axis cine images are ideal to evaluate left and right ventricular mass, volumes, and function in order to obtain estimates of end-diastolic volume (EDV), end-systolic volume (ESV), and ejection fraction (EF). Differences in stroke volume from the left heart compared to the right heart quantify shunt volumes or valvular regurgitation. Furthermore, this plane is suitable for identifying focal wall motion abnormalities.

## CLINICAL APPLICATIONS OF CARDIAC MAGNETIC RESONANCE IMAGING

### Cardiac Mass and Function

Left ventricular mass is a strong independent predictor of fatal and nonfatal cardiovascular events.[10,11] Cardiac MRI is currently the most accurate and reproducible method for the assessment of cardiac volumes, mass, and function.[12] To evaluate the left ventricular mass, short-axis cine MR images are used. The endocardial and epicardial contours of the left myocardial wall are automatically or semiautomatically traced on each slice using special software. The contours of the cardiac chambers are then summed and multiplied by the slice thickness and slice gap (Simpson method) to obtain the contour volumes (Fig. 57-5). Finally, left ventricular wall mass is calculated from the volumes based on a myocardial density of 1.05 g/cm$^3$. By tracing ESV and EDV, cardiac function parameters like EDV, ESV, and EF can be calculated according to the same principle.

Cardiac MRI using bright-blood cine imaging is used to assess cardiac wall motion. Most centers grade wall motion visually, as either normal, hypokinetic, akinetic, or dyskinetic at the base, middle, and apex of the left ventricle. Qualitative

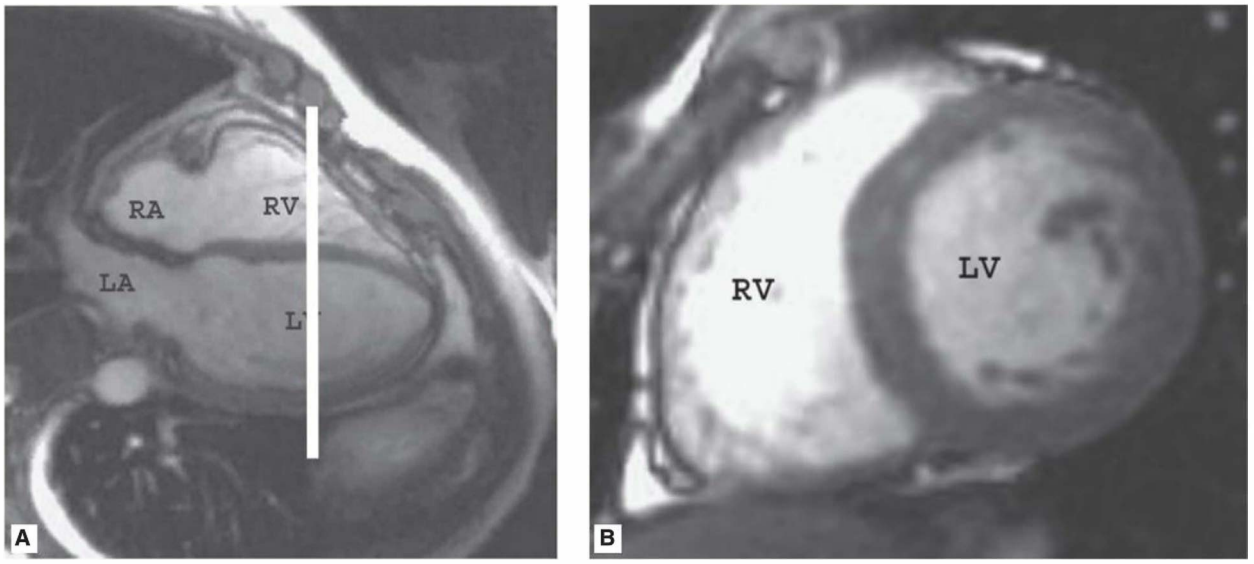

**FIGURE 57-4** By imaging along the axis prescribed by the white bar on the long-axis image (**A**), the short-axis view is obtained (**B**). The short-axis view is acquired with the bright-blood FIESTA MRI technique (**B**). RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

assessment of wall motion by MRI, like that of echocardiography, depends on the use of experienced readers for greatest reproducibility.

A limited number of centers have experience using "tagged MRI" to quantitatively measure regional cardiac wall motion. These methods, developed by Zerhouni and colleagues,[13] represent the most precise way for measuring both systolic and diastolic function. The method involves placing a magnetic strip on the myocardium at end diastole. As the heart contracts, the magnetic strip moves and bends along with the motion and contraction of the myocardium. Measuring the distances between the magnetic strips on each image assesses regional contractility. By using these methods, the contraction of the heart in any direction (circumferential, radial, and longitudinal) may be accurately measured (Fig. 57-6). Currently the primary use of quantitative methods to measure regional cardiac contraction has been in

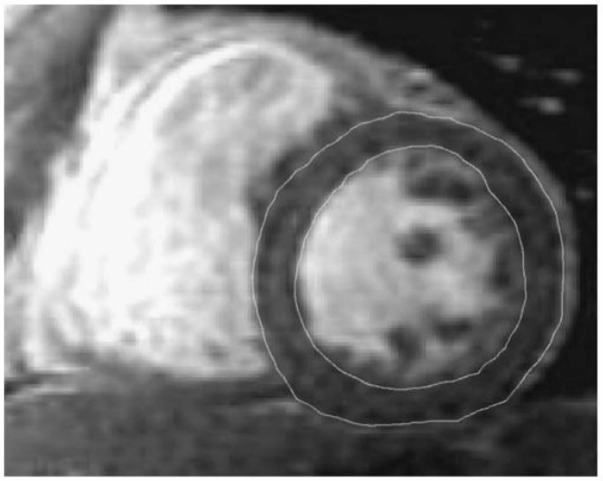

**FIGURE 57-5** Short-axis fast-gradient echo MRI demonstrates automatic outline of endo- and epicardial borders of the left ventricle for left ventricular mass evaluation with dedicated software.

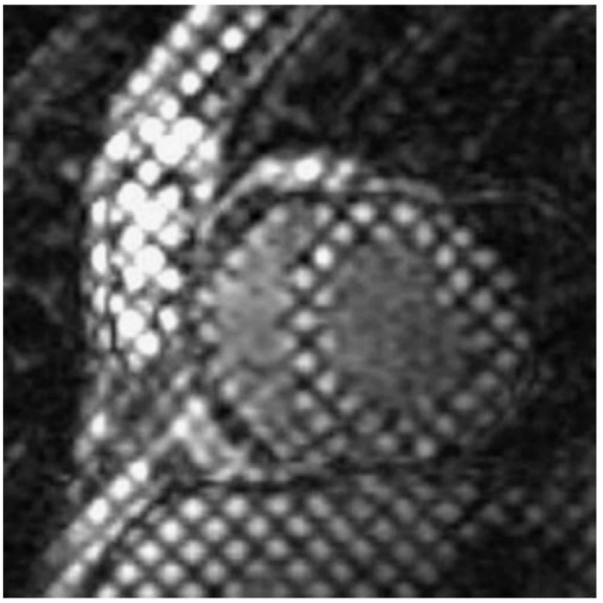

**FIGURE 57-6** To assess for focal wall motion abnormalities, MR tagging can be used, as demonstrated on this short-axis view of the heart. During myocardial contraction, the distance between magnetically placed tag lines decreases, directly measuring regional shortening.

specific research protocols. Given the nature of cardiovascular imaging, however, it is likely that these methods will gain further importance in the future. Tagged MRI has other specialized uses, such as the detection of pericardial to myocardial adhesions in constrictive pericarditis.

## Assessment of Valvular Heart Disease

Conventional and transesophageal echocardiography are still the most widely applied methods to evaluate valvular cardiac anatomy, such as leaflet quantity and thickness, vegetations, and valvular function. Recent developments in cardiac MRI techniques demonstrate that valve evaluation by MRI can be an attractive alternative or complementary to echocardiography. MRI evaluation is noninvasive and provides three-dimensional anatomic and functional data, which are potentially more accurate and reproducible than that of echocardiography.[14,15]

Black-blood sequences are used to analyze valvular anatomy (e.g., valve thickening or bicuspid valves). Cine MRI bright-blood techniques are used to evaluate abnormal flow patterns as seen in valvular stenosis or regurgitation, which cause loss of signal and appear as a dark signal void (Fig. 57-7). This signal void is caused by turbulent flow and the acceleration of flow within the normal bright-blood pool, similar to aliasing in Doppler ultrasonography. This signal void also depends on technical factors, which may vary in appearance depending on the MRI scanner. Thus, this signal void is usually evaluated only qualitatively. The degree of valvular regurgitation is measured by the area of the signal void volume and the maximum length of the signal void in the receiving chamber.

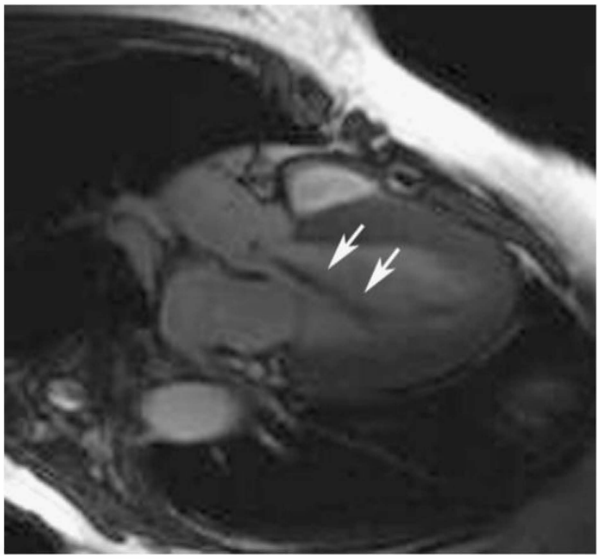

**FIGURE 57-7** Bright-blood (FIESTA) image of the heart demonstrates moderate aortic valve regurgitation (arrows).

A method to quantitate valvular regurgitation is to calculate the RF with ventricular volumetric measurements. As described above, end-systolic and end-diastolic volumetric measurements of the blood pool are first performed. In the normal heart, the right and left ventricular stroke volumes (EDV – ESV) are equal. If there is unilateral valvular regurgitation, the EDV is higher on the affected side than on the unaffected side of the heart; therefore the stroke volume on the affected side is also higher. The difference in stroke volume between a regurgitant and a normal ventricle is the regurgitant volume.

The RF can be calculated by dividing the regurgitant volume by the stroke volume of the regurgitant ventricle. An RF of 15 to 20 percent corresponds to mild valvular regurgitation; an RF of 20 to 40 percent to moderate regurgitation; and an RF of more than 40 percent to marked regurgitation. In the presence of unilateral combined valvular insufficiency (e.g., mitral and aortic regurgitation), this technique can calculate only the combined volume of regurgitation. In cases of bilateral valvular regurgitation (e.g., pulmonary and aortic valves), this technique will not provide accurate results. The method, however, may be used to assess the functional consequences of a VSD.

Flow-sensitive or velocity-encoded MRI is the best way to quantify valvular regurgitation. In this method, the velocity of blood flow is linearly related to the brightness of the MR image. Stationary tissue appears gray, whereas antegrade or retrograde flow along the phase-encoding axis appears as black or bright pixels. Velocity-encoded MRI makes it possible to quantify blood-velocity profiles at different time points of the cardiac cycle. Blood velocity can be encoded for imaging planes perpendicular to (through plane velocity measurement) or parallel to the direction of blood flow (in-plane velocity measurement). Flow–volume curves can map the absolute stroke volume and regurgitant volume in different phases of the cardiac cycle.

## Ischemic Heart Disease

Compared to nuclear medicine techniques such as single photon emission computed tomography (SPECT) or positron emission tomography (PET), cardiac MRI is capable of visualizing subendocardial or even papillary muscle infarctions owing to its superior spatial resolution.[16] Furthermore, cardiac MRI is more cost-effective than PET imaging.

## Myocardial Viability

Viable myocardium is myocardium that may recover function following coronary revascularization. Hibernating myocardium (with reduced blood flow) will recover function, but scar/fibrosis in an area of infarction will not. After myocardial infarction, accurate assessment of myocardial viability is crucial for optimal clinical decision making. Cardiac MRI is capable of accurately delineating nonviable or infarcted

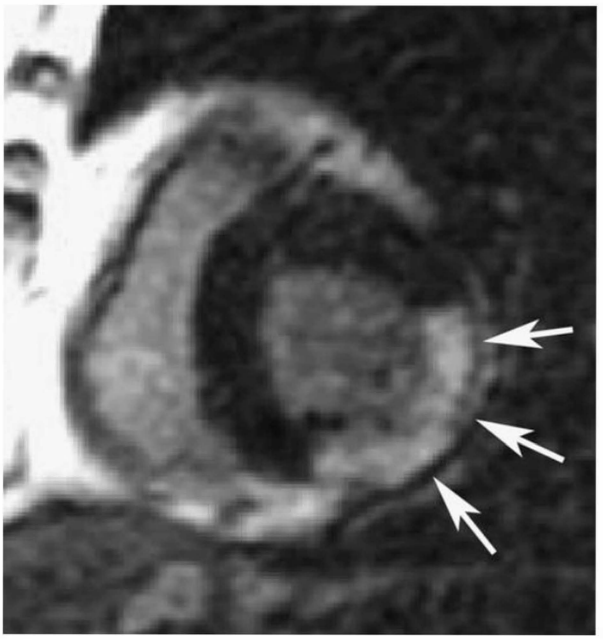

**FIGURE 57-8** Short-axis gadolinium-enhanced delayed MRI demonstrates transmural delayed enhancement of the myocardium in the distribution of the left circumflex coronary artery due to myocardial infarction (arrows).

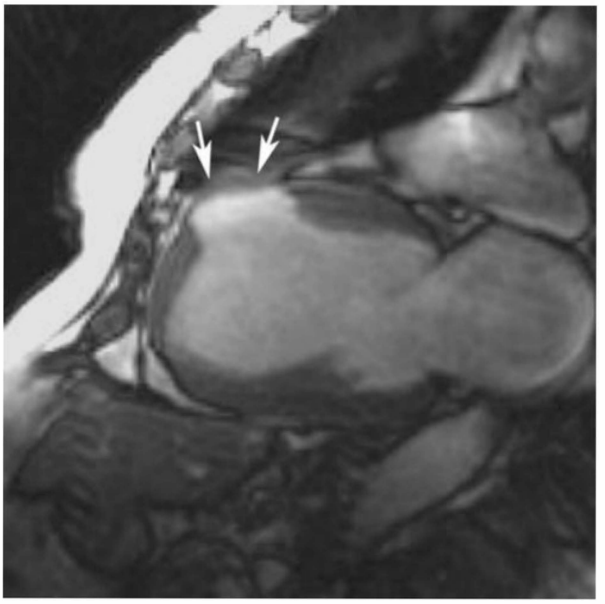

**FIGURE 57-9** Bright-blood (FIESTA) long-axis view demonstrates focal thinning and outpouching of the anterior left ventricular wall (arrows), compatible with aneurysm formation after myocardial infarction.

myocardium from potentially salvageable myocardium. The advantages of cardiac MRI as compared with nuclear, echocardiographic, or PET methods include (1) high spatial resolution, (2) lack of ionizing radiation, and (3) short examination time. Disadvantages include (1) reduced image quality in patients with arrhythmias and (2) patient safety exclusions, as discussed under "Contraindications," above.

For identifying viable versus nonviable myocardium, an intravenous injection of a gadolinium-based contrast agent is used. On delayed images, obtained 10 to 20 min after contrast injection, myocardial scar ("nonviable") retains the gadolinium contrast agent, while washout of the contrast agent occurs in viable myocardium (Fig. 57-8). MR images are optimized so that normal myocardium is "suppressed" on GRE images. Another commonly used term for MRI imaging of this type is *myocardial delayed enhancement* (MDE), or "viability" imaging. This terminology refers to the characteristic 10- to 20-min delay during which the contrast agent in scar/fibrosis distributes differently to normal, viable myocardium.

In viability imaging, scar/fibrosis is depicted as an area of high signal intensity that is typically subendocardial or transmural in a coronary artery distribution. Images are readily interpreted at the base, middle, and apex of the heart on short- and long-axis views. The concept that "bright is dead" is that myocardium with high signal on these MR images corresponds to noncontracting scar/fibrosis. The basis for this relates to both animal models following myocardial infarction and human studies that show lack of contraction of the enhanced myocardium following coronary revascularization.[17,18]

Because of the high spatial resolution of MRI, subendocardial and transmural infarction can be readily identified. In chronic myocardial infarction, myocardial scar may also show thinning of the ventricular wall, particularly in transmural infarction. In addition, thrombus in regions of aneurysm formation may be identified (Fig. 57-9). In general, myocardial scar/fibrosis involving more than 50 percent of myocardial wall thickness by cardiac MRI is unlikely to recover contractile function following coronary revascularization.[18]

## Acute Myocardial Infarction/ Myocardial Necrosis

With acute myocardial infarction, there is loss of integrity of myocyte cellular membranes. In addition, large myocardial infarctions may be associated with capillary occlusion and plugging with cellular debris, termed microvascular obstruction. This is more commonly observed in large Q-wave myocardial infarctions. Cardiac MRI may be used to image infarctions resulting in myocardial necrosis and microvascular obstruction. The MRI methods are similar as those described above for assessing myocardial scar/necrosis. In addition, MRI perfusion imaging is performed in order to assess microvascular obstruction.

After acute myocardial infarctions, first-pass perfusion images obtained immediately after bolus administration of the gadolinium contrast agent demonstrate lack of enhancement at the region of microvascular obstruction. This is typically at the "core" of the area of myocardial necrosis. Lack of enhancement of this infarct core, or microvascular obstruction, is related to poor patient prognosis, as documented by Wu and coworkers, with an increased incidence of congestive heart failure, recurrent infarction, and chest pain.[19]

The delayed-enhancement MR images in this setting typically show diffuse enhancement of the entire infarct area, or the zone of myocardial necrosis, which may be either subendocardial or transmural. The mechanism of enhancement is likely related to an increased volume of distribution of the gadolinium contrast agent due to disruption of cell membranes in the area of myocardial infarction. Areas of stunned myocardium, which have decreased function but intact cell membranes, do not show delayed enhancement on MRI. Cine MR images are obtained in conjunction with the delayed enhancement MR images and show akinesis in areas of myocardial stunning.

Note that areas of acute or chronic infarction may be difficult to distinguish using these methods. Both acute and chronic infarctions show bright areas on delayed enhancement MRI. If the infarction is transmural and chronic, the myocardium will show thinning. However, enhancement of the myocardium on MRI is very nonspecific and requires clinical correlation. Knowledge of the coronary catheterization results may aid in interpretation of the MRI results. For example, patients with large acute myocardial infarctions often have microvascular obstruction with delayed first-pass enhancement on MRI. However, a patient with a chronic infarction and total occlusion of a coronary territory may also show delayed first-pass enhancement in that coronary distribution. Both types of patients will have delayed enhancement on MR images obtained 10 to 20 min after injection of the gadolinium contrast agent.

If the clinical setting is ambiguous, T2-weighted images may be obtained for increased specificity for acute versus chronic infarction. T2-weighted MR images depict the distribution of edema in acute myocardial infarction, which is not present in scar/fibrosis.

## Myocardial Ischemia

Myocardial ischemia induced by exercise or pharmacologic stress may be evaluated using MRI.[20] The principles of these stress tests are identical to those used in nuclear medicine techniques except that exercise-induced ischemia is difficult to achieve in the MRI environment. MRI stress testing is currently done at relatively few institutions, although the results have rivaled those of nuclear pharmacologic stress testing. Advantages of MRI in this setting include a higher spatial resolution than can be obtained with nuclear methods (2 vs 6 mm, respectively); lack of false positives due to breast or soft tissue attenuation as seen with nuclear methods, and direct identification of myocardial scar/fibrosis with MRI. Compared to dobutamine stress echocardiography, MRI may be an alternative in patients with poor acoustic windows and indeterminate echocardiographic results.

MRI stress testing has been performed with dobutamine, dipyridamole, or adenosine as a pharmacologic stress agent. Dobutamine causes increased contractility of the myocardium. Ischemia-induced wall motion abnormalities at peak stress are readily visualized on cine MR images. In addition, chronic ischemic or hibernating myocardium will demonstrate increased contractility with dobutamine, resulting in improved wall motion in the affected areas compared to rest imaging. Dobutamine MRI is performed by performing MR cine imaging at increasing levels of dobutamine infusion, typically from 5 to 50 μg/kg/min. MRI must be performed rapidly in near real time and the examining physician must detect wall motion abnormalities, at which time the test is terminated.

Dipyridamole and adenosine are direct vasodilators. These agents result in augmented blood flow in normal coronary arteries, while stenotic vessels will show lack of increased blood flow. At our institution, we primarily administer adenosine to induce vasodilatatory stress, because of its short half-life and ease of use. For MRI stress perfusion imaging, we infuse adenosine intravenously at a rate of 140 μg/kg/min. At 2 to 3 min into the adenosine infusion, we inject a half dose of an MRI contrast agent through a separate intravenous line at a rate of 5 $cm^3/s$ and follow the contrast bolus with 3 to 6 short-axis fast GRE MR images, imaging the left ventricle as the contrast agent passes through the cardiac chambers and the myocardium with a temporal resolution of 1 to 2 heart beats. After about 10 min, we inject a second half dose bolus of contrast agent and apply the same short-axis GRE MR images to image the first pass of the contrast bolus at rest.

Transient ischemia can be detected as an area of myocardial hypoperfusion ("perfusion defect") during adenosine stress in a coronary artery distribution, which is reversible during rest (Fig. 57-10A–C). In a recent multicenter trial, the accuracy of adenosine stress perfusion MRI has been shown to be equal to or better than SPECT.[21] It also has been shown that the combination of stress perfusion MRI and *MDE MRI* improves the specificity of this test.[22] Stress first-pass perfusion MRI has also been used successfully in the emergency room setting in patients with chest pain and negative cardiac enzymes in order to triage and risk-stratify these patients, because the negative predictive value of a normal comprehensive stress MRI exam is high.[23,24]

## Coronary Artery Imaging

Direct visualization of the coronary artery wall and lumen is crucial for the diagnosis of coronary artery arteriosclerosis.

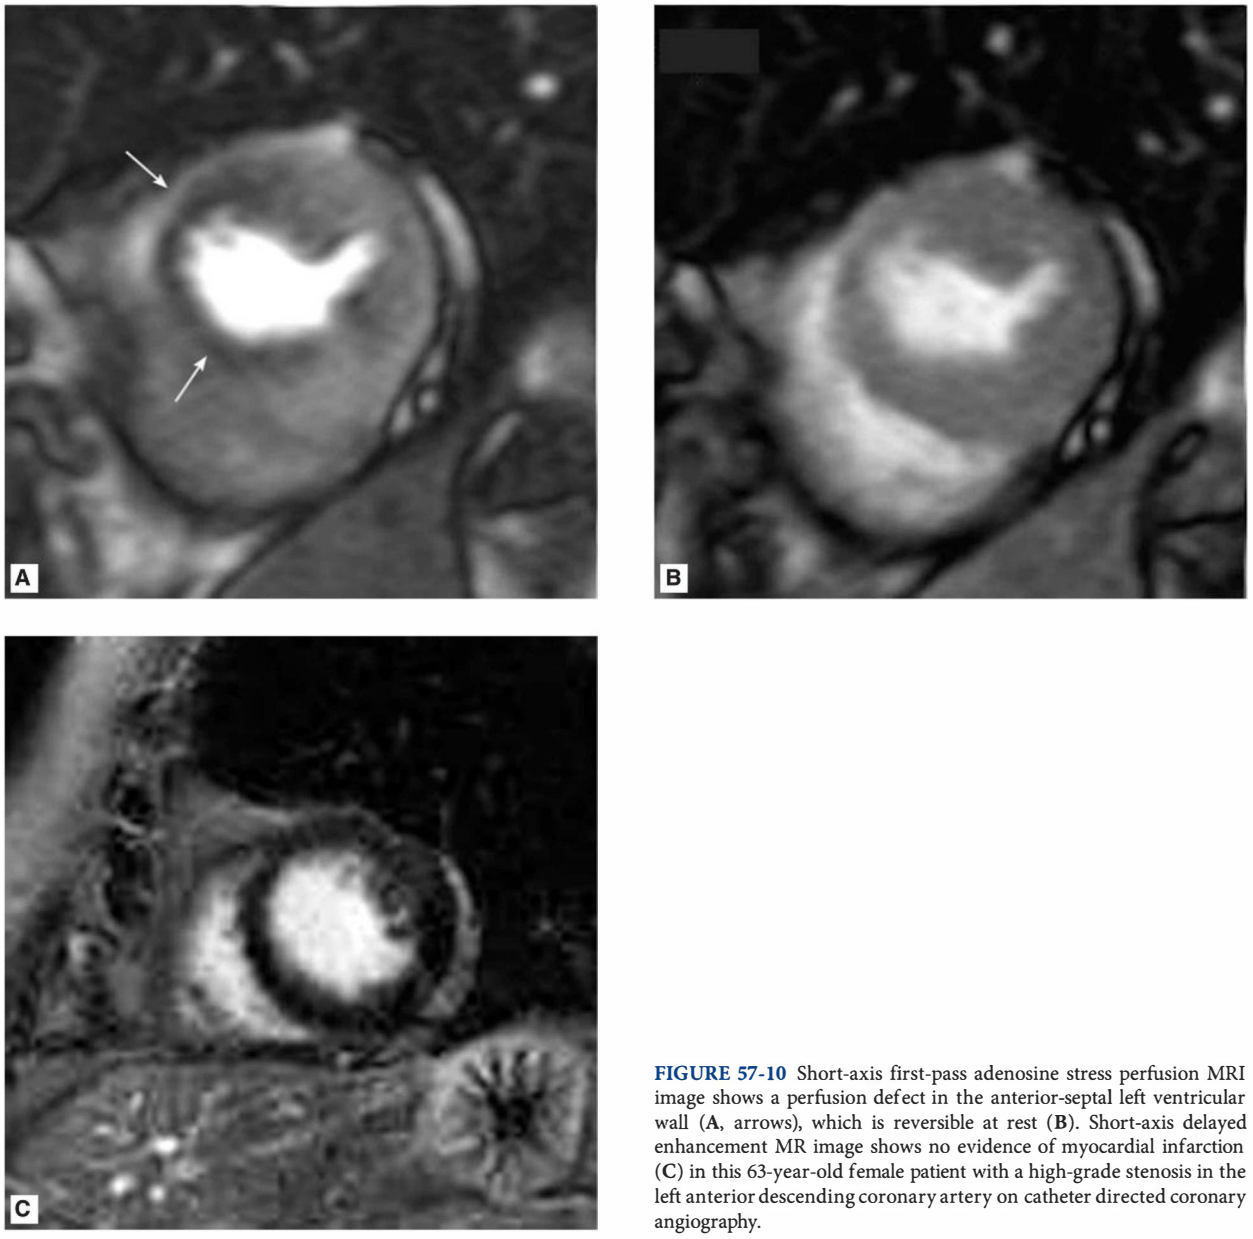

**FIGURE 57-10** Short-axis first-pass adenosine stress perfusion MRI image shows a perfusion defect in the anterior-septal left ventricular wall (**A**, arrows), which is reversible at rest (**B**). Short-axis delayed enhancement MR image shows no evidence of myocardial infarction (**C**) in this 63-year-old female patient with a high-grade stenosis in the left anterior descending coronary artery on catheter directed coronary angiography.

It is also necessary to determine the degree of luminal stenosis in evaluating a patient and planning treatment by coronary artery angioplasty, stenting, or bypass surgery. Conventional coronary digital subtraction angiography (DSA) remains the "gold standard" to visualize the coronary artery lumen and the degree of stenosis. However, this procedure is not risk-free, owing to its invasive nature. Furthermore, the cost of conventional angiography far exceeds the cost of coronary artery MRI.

In the last decade, MRI coronary angiography has made significant advances and demonstrated its feasibility.[25,26] At present, pilot studies with healthy volunteers can depict nearly the full length of the left circumflex, left anterior descending, and right coronary arterial lumen and wall (Figs. 57-11 and 57-12). The current spatial resolution ranges between $0.7 \times 0.7$ and $0.9 \times 0.9$ mm$^2$. However, in vivo coronary artery imaging can be challenging because of artifacts caused by complex cardiac, respiratory, and patient movement. For patients in a normal sinus rhythm, cardiac motion can be reliably suppressed by electrocardiographic gating. Respiratory gating can be challenging owing to more unpredictable diaphragmatic motion.

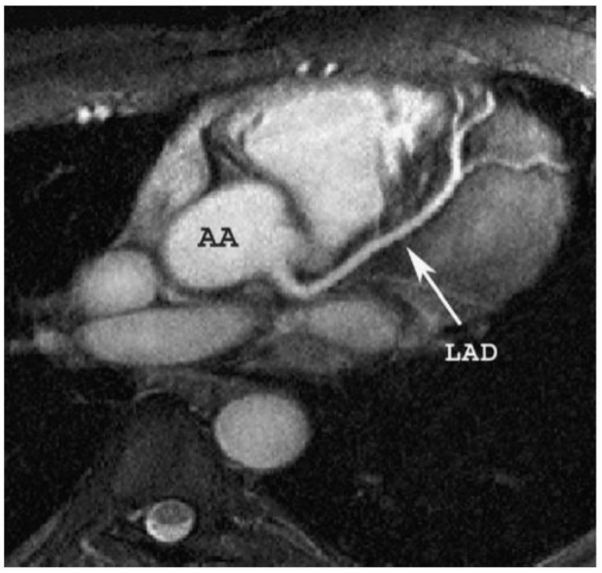

**FIGURE 57-11** Navigator free-breathing (3 T) MRI of the left anterior descending (LAD) coronary artery in a healthy volunteer. AA, ascending aorta. (Reproduced with permission from Stuber M, Botnar RM, Fischer SE, et al. Preliminary report on in vivo coronary MRA at 3 Tesla in humans. *Magn Reson Med* 2002;48(3):425–429.)

Several strategies have been pursued to minimize these factors. At present, three-dimensional GRE coronary MR angiography (MRA) techniques are the state of the art. Most recently, stronger field magnets (up to 3 T compared to most of the current 1.5-T MRI scanners) have become available commercially. These are likely to be applied to the challenging area of coronary MRI because they offer an improved tissue signals.[27]

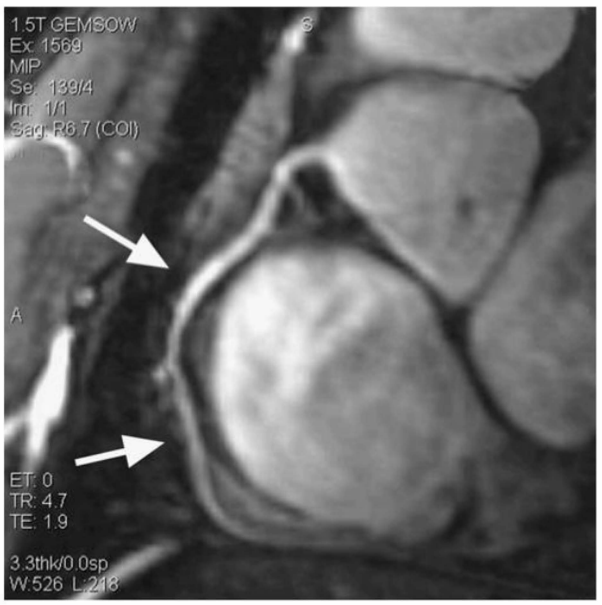

**FIGURE 57-12** A high-resolution MRI of the right coronary artery with intravenous contrast (arrows). (Reproduced with permission from Stuber M, Botnar RM, Fischer SE, et al. Preliminary report on in vivo coronary MRA at 3 Tesla in humans. *Magn Reson Med* 2002;48(3):425–429.)

Coronary artery calcifications may cause signal void and can mimic stenosis, although these effects appear to be less severe than with coronary CT angiography. Coronary artery bypass grafts and stents are difficult to evaluate because of artifacts from surgical clips, sternal wires, and stent material. Tantalum stents have more favorable MRI characteristics than stents made of stainless steel.

At present, the most common clinical indication for coronary MRA is the evaluation of aberrant coronary arteries. Knowledge of coronary anomalies is useful in planning cardiac surgery and in the prevention of sudden cardiac death (Fig. 57-13A and B). Coronary MRA has been proven to be equal or even superior to DSA in the analysis of congenital vascular anomalies and has become the gold standard for their evaluation. There may be an additional application in patients with Kawasaki disease in order to avoid repeat catheterization. Coronary MRA can reliably detect coronary aneurysms and is the preferred method for noninvasive follow-up of such patients (Fig. 57-14).[28]

## Magnetic Resonance Imaging of Cardiac Masses

MRI is the examination of choice to confidently exclude cardiac masses in cases where echocardiography is equivocal. MRI has superior tissue characterization capabilities to better define cardiac masses compared to cardiac CT imaging and does not require irradiation.

The most common cardiac mass is a ventricular or atrial thrombus. Acute thrombi may appear mass-like, whereas chronic thrombi conform to the contour of the cardiac cavity and may be more difficult to detect. The vascular supply of most thrombi is poor, so that the majority do not enhance after the administration of gadolinium contrast (Fig. 57-15).

Metastases to the heart and pericardium are 20 to 40 times more common than primary tumors and are generally associated with a poor prognosis.[29] Noncardiac tumors may spread to the heart or myocardium via hematogenous dissemination, lymphatic spread, direct local invasion, or via the transvenous route (Fig. 57-16). Tumors that most likely metastasize to the heart are malignancies of the lung and breast, melanoma, and lymphoma. Melanoma is the most common tumor metastasizing hematogenously to the heart. Melanoma metastases to the myocardium may show the characteristic MRI appearance of bright lesions on T1 and T2 images, which enhance with intravenous contrast. The brightness is attributed to paramagnetic metals bound to melanin.

MRI can depict direct invasion of the heart by bronchogenic or esophageal carcinomas, lymphoma, invasive thymoma, or mesothelioma. Obliteration of the pericardial fat plane by the tumor on MR images is a sign of involvement of the myocardium.

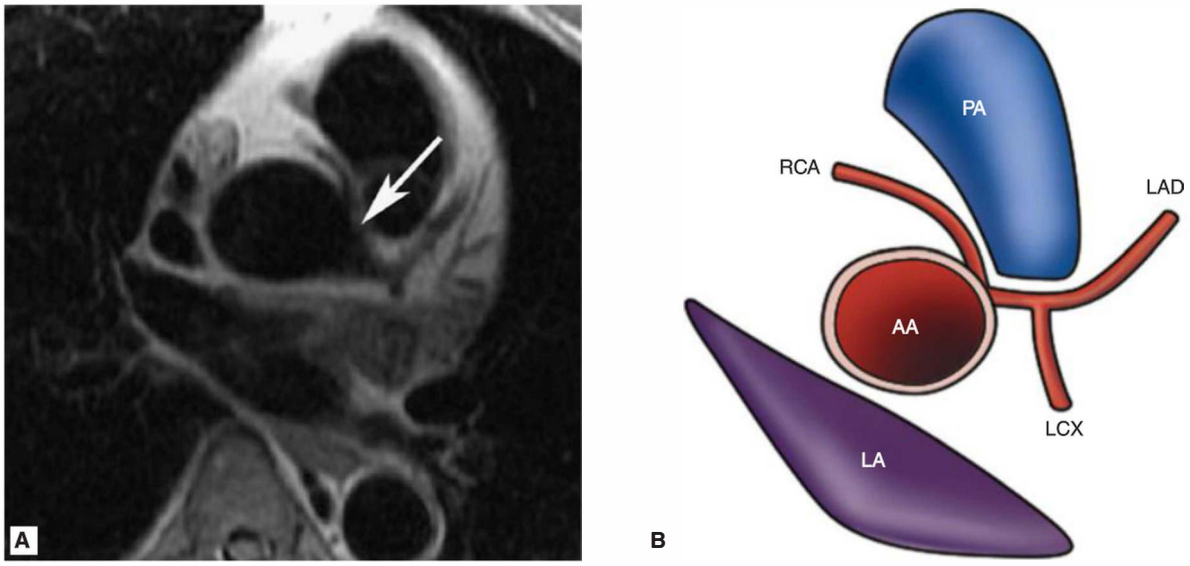

**FIGURE 57-13** A black-blood axial MRI demonstrating anomalous origin of the right coronary artery (arrow). The anomalous RCA travels between the pulmonary artery and the aortic root. This anomaly is potentially lethal and requires surgical reimplantation of the RCA (**A**). The anatomy is illustrated in the diagram (**B**). RCA, right coronary artery; LAD, left anterior descending coronary artery; AA, aortic artery; LCX, left circumflex coronary artery; PA, pulmonary artery; LA, left atrium.

Hepatocellular carcinoma, renal cell carcinoma, and adrenal tumors are the most likely to spread via direct extension into the inferior vena cava and the heart. Coronal and sagittal MRI is useful to depict this process. Gadolinium-enhanced MRI can further distinguish between tumor extension versus thrombus in the inferior vena cava and right atrium. In contrast to echocardiography, MRI can detect not only intracardiac but also extracardial masses, as found in the lungs.

Primary tumors of the heart are rare and most often benign. In general, most benign tumors are intralumenal

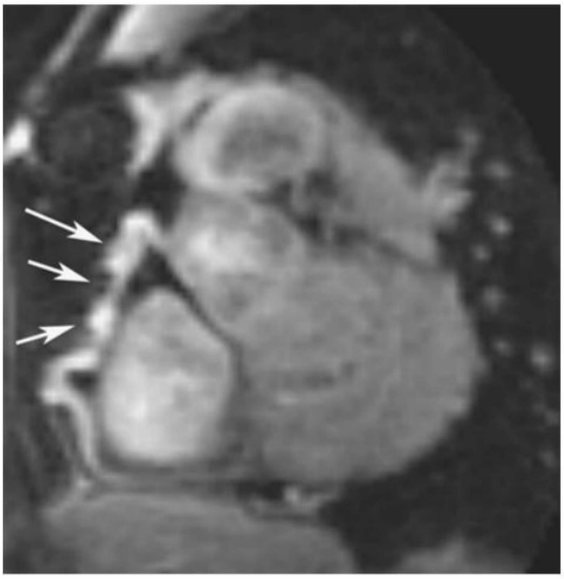

**FIGURE 57-14** This 16-year-old male presented with acute chest pain. Coronary MR angiography demonstrates aneurysmal dilatation and intermittent narrowing of the proximal right coronary artery (arrows) compatible with Kawasaki's disease.

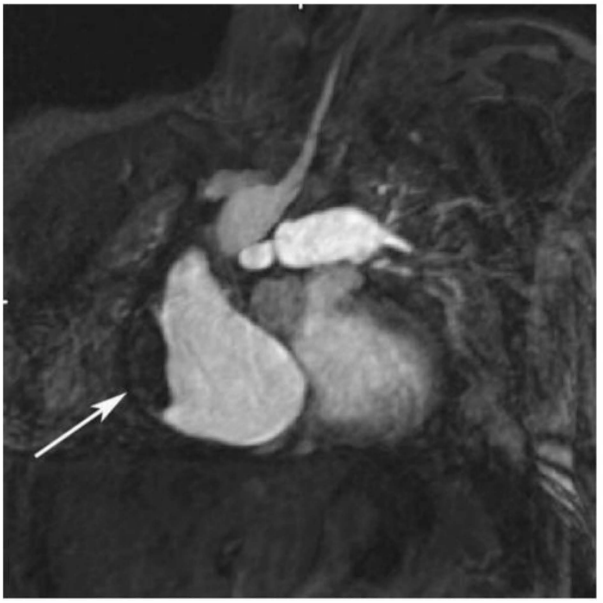

**FIGURE 57-15** This gadolinium-enhanced coronal oblique image demonstrates a nonenhancing mass in a patulous right atrium compatible with thrombus (arrow).

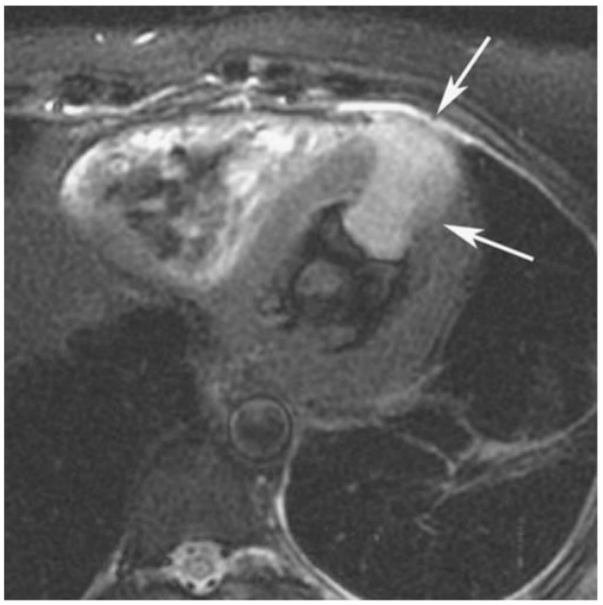

**FIGURE 57-16** Metastatic leiomyosarcoma involving the left ventricle. This axial cardiac black-blood MRI with fat suppression demonstrates a high-signal-intensity mass in the apex of the left ventricle (arrows). The tumor was resected surgically.

and are attached by a narrow stalk. Most malignant primary and secondary malignancies are broad-based or invade the myocardium. Most tumors enhance with intravenous contrast.

The benign cardiac myxoma is the most common primary cardiac tumor, representing 50 percent of all primary cardiac neoplasms.[30] It is usually located in the left atrium in the region of the fossa ovalis of the intra-atrial septum (Fig. 57-17A and B). The MRI appearance of cardiac myxomas varies depending of the amount of myxomatous and fibrous tissue. In general, myxomas will show increased T2 signals because of the myxomatous components of the tumor.

The second most common benign cardiac tumor is fibroma. It commonly arises from the interventricular septum, right ventricle, or atria and can be quite large. Because of their homogeneous fibrous nature, these tumors are hypointense on T2-weighted images and isointense on T1-weighted images, usually showing little or no contrast enhancement. Calcifications may occur; these are not well appreciated with MRI and are better evaluated by CT.

Cardiac lipomas usually occur in the pericardial space and less frequently in a cardiac chamber. Owing to their fat content, they have a homogeneous, bright T1 signal and usually do not enhance with intravenous gadolinium-based contrast agents. MRI can specifically identify fat because of the chains of fatty acid present; it is the method of choice to diagnose this tumor (Figs. 57-18A and B, and 57-19A and B). Paragangliomas are commonly located in the left atrium, coronary arteries, or aortic root. Characteristically, they show marked enhancement with gadolinium. Nuclear medicine imaging with iodine 123 or iodine-131 metaiodobenzylguanidine (MIBG) is also widely used to localize and diagnose extra-adrenal paragangliomas.[31]

Primary malignant cardiac tumors are extremely rare.[32] Angiosarcoma is the most common neoplasm of this kind, usually presenting as a bulky, infiltrative, right-sided cardiac mass, the right atrium being the most frequent site of origin (Fig. 57-20). Pericardial involvement is common,

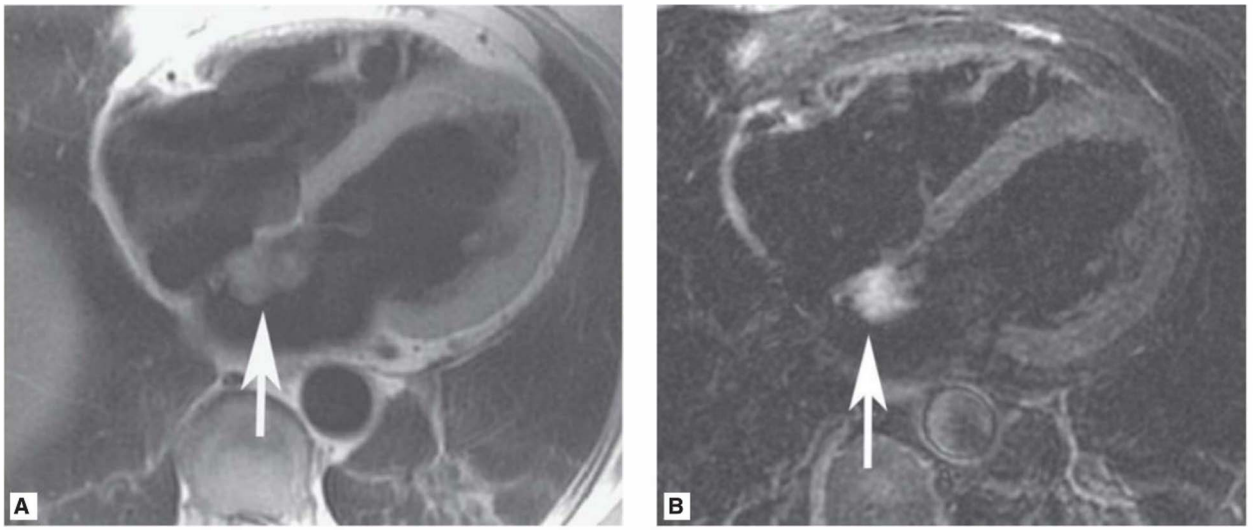

**FIGURE 57-17** Cardiac myxoma. This T1-weighted axial black-blood MRI of the heart shows a lobulated mass (arrow) in the left atrium arising from the atrial septum (**A**); it has high signal intensity on the fat-suppressed T2-weighted axial black-blood MRI due to the myxomatous component in this tumor (**B**).

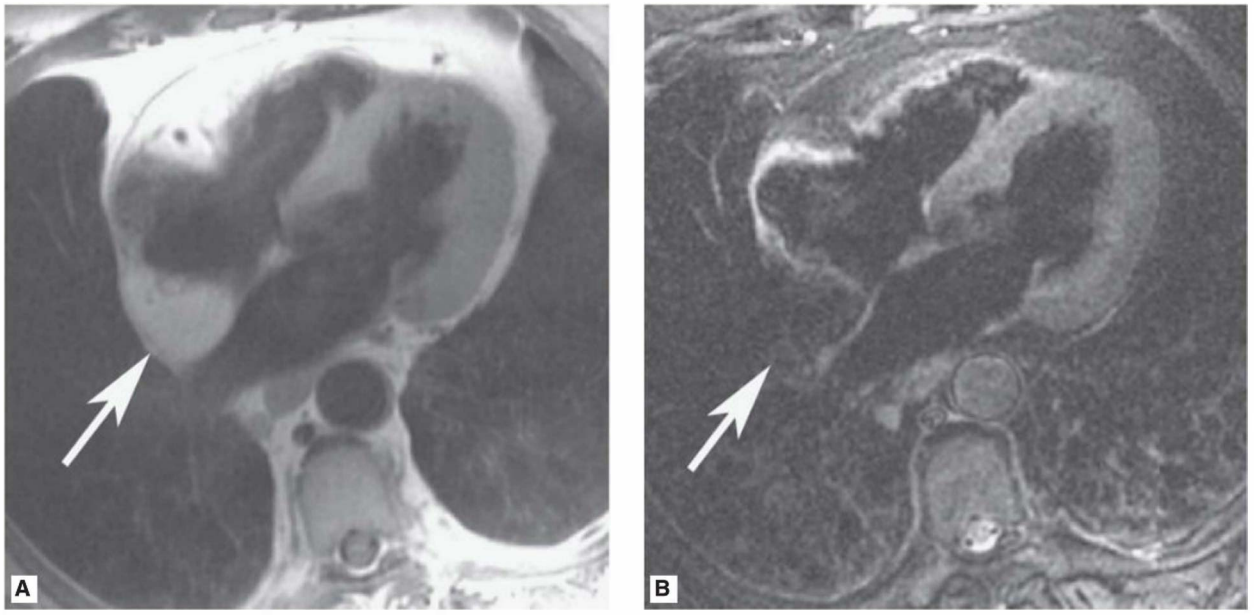

**FIGURE 57-18** This T1-weighted axial black-blood image without (**A**) and with (**B**) fat suppression demonstrates a paracardial lipoma (arrows). In B, the fat signal was selectively suppressed in a manner that is chemically specific for lipid.

and patients may present with a hemorrhagic pericardial effusion. Metastatic disease to bone, liver, adrenal gland, and spleen is often present at the time of diagnosis. Owing to their high vascularity, angiosarcomas enhance with gadolinium. Depending on the degree of tumor necrosis, MRI will show high signals in these areas on T2-weighted images. Rhabdomyosarcomas arise from cardiac striated muscle; their signal characteristics are similar to those of myocardium and they enhance after gadolinium administration. Leiomyosarcomas and fibrosarcomas are

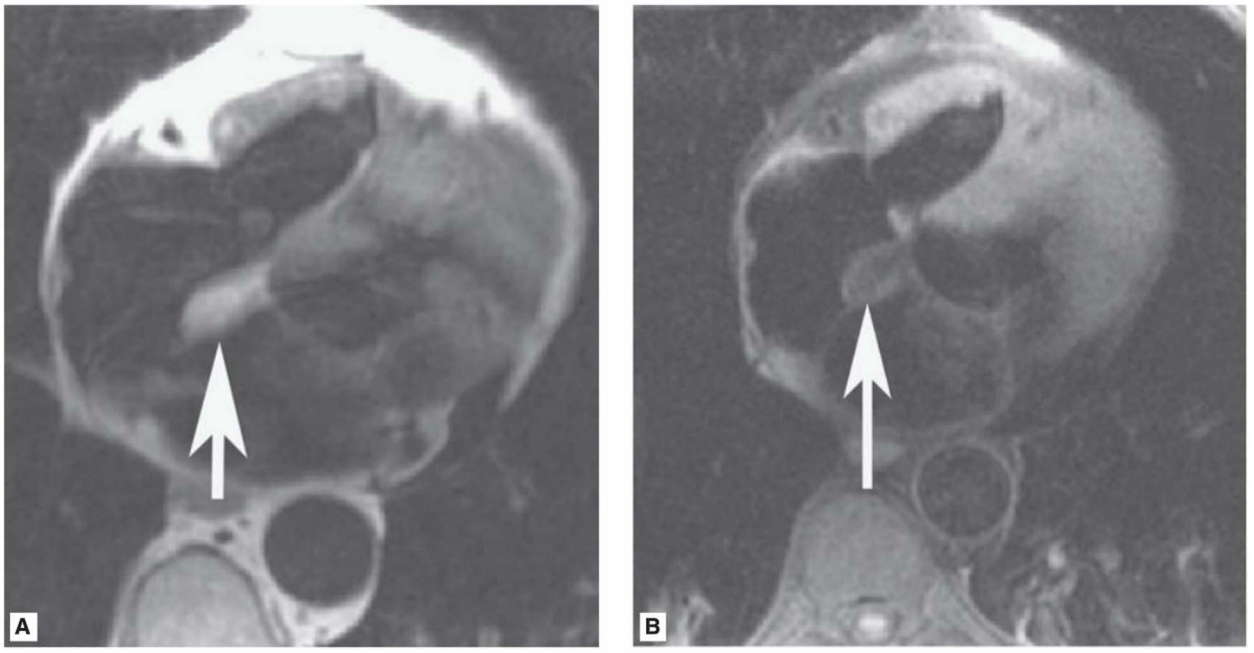

**FIGURE 57-19** Lipomatous hypertrophy of the atrial septum. This axial T1-weighted black-blood MRI demonstrates bright signal within a prominent atrial septum (**A**), which drops in signal with fat suppression (**B**).

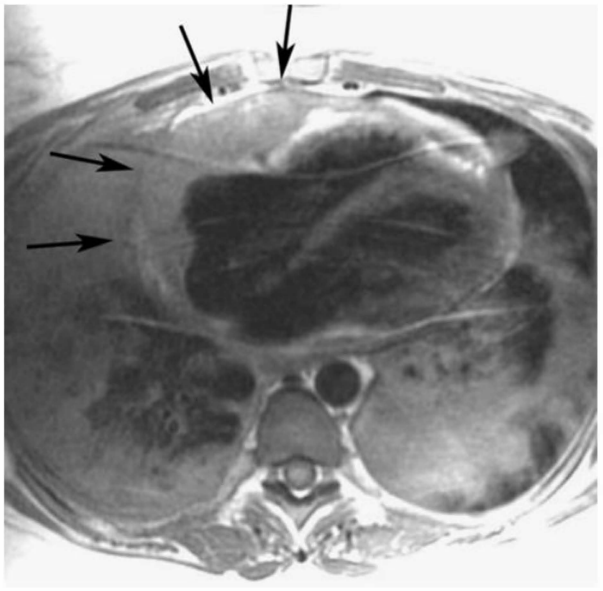

**FIGURE 57-20** Cardiac angiosarcoma. This T1-weighted axial black-blood MRI demonstrates an ill-defined mass (arrows) involving the right atrial and right ventricular wall (A), which avidly enhances with intravenous gadolinium. Note the pulmonary edema in both lower lungs.

exceedingly rare cardiac malignancies with variable signal characteristics and contrast enhancement.

## Pericardial Disease

The pericardium is a double-walled sac, of which the outer wall is fibrous. Beneath this is an internal sac called the serous pericardium, which consists of outer (parietal) and inner (visceral) layers separated by a potential space, the pericardial cavity. Echocardiography is usually the initial examination of choice to evaluate pericardial disease. MRI is complementary and more definitive in the evaluation of constrictive pericarditis, pericardial thickening, or loculated pericardial effusion.

The normal pericardium appears as a low-signal band around the heart usually measuring 1 to 2 mm in thickness; it is outlined by the high signal intensity of mediastinal and epicardial fat. The actual pericardium is thinner and measures about 0.4 to 1.0 mm. This discrepancy between MRI and pathologic measurements is likely due to a combination of chemical shift artifact (caused at fat–fluid interfaces), motion artifact, volume averaging, and the inclusion of small amounts of pericardial fluid in MRI measurements.[33] Small amounts of pericardial fluid also accumulate in the superior pericardial recess, a normal structure between the aortic root and main pulmonary artery, which should not be confused with a mass or focal aortic dissection.

Multiple pathologies can cause pericardial effusions. Pericardial fluid in excess of 50 mL is considered abnormal. Pericardial effusions are usually easily detected with ultrasound. However, loculated pericardial fluid or a limited acoustic window (e.g., in patients with chronic obstructive pulmonary disease) can make evaluation with ultrasound difficult. Simple effusions demonstrate low signal intensity on proton density–weighted spin-echo sequences or double-inversion sequences and high signal intensity on T2-weighted spin-echo, fast spin-echo, and steady state free precession (SSFP) as well as fast cine sequences. However, the movement of pericardial fluid during the cardiac cycle can result in signal void, especially on proton density–weighted and T2-weighted sequences. Hemorrhagic, proteinaceous, or exudative pericardial effusions often show increased signal intensity on T1-weighted images. Blood products of varying age within the pericardial space demonstrate variable T1 and T2 signals. Contrast enhancement with gadolinium may be seen in pericarditis or neoplastic effusions.

MRI findings of pericarditis include pericardial thickening of 4 mm or more and an associated simple or complex effusion. MRI is particularly helpful in diagnosing constrictive pericarditis; this is a common indication for MRI of the pericardium at our institution. The diagnostic hallmark of constrictive pericarditis in the correct clinical setting is pericardial thickening with or without calcifications (Fig. 57-21). Before antibiotic treatment was available, tuberculosis was the most common cause of constrictive pericarditis, often associated with large, extensive calcifications. Today, the most common cause of constrictive pericarditis is idiopathic (49 percent), followed by iatrogenic causes such as previous pericardiotomy (30 percent) and irradiation (11 percent).[34] Less common etiologies include viral pericarditis, connective tissue disease, neoplasm, and uremia. Gross calcifications are present in only 28 percent of cases of constriction. CT is more sensitive than MRI in detecting calcifications. However, owing to superior soft tissue contrast, MRI is superior in the distinction of pericardial thickening from

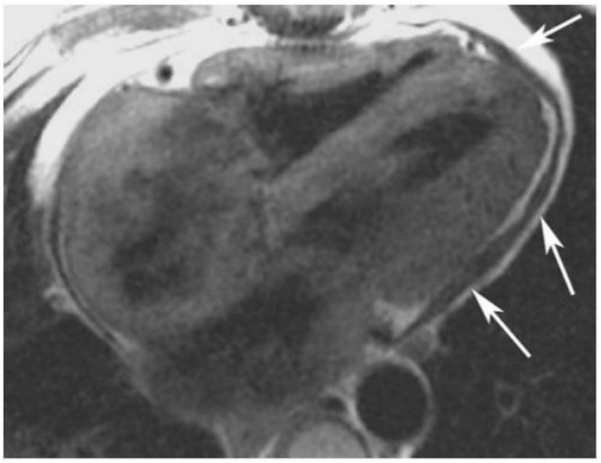

**FIGURE 57-21** Constrictive pericarditis. A T1-weighted axial black-blood MRI of the heart shows moderate thickening of the pericardium (arrows).

pericardial effusion. In a series of 29 patients with clinical symptoms, pericardial thickening determined by MRI was associated with constrictive pericarditis with a sensitivity of 93 percent.[35] However, constrictive pericarditis can be seen without evidence of pericardial thickening. Therefore, clinical history and additional findings (e.g., tubular ventricles, enlarged atria, focal contour deformities of the ventricles, enlarged inferior vena cava, ascites, and pleural effusions) are helpful.[36] Also, postoperative pericardial adhesions can be seen in the setting of constrictive pericarditis.

Pericardial cysts derive from embryonic pericardium, which is pinched off during development. The most common location is the right anterior costophrenic angle. Pericardial cysts have a thin, nonenhancing rim and are indistinguishable from bronchogenic cysts by MRI. If pericardial cysts contain simple fluid, they are dark on T1-weighted sequences and bright on T2-weighted images. If they contain proteinaceous fluid or blood products, they may have a bright signal on T1-weighted images.

Rarely, complete or partial absence of the pericardium occurs, and these conditions can be diagnosed by MRI. However, portions of the pericardium overlying the left lateral ventricle and right atrium may not normally be visualized. Partial absence of the pericardium can be challenging in these cases.

Metastatic pericardial involvement is far more common than primary pericardial malignancies and can be imaged with cardiac MRI.

## Magnetic Resonance Imaging of Congenital Heart Disease

Cardiac MRI complements echocardiography in the evaluation of congenital heart disease and provides explicit depiction of the morphology of the chambers and great vessels. Often MRI makes invasive angiocardiography in pediatric and adult patients unnecessary and decreases the morbidity in the diagnostic workup of these patients.

Dedicated imaging coils for infants for higher signal-to-noise acquisitions allow thinner slice selection and smaller fields of view for higher resolution. This improves image quality and the confidence in diagnosis of congenital heart disease. Single-breath-hold MRI is obtained in ventilated patients by suspending respiration for short periods.

For the evaluation of aortic coarctation, the oblique sagittal plane is most useful in defining the location and anatomy of the isthmus in relation to the aortic arch arteries (Fig. 57-22). Most frequently, gadolinium-enhanced three-dimensional MRA techniques are used to depict collateral circulation and vascular variants, such as a right aberrant subclavian artery. After surgical treatment, MRI is routinely used for postoperative follow-up. Other great vessel variants, such as double aortic arch, pulmonary sling, or transposition, are easily depicted with MRI (Fig. 57-23).

MRI of a patent ductus arteriosus can be challenging due to the generally small size, length, and orientation of

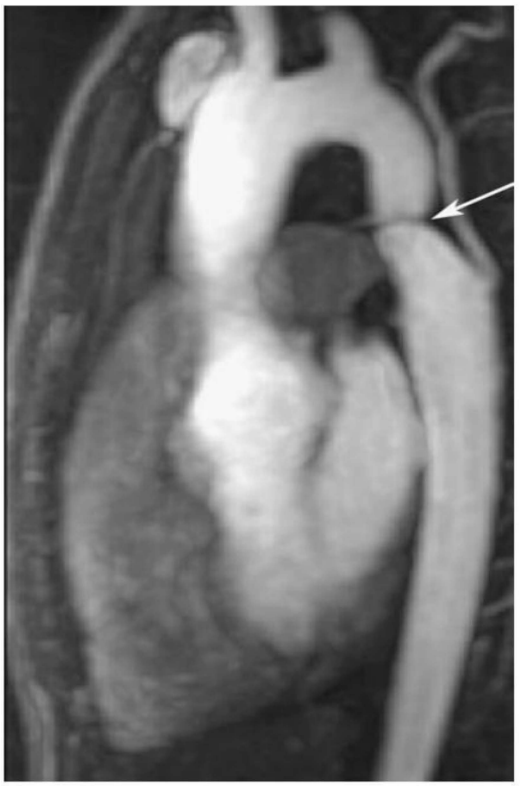

**FIGURE 57-22** A double-oblique MR angiogram of the aortic arch with intravenous gadolinium shows an aortic coarctation of the distal arch (arrow) with mild poststenotic dilatation of the descending thoracic aorta.

**FIGURE 57-23** Transposition of the great arteries. A multi-planar reconstructed gadolinium-enhanced MRI of the heart shows an anomalous pulmonary artery arising from the left ventricle (black arrow) and an anomalous ascending aorta arising from the right ventricle (white arrow).

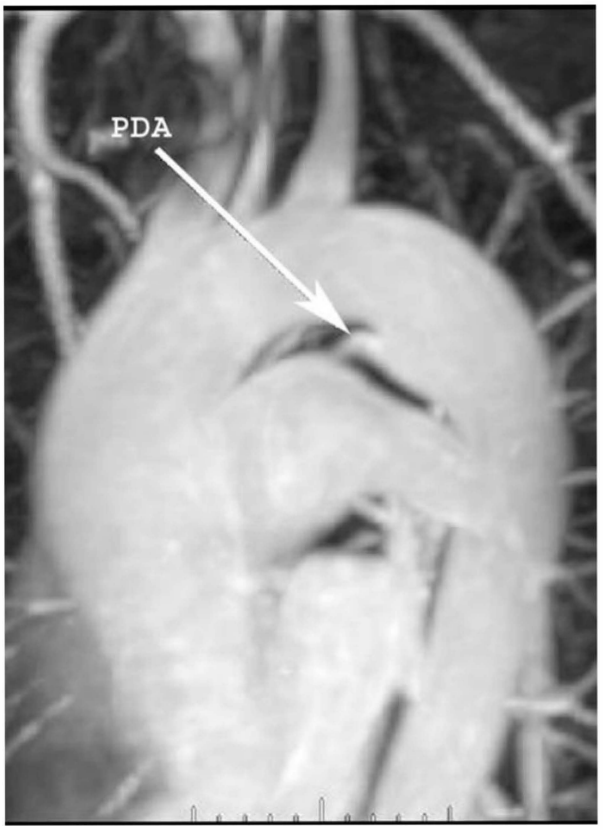

**FIGURE 57-24** Patent ductus arteriosus (PDA). A double-oblique MRI of the aortic arch with intravenous gadolinium shows a patent vascular connection (arrow) between the main pulmonary artery and distal aortic arch.

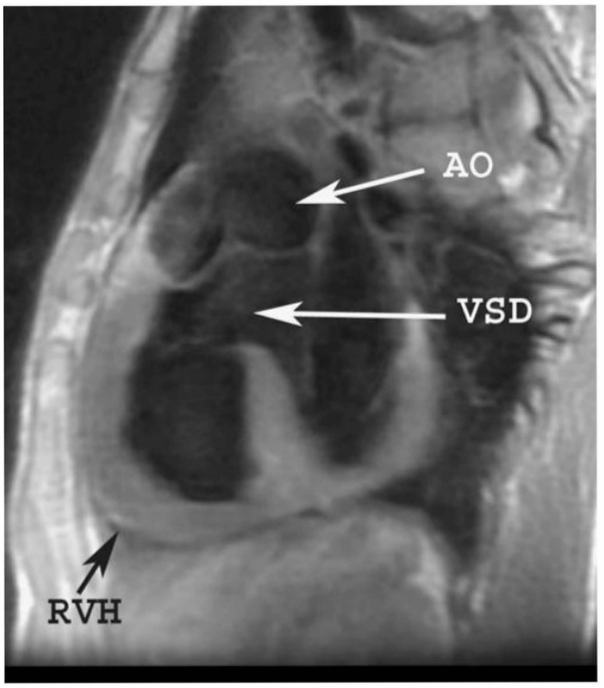

**FIGURE 57-25** Tetralogy of Fallot. A black-blood MRI of the heart demonstrates the key features of tetralogy of Fallot: a large ventricular septal defect (VSD), high-riding aorta (AO), and right ventricular hypertrophy (RVH) due to pulmonary artery stenosis.

the duct and limited MRI resolution (Fig. 57-24). Therefore optimized coils, software, and patient sedation, which are especially vital in newborns and infants, are necessary. On coronal imaging, communication between the underside of the distal aortic arch and the superior aspect of the origin of the left pulmonary artery is often demonstrated. Finally, flow-sensitive imaging (phase contrast-MRI) can further quantify the amount of shunting.

As in the evaluation of cardiac valves, the anatomy and severity of intracardiac shunts with depiction of changes in secondary chamber morphology (e.g., hypertrophy or dilatation) can also be obtained with MRI. Axial or left anterior oblique projections are useful for evaluating the intra-atrial septum. Axial MRI has a 97 percent sensitivity and 90 percent specificity for detecting atrial septal defects.[37] Often the atrial septum is infiltrated with fat, which produces good contrast in evaluating the signal void due to turbulent flow and the direction of shunt flow with bright-blood cine GRE or FIESTA MRI. Flow-sensitive imaging can further quantify the amount of shunting. Accordingly, membranous and muscular defects of the ventricular septal wall can be depicted with MRI. Muscular VSDs may be difficult to detect with black-blood imaging and may be diagnosed indirectly by signal-void jets of the shunted blood. Careful evaluation of cine images allows distinction between left-to-right, right-to-left, and bidirectional shunts.

MRI is capable of confidently diagnosing the tetralogy of Fallot anomaly (Fig. 57-25). MRI evaluation in these patients includes characterization of the VSD, degree of pulmonary stenosis and aortic insufficiency, as well as depiction of right ventricular morphology. The usually large subaortic VSD is well demonstrated in axial, long-axis, or sagittal views. MRI evaluation of flow dynamics across the VSD is very important to assess for Eisenmenger physiology (right-to-left shunting). Coronal imaging is useful in evaluating the extent of systemic-to-pulmonary artery collaterals and the degree of pulmonary artery stenosis. Sagittal views are helpful in examining the overriding aortic root and degree of aortic regurgitation. Furthermore, MRI is vital for the preoperative planning and postoperative evaluation of surgical shunts. For example, Blalock–Taussig shunts are best evaluated along the long axis of the graft.

In infants with Ebstein's anomaly, imaging is necessary to diagnose the anatomic displacement and malfunction of the tricuspid valve and degree of right-sided cardiac dilatation due to tricuspid valve insufficiency. Postoperative MRI is helpful in evaluating the artificial tricuspid valve as well as chamber morphology. Sometimes MRI imaging of artificial

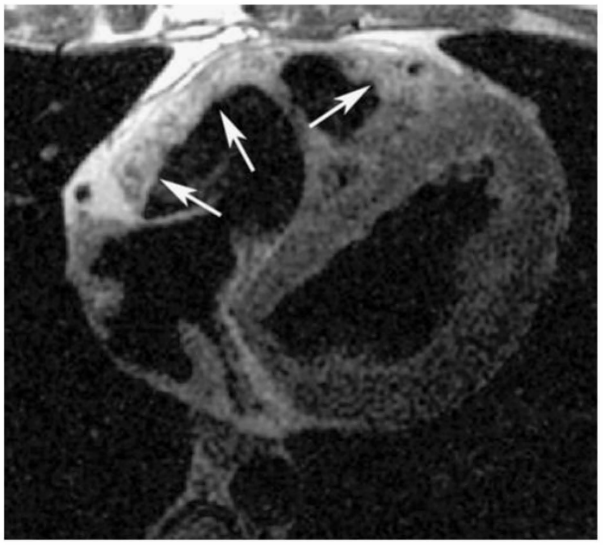

**FIGURE 57-26** Arrhythmogenic right ventricular dysplasia (ARVD). An axial black-blood cardiac MRI demonstrates fat infiltration and focal thinning of the right ventricular wall (arrows), key features of ARVD.

valves in postoperative hearts can be challenging owing to artifacts caused by artificial valves and surgical clips.

## Magnetic Resonance Imaging of Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic right ventricular dysplasia (ARVD) is a rare disease in which tachyarrhythmias are associated with predominantly right-sided cardiomyopathy. These tachyarrhythmias are associated with sudden cardiac death. MRI is the preferred noninvasive imaging test for this condition.

The diagnosis of ARVD is challenging because clinical signs may be absent or ECG changes inconclusive. MRI findings in ARVD include an abnormal right ventricular myocardium with fatty infiltration and regional right ventricular akinesia or dyskinesia (Fig. 57-26).[38] Increased EDV and decreased right ventricular EF may also be observed. The high resolution of turbo spin-echo and double-inversion recovery images permits confident differentiation between epicardial fat, myocardium with trabeculations, and blood pool of the right ventricle. In addition, the high temporal resolution of cine GRE and SSFP images provides adequate temporal resolution of right ventricular wall motion abnormalities and permits calculations of EF and EDV.

## SUMMARY

Because of the high prevalence of cardiovascular disease and its socioeconomic impact, there is a need for improved means of noninvasive diagnosis. Cardiac MRI is a noninvasive technique that allows comprehensive examination of cardiac anatomy, function, and vasculature. With rapidly emerging and improving MRI techniques and the more widespread availability of this modality, cardiac MRI continues to play an important role in patient management.

## CARDIAC MAGNETIC RESONANCE IMAGING BOARD REVIEW QUESTIONS (CHAPTER 57)

1. What is the purpose of delayed enhancement MRI?
   A. Identification of perfusion changes
   B. Delineation of myocardial edema due to contusion
   C. Coronary angiography
   D. Detection of myocardial scar and infarction (nonviable myocardium)
   E. Verification of CT coronary angiography

2. Patients undergoing gadolinium enhanced MRI are at risk for developing NSF if they have:
   A. Liver failure
   B. Heart failure
   C. Pancreatic insufficiency
   D. Renal failure
   E. Prior CVA

3. Valvular regurgitation is best quantified using:
   A. Delayed enhancement MRI
   B. Velocity-encoded MRI
   C. Bright-blood steady state free precession MRI
   D. T2-weighted MRI
   E. First-pass perfusion GRE MRI

4. Which is the best MR plane for imaging the mitral valve?
   A. Axial
   B. Coronal
   C. Double-oblique
   D. Vertical long axis
   E. Short axis

5. What MR sequence can be used to quantify regional wall motion?
   A. Steady-state cine MRI
   B. Tagged MRI
   C. Black-blood MRI
   D. Delayed enhancement MRI
   E. First-pass perfusion GRE MRI

## ANSWERS

1. **Answer: D.** For identifying viable versus nonviable myocardium, an intravenous injection of a gadolinium-based contrast agent is used. On delayed images obtained 10 to 20 min after contrast injection, myocardial scar (nonviable myocardium) retains the gadolinium contrast agent. Washout of the contrast agent occurs in viable myocardium. MR images are optimized so that normal myocardium is "suppressed" on GRE images. Another commonly used term for MRI of this type is MDE or "viability" imaging. This terminology refers to the characteristic 10- to 20-min delay during which the contrast agent in scar and fibrosis distributes differently compared to viable myocardium.
2. **Answer: D.** Patients with renal failure should not receive gadolinium enhanced MRI, because they are risk for developing NSF. NSF is a rare but potentially debilitating or fatal fibrosing condition that has recently been linked to gadolinium-based contrast agents. For patients with chronic renal failure, the FDA has determined that the risk is greatest when the estimated GFR is less than 30 mL/min/1.73 $m^2$.
3. **Answer: B.** Flow-sensitive or velocity-encoded MRI (phase-contrast MRI) is the best way to quantify valvular regurgitation.

4. **Answer: D.** The vertical long-axis view provides the optimal plane for mitral valve evaluation. The axial plane is best for the overall heart view and extracardiac structures. The coronal plane visualizes the left ventricular outflow tract and aortic valve. The double-oblique plane is best for the arch and evaluation of dissection. The short-axis plane is best for assessing wall motion abnormalities.

5. **Answer: B.** A limited number of centers have experience using "tagged" MRI to quantitatively measure regional cardiac wall motion. These methods represent the most precise way for measuring both systolic and diastolic function. The method involves placing a magnetic strip on the myocardium at end diastole. Measuring the distances between the magnetic strips on each image assesses regional wall contractility. The contraction of the heart in any direction (circumferential, radial, and longitudinal) can be accurately measured.

***"There is nothing more difficult to take in hand, more perilous to conduct, nor uncertain in its success, than to take the lead in the introduction of a new order of things. For the innovator has for enemies all of those who have done well under the old, and lukewarm defenders in all of those who may do well under the new."***

—Niccoló Macchiavelli (1469–1527)

Few other medical disciplines have required for their development the degree of daring courage, tenacity, and drive that characterized the efforts of the early pioneers in the field of congenital cardiac surgery. Only a century ago, Theodore Billroth publicly condemned the dream of cardiac surgical intervention by stating that "Any surgeon who wishes to preserve the respect of his colleagues would never attempt to operate on the heart."[1] Over the past six decades, the specialty of pediatric cardiac surgery has evolved from a heroic effort with occasional success into a consolidated, sophisticated specialty with excellent outcomes and, essentially, few limits imposed by pathology or age of the patient.

The history of pediatric heart surgery initially coincided with that of cardiac surgery itself. By far, the majority of early extra- and intracardiac procedures were in fact performed to address various forms of congenital (rather than acquired) heart disease. The adventure of intracardiac repair of congenital malformations, in turn, paved the way for technical advancements that pushed forward the field of adult cardiac surgery.

Each of the chapters in Part III of this book briefly touches on the historical highlights that pertain to specific malformations. In this chapter, the reader is offered a broad overview and key historical references that pertain to the initial evolution of this challenging field (Table 58-1), identifying four successive eras: (1) that of closed extracardiac operations; (2) the era of early closed or semiclosed intracardiac operations; (3) the initial phase of complete intracardiac repair; and (4) a subsequent period marked by the refinement of techniques and the expansion of the field to the correction or palliation of virtually any type of congenital heart disease.

## THE INITIAL PHASE: EARLY EXTRACARDIAC OPERATIONS

At a time when transpleural surgery was at its dawn,[2–4] the repair of simple cardiovascular malformations was a natural initial surgical goal. Although these conditions were anatomically simple, the too often advanced disease state of the patients and the threat of infection in the preantibiotic era often made these initial daring attempts unsuccessful.

John Strider of Boston first performed surgical ligation of a patent ductus arteriosus on March 6, 1937, immediately noticing that the palpable thrill had disappeared after duct interruption.[5] The 22-year-old patient was correctly diagnosed preoperatively with subacute bacterial endocarditis of the ductus arteriosus and succumbed to overwhelming sepsis on the fourth postoperative day. Necropsy disclosed a large endocarditic vegetation, extending from the arterial duct to the level of the pulmonary valve.

Robert Gross (Fig. 58-1) ushered in the field of congenital heart surgery by successfully interrupting a patent ductus arteriosus at Boston Children's Hospital on August 26, 1938.[6] Although he was the chief resident at the time, Gross performed the procedure in a very ill 7-year-old child, apparently against the advice of his chairman William Ladd.[7,8] The procedure took place while the latter was in Europe; the patient was uneventfully discharged in 10 days and survived for many years. Even though primacy of this milestone in cardiothoracic surgery has been debated,[9] this landmark operation demonstrates that intervention on the great vessels within the depth of the chest was possible, with curative outcome.

Following this initial procedure, coarctation of the aorta was addressed. Alfred Blalock was the first to attempt correction of this problem in a canine model, by turning down the distally transected left subclavian artery and anastomosing the vessel to the proximal descending aorta (Blalock-Park procedure).[10] A discouragingly high rate of paraplegia was noted, likely the consequence of relatively long clamp times, which limited flow through a normal-caliber subclavian artery and poor collateral circulation. Clarence Crafoord routinely clamped the aorta during ligation of the arterial duct, and first reported coarctation repair with end-to-end anastomosis in two patients operated at the Karolinska Institute in 1944.[11] Robert Gross described a case of successful coarctation repair shortly thereafter[12] and was first in addressing this malformation with an interposition homograft in 1949.[13]

These initial interventions were indeed curative, but the long-term outlook of children with complex cyanotic congenital heart disease remained dismal until the mid-1940s. Although somewhat approximative, preoperative diagnosis was possible and solely relied on clinical examination, chest radiographs, and electrocardiography; at Johns Hopkins, Helen Taussig was able, with such a rudimentary diagnostic armamentarium, to place children with congenital heart disease into broad diagnostic categories, underscoring the urgency of developing a method for stable palliation of cyanotic patients. The creation of an "artificial ductus arteriosus" was deemed unfeasible by Robert Gross; Taussig then turned to Alfred Blalock, the newly appointed chief of surgery at the Johns Hopkins Hospital (Fig. 58-2). While in Nashville, Dr. Blalock and Vivien Thomas (his laboratory technician) had established an experimental model of pulmonary hypertension that entailed ligation of the left pulmonary artery and anastomosis between the left subclavian and left branch pulmonary arteries.[14] Although they were unable to augment pulmonary pressure because of the low impedance of the pulmonary vascular bed, the technique provided the increase in pulmonary blood flow that cyanotic children so desperately needed. This concept was introduced in the clinical arena on November 29, 1944, when Blalock successfully performed the first systemic-to-pulmonary artery shunt, thus opening the doors to long-term palliation for cyanotic patients (Fig. 58-3).[15,16] Eileen Saxon, then a 16-month-old infant with pulmonary stenosis (Fig. 58-4), had barely reached the operative weight of 4 kg from a nearly prohibitive birth weight of 1.1 kg.

Several modifications of this initial concept have followed and were all eventually rendered obsolete by the introduction of the "modified" Blalock-Taussig shunt.[17] Among these, anastomosis of the descending aorta to the left pulmonary artery (Potts shunt)[18] and of the ascending aorta to the right pulmonary artery (Waterston shunt)[19] was reported in 1946 and 1962, respectively. These approaches often proved to be unreliable in regulating pulmonary blood flow, and were extraordinarily difficult to control at the time of late complete intracardiac repair.

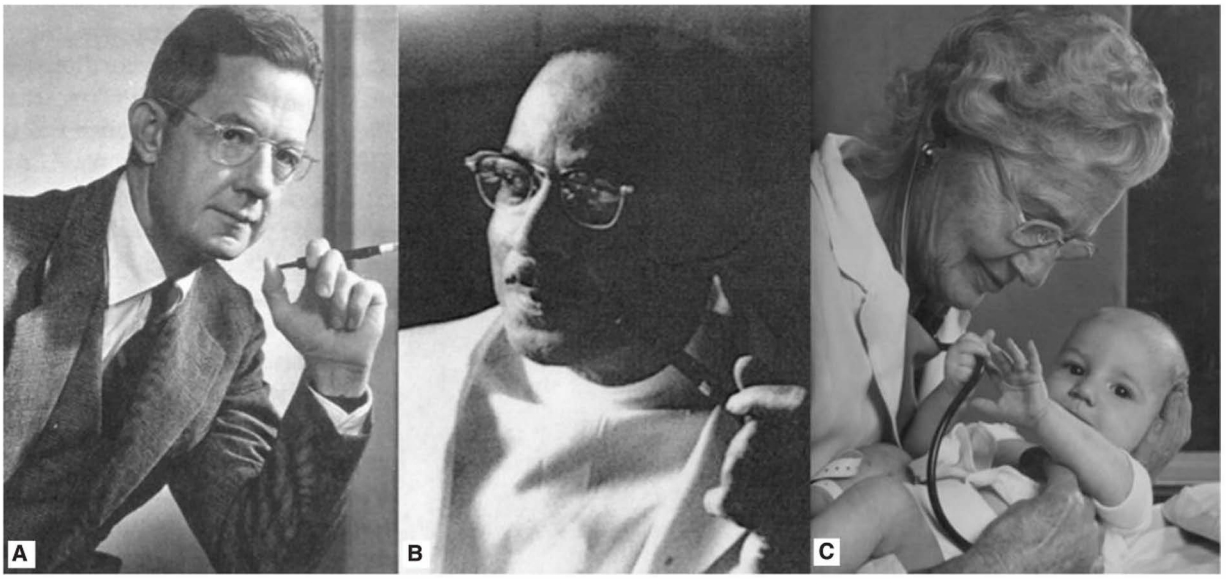

**FIGURE 58-2** Protagonists of the first systemic-to-pulmonary shunt on November 29, 1944, at the Johns Hopkins Hospital. Over the ensuing decades, systemic-to-pulmonary shunts—rather than the initial approach to staged repair of biventricular hearts—became the mainstay of palliation for univentricular heart disease (Fig. 58-5). Extracardiac palliative procedures are now more typically performed as the initial step toward achievement of complete right heart bypass, the so-called Fontan circulation (Fig. 58-6).[20–26]

**FIGURE 58-4** Eileen Saxon, the first infant to undergo a systemic-to-pulmonary shunt for palliation of cyanotic heart disease. Note the left-sided thoracotomy scar. In the first few patients undergoing the procedure, the thoracotomy was performed on the side ipsilateral to the aortic arch. The technique very rapidly evolved to a turndown of the subclavian artery contralateral to the side of the aortic arch, as technically more straightforward. (WP Longmire. *Alfred Blalock. His Life and Times.* Privately published by the author, 1991: 99. With permission.)

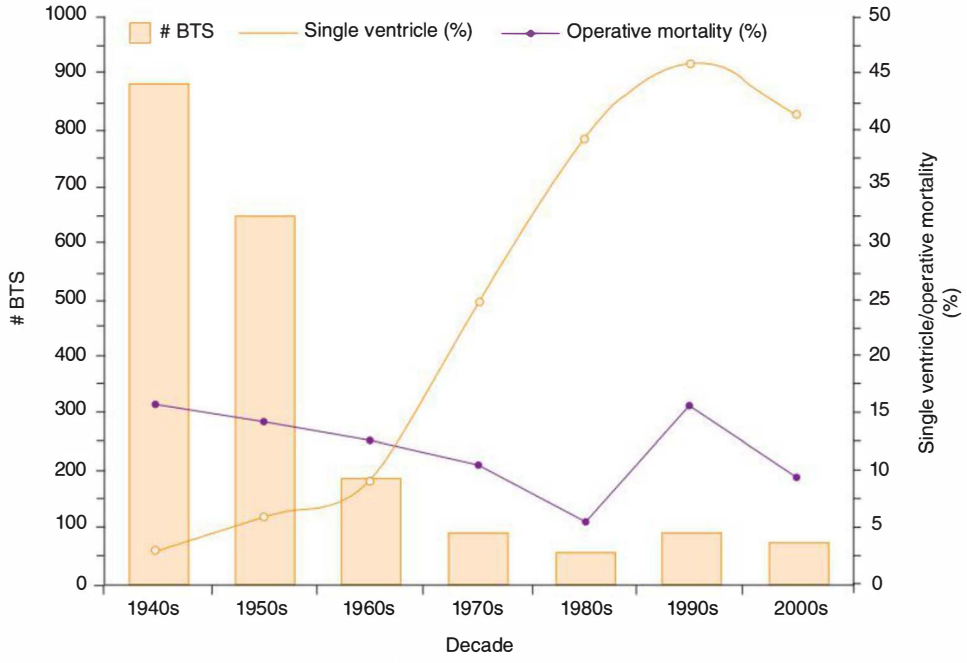

**FIGURE 58-5** Trends in systemic-to-pulmonary shunts: the Johns Hopkins experience with 2029 shunts over six decades (1944–2006). A decrease in the total number of procedures is paralleled by a rise of the percentage of shunts performed as palliation for univentricular heart disease. A reduction in mortality and the subsequent peak in the late 1980s and early 1990s is possibly related to shunts being mainly utilized as part of the initial treatment of hypoplastic left heart syndrome. (Reproduced with permission from Williams JA, Bansal AK, Kim BJ, et al. Two thousand Blalock-Taussig shunts: a six-decade experience. *Ann Thorac Surg*. 2007;84(6):2070-2075.)

Surgical repair of tricuspid atresia. *Thorax* 1971;26:240.) Atriopulmonary connection with (upper panel) and without (lower panel) interposition of a valved homograft.

For children with malformations characterized by left-to-right shunting and pulmonary overcirculation, initial treatment of pulmonary hypertension by pulmonary arterial banding was first introduced by Muller and Dammann in 1952.[27] Although rarely utilized in biventricular hearts, pulmonary arterial banding still has a role in the initial staging of cardiac malformations characterized by univentricular morphology and pulmonary hyperperfusion (Chapter 77).

## EARLY CLOSED OR SEMICLOSED INTRACARDIAC OPERATIONS

The first attempts at closed intracardiac intervention were made to address pulmonic stenosis in cyanotic infants. T. Holmes Sellors of London reported the first successful transventricular pulmonary valvotomy in December 1946.[28] He had originally intended to perform a systemic-to-pulmonary shunt, but the chronic sequelae of tuberculosis made this initial plan unfeasible in his patient with Fallot's tetralogy. This approach was subsequently popularized by Lord Brock at Guy's Hospital and became the standard of care for pulmonic stenosis for much of the following decade. This procedure was later to be largely supplanted by open valvotomy on cardiopulmonary bypass and, eventually, by the much more often utilized percutaneous balloon valvotomy, first introduced in 1982 by Jean Kan at the Johns Hopkins Hospital.[29]

The initial growing success of palliative and closed procedures in prolonging the lives of patients affected by pathologies that would then, without intervention, have been unsurvivable[30] led to the development of several semiclosed procedures to address simple malformations (such as atrial septation defects) or to achieve initial palliation for more complex congenital anomalies.

Although an initial partially successful attempt at closure of an atrial septal defect (ASD) with the external suturing technique was described by Murray in 1948,[31] Robert Gross in 1952 reported the ingenious use of an "atrial well" to close ASDs.[32] The well was constructed by suturing a rubber funnel to the right atrial wall (Fig. 58-7), which made it possible to prevent exsanguination and air embolization. Through the well and under the stable and contained column of blood, the surgeon identified the defect by palpation and repaired it primarily without any direct visualization. Although the technique was by necessity quite rudimentary and imperfect, John Kirklin in 1956 reported a series of 29 patients undergoing successful ASD closure with the atrial well technique and without operative mortality.[33]

The "atrial well" could also be utilized to create an interatrial communication in patients with cyanotic lesions characterized by poor mixing. Atrial septectomy was nevertheless mainly performed in the era of semiclosed techniques with the method introduced by Blalock and Hanlon in 1948.[34] In this method, right-lung isolation was performed by temporarily occluding the right pulmonary artery and veins and by applying an appositely designed clamp (Fig. 58-8) to the groove of Sondergaard. The dorsal and right-lateral portion of the interatrial septum could then be excised and the interatrial groove closed primarily. These difficult operations[35,36] were eventually rendered obsolete by Rashkind's introduction of balloon septostomy in 1966.[37]

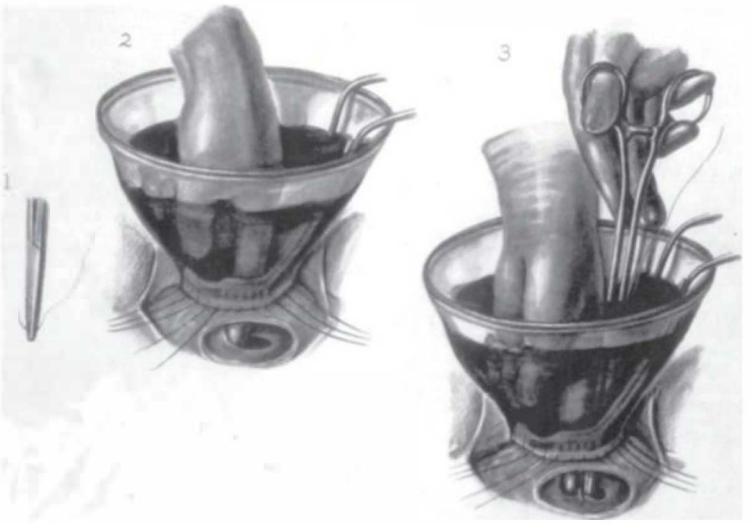

**FIGURE 58-7** The "atrial well" technique for closure of atrial septal defects, introduced by Robert E. Gross in 1952. A rubber cone is anastomosed to the convexity of the right atrium and the defect is palpated by the index finger of the operator under the column of blood (2). An appropriately loaded suture (1) is then utilized to close the defect (3). (From Westaby S. The foundation of cardiac surgery. *Landmarks in Cardiac Surgery.* Oxford, UK: Isis Medical Media Ltd, 1997: 400. With permission.)

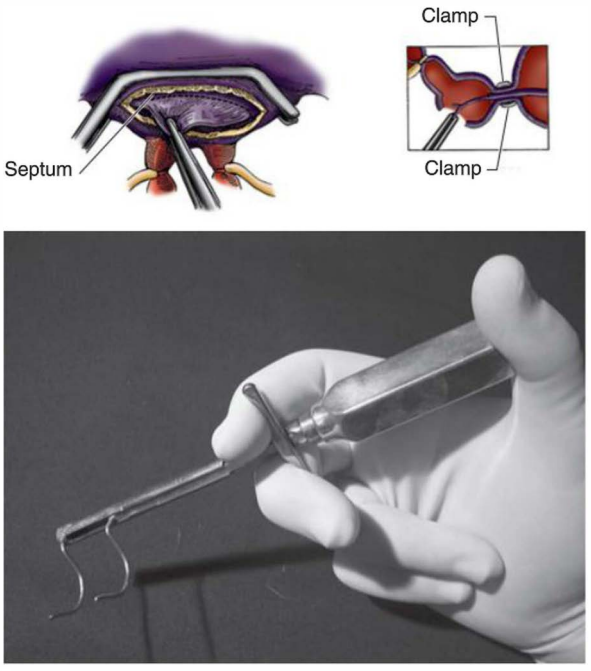

**FIGURE 58-8** Blalock-Hanlon atrial septectomy. ## INITIAL PHASE OF COMPLETE INTRACARDIAC REPAIRS

Closed or semiclosed operations failed to successfully address more complex morphologic problems, for which a true correction under direct vision was considered utopic until the early 1950s. The parallel investigation of hypothermia by the pioneering work of Wilfred Bigelow[38] and the introduction and development of extracorporeal circulation by John Gibbon, and the groups at the University of Minnesota and the Mayo Clinic made true intracardiac surgery a reality.

On September 2, 1952, John Lewis (Fig. 58-9) first achieved closure of an ASD under direct vision in a 5-year-old child at the University of Minnesota.[39,40] The procedure lasted 58 minutes and was preceded by a period of systemic surface cooling of 2 hours and 10 minutes. At a core temperature of 28°C, a right thoracotomy was performed and, during 5 minutes of inflow occlusion, the 2-cm ASD was primarily closed (Fig. 58-10). In merely a decade, the mortality for ASD closure was lowered from 30.2 percent (Gross's original series on ASD closure using the atrial well) to 12.1 percent (Lewis's inflow occlusion series).[41]

With the inflow occlusion technique, the time allowed for repair was below 10 minutes; to allow some degree of safety, the next natural evolution of intracardiac repair techniques was the introduction of extracorporeal circulation. John Gibbon was first to report successful direct closure of an ASD with the assistance of extracorporeal circulation in an 18-year-old patient at the University of Pennsylvania in 1953.[42]

Success and failure rapidly alternated in the early history of extracorporeal circuits. Two main techniques rapidly emerged: controlled cross-circulation and mechanical extracorporeal perfusion, championed by the University of Minnesota and the Mayo Clinic, respectively.

C. Walton Lillehei (Fig. 58-11) spearheaded the efforts to achieve intracardiac repair of complex cardiac lesions with the clinical introduction of controlled cross-circulation on March 26, 1954.[43] Lillehei, Varco, Cohen, and Warden pioneered this technique after extensive laboratory investigation in canines.[44,45] The first patient, a 1-year-old boy with an operative weight of 6.9 kg, was supported by his father (Figs. 58-12 and 58-13) for 19 minutes while the ventricular septal defect was closed primarily. The patient succumbed

**FIGURE 58-10** Intraoperative photograph from the first atrial septal defect closure performed by F. John Lewis on September 2, 1952. This is the first intraoperative picture of a patient with successful outcome after open-heart surgery.

**FIGURE 58-11** Clarence Walton Lillehei (1918–1999). (From Westaby S. The foundation of cardiac surgery. *Landmarks in Cardiac Surgery.* Oxford, UK: Isis Medical Media Ltd, 1997: 45. With permission.)

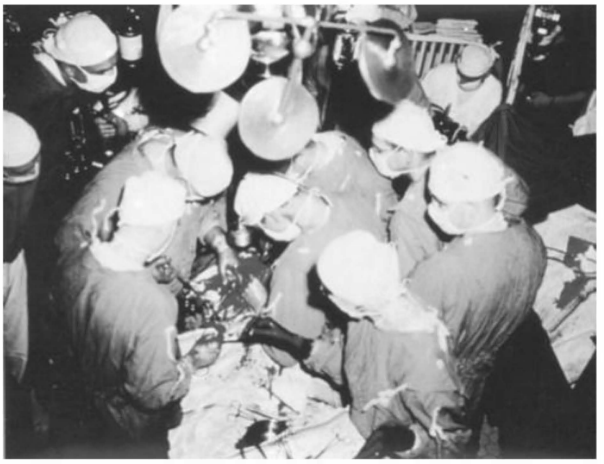

**FIGURE 58-12** University of Minnesota, Operating Room B, March 26, 1954: the first case of controlled cross-circulation. Dr. C. Walton Lillehei, to the right of the scrub nurse, is seen wearing a headlight. Opposite to Dr. Lillehei is Richard Varco. The patient's father is in the right background, and visible is the femoral donor cannulation site. Morley Cohen and Herbert Warden are seen behind Dr. Lillehei. Vincent Gott, the surgical intern on the cardiac service, is seen at the left upper corner of the picture, while assistant resident Norman Shumway is to his right. (Image courtesy of the University of Minnesota photographic archives.)

to pneumonia after 11 days, but this partial success did not undermine the morale of the surgeons at the University of Minnesota. Against institutional bias but with the support of Owen Wangensteen (Fig. 58-14), Lillehei, 2 weeks later, closed the ventricular septal defect of a 4-year-old girl, achieving long-term survival. Lillehei and coworkers performed a total of 45 operations with controlled cross-circulation. Among these was the first successful repair of tetralogy of Fallot, ventricular septal defect, and atrioventricular canal.[46–48] In this extraordinary series, operative mortality was 38 percent, and 79 percent of hospital survivors were alive at 30-year follow-up.[49] No operative deaths were directly attributable to extracorporeal perfusion, and postoperative heart block was most certainly implicated in several of the early failures. Because of this early, apparently insurmountable complication, Lillehei, Bakken, and coworkers also developed, from pressing necessity, the first temporary and, eventually, permanent implantable pacemakers.[50,51] By the end of the 1950s, the University of Minnesota turned to circulatory support with the DeWall-Lillehei oxygenator[52] and abandoned controlled cross-circulation.

John Kirklin (Fig. 58-15) at the Mayo Clinic concentrated all his efforts on cardiopulmonary bypass, developing the Mayo-Gibbon apparatus and its modifications.[53] In 1955, Kirklin reported a cohort of 38 patients with ventricular and other septation defects corrected with the aid of mechanical cardiopulmonary support.[54] This initial work established the relative safety of mechanical extracorporeal circulation

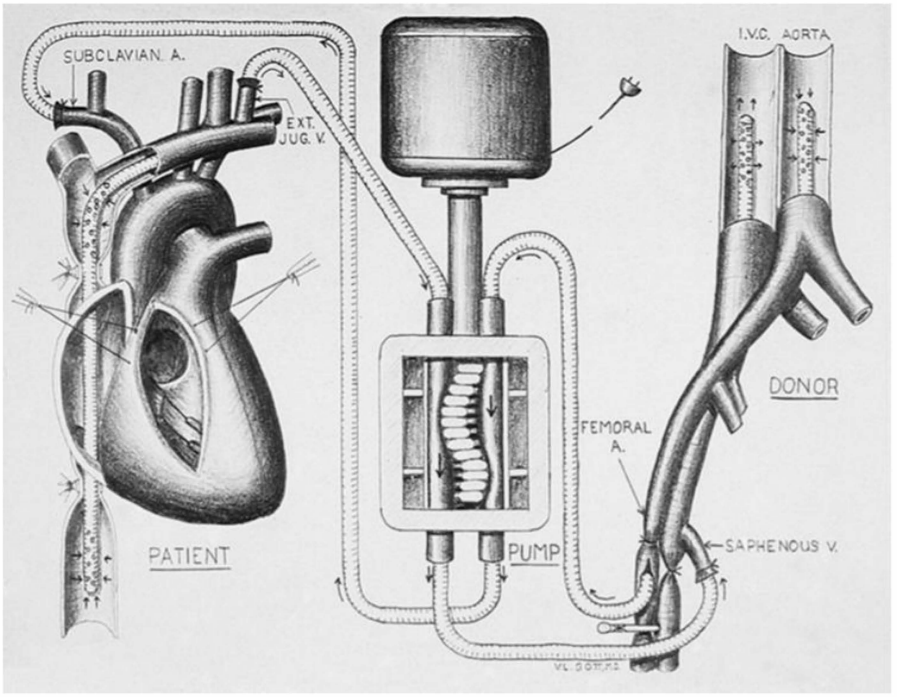

**FIGURE 58-13** Schematic illustration of the first case of controlled cross-circulation, 1954. Original drawing by the intern on C. Walton Lillehei's service, Vincent L. Gott.

and served as a platform for the development of the field of pediatric cardiac surgery. Utilizing the techniques developed in Minnesota, more complex anomalies could be successfully approached in the early 1960s without excessive mortality.[55–61]

In spite of this initial success, intracardiac repair remained as a daring undertaking in neonates and infants, largely because of the deleterious effects of cardiopulmonary bypass

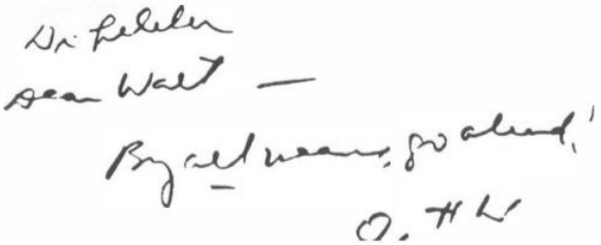

**FIGURE 58-14** Note from Owen H. Wangensteen written to C. Walton Lillehei on March 25, 1954, the eve of the first parental cross-circulation:
Dr. Lillehei
Dear Walt –
By all means, go ahead!
OHW
(From Lillehei CW. Section III: Cardiopulmonary bypass and myocardial protection. In: Stephenson LW, Ruggero R (eds). Heart Surgery Classics. Boston: Adams Publishing Group, 1994:126. With permission.)

**FIGURE 58-15** John Kirklin (1917–2004). (Courtesy of Dr. Joseph Dearani, Division of Cardiac Surgery, The Mayo Clinic. With permission.)

in children.[62] The size of the bypass circuits, the crudeness of the materials, and the underdevelopment of pediatric critical care made correction of cardiac anomalies in early infancy prohibitive. Between 1955 and the mid-1960s, smaller patients underwent correction almost exclusively following initial palliation by closed cardiac techniques.

## EXPANSION OF THE FIELD OF CONGENITAL CARDIAC SURGERY

Brian Barratt-Boyes was without doubt one of the most influential figures in the further advancement of congenital cardiac surgery. He returned to Green Lane Hospital (Auckland, New Zealand) after 2 seminal years at the Mayo Clinic (1953–1955). Sir Brian pioneered the concept of profound hypothermia and hypothermic circulatory arrest. This approach aggressively minimized the duration of exposure to extracorporeal surfaces and the subsequent inflammatory response, limiting it mainly to that needed for cooling and rewarming. The actual intracardiac repair could then be carried out expeditiously with no cannulae crowding an asanguinous field, thus greatly facilitating exposure in neonates and small infants. Furthermore, systemic cooling permitted relatively reliable myocardial protection before the routine introduction of cardioplegia[63–65]. This radical innovation allowed intracardiac repair of complex anomalies in neonates and infants, with excellent outcomes.[66,67] Of the 37 infants reported in his original 1971 article,[68] 33 had operative weight below 10 kg, and 25 patients were between 8 days and 12 months of age at the time of surgical correction. A gradual but steady shift toward early, complete one-stage intracardiac repair rather than initial palliation followed.[69–73] Complex anomalies such as total anomalous pulmonary venous connection, transposition of the great arteries,[72,73] complete atrioventricular canal,[74–76] and aortic arch anomalies[77,78] could be repaired in the neonatal period or in early infancy with much more acceptable morbidity and mortality as compared with the results of earlier corrective attempts.

This pioneering work was further developed by Castaneda (Fig. 58-16),[70–71] Jatene,[79,80] Norwood,[81,82] Bailey,[83,84] and others.[85–88] Thanks to the vision and determination of these contributors and to the exponential progress of perioperative care (Chapter 53),[37,89] the field had evolved over a mere 25-year period from treacherous attempts at palliation in older children to routine complete correction in neonates and infants.

# The Anatomy of Congenital Cardiac Malformations

*Robert H. Anderson*
*Andrew C. Cook*

## INTRODUCTION

The results of the surgical treatment of congenital cardiac malformations have been transformed within the last half-century. Prior to the development of cardiopulmonary bypass, it was impossible to even contemplate the repair of major malformations, even though ingenious surgeons had successfully closed simple intracardiac lesions such as holes between the atrial chambers. Even when it proved possible for the surgeon to work within the heart in the setting of a bloodless operative field, the results of operative repair were far from perfect, and many patients died subsequent to the operative procedure. Nowadays, it is unusual for any patient with a relatively simple defect to die, and even those with "complex" lesions are now expected to survive. There have been many reasons for these truly remarkable advances, but without question one has been the knowledge of detailed intracardiac anatomy accrued within recent decades. In the past, it was often thought that, in the setting of so-called complex malformations, this anatomy was difficult to understand. It is now recognized that, although the combination of given lesions can truly be complex, the anatomy itself is relatively straightforward provided that it is approached in straightforward fashion and using a system of analysis that is simple and logical. To achieve success, therefore, the pediatric cardiac surgeon must hone not only the surgical skills but also the intellectual rigor needed to analyze the structure of the congenitally malformed heart. It would be foolish to suggest that problems do not still exist in obtaining the necessary morphologic understanding, but these problems can be minimized by using a simple philosophy combined with use of words in their vernacular sense. Too many of the problems of the past have reflected linguistic rather than scientific disagreements. It remains appropriate to remember the aphorism attributed to Rudolf Virchow, namely that "those who fail to learn from the mistakes of the past are condemned to repeat them." In this chapter, therefore, we describe the basics of cardiac anatomy that permit the surgeon to diagnose and recognize the arrangement of the cardiac chambers during surgical procedures and at the same time appreciate the likely position of the vital conduction tissues. The concomitant advances made over recent years in diagnostic techniques are now such that the basic layout of the heart will have almost certainly been established prior to commencement of intracardiac procedures. Nonetheless, even in the most complex cases, preliminary diagnosis demands little more, in terms of morphology, than the distinction of a right atrium from a left atrium, a right ventricle from a left ventricle, and an aorta from a pulmonary trunk. It is such distinctions that provide the basis for simple sequential segmental analysis.[1] For the surgeon, the anatomy of holes and blockages within the heart and great vessels are of equal or even greater significance. This morphology is addressed elsewhere in the appropriate chapters of this book; therefore, we confine ourselves to showing how the anatomy of some important defects differs markedly from the normal arrangement. Our primary concern, however, is to establish the requirements for a systematic and simple approach to cardiac anatomy.

## APPROACHES TO THE HEART

The heart lies in the mediastinum. In most instances, it is found with its apex pointing to the left, and with about two-thirds of its bulk to the left of the midline. If not thus located, the surgeon should immediately consider the possibility that complex malformations lurk within the heart. When the heart is abnormally located, it is our preference to describe the arrangement in simple terms, such as "heart mostly in the right chest with the apex pointing to the left" or as appropriate. In this way, we avoid the need to define arcane terms, such as "pivotal dextrocardia" and comparable locutions. The surgeon usually approaches the heart through the midline anteriorly or via the thoracic cavities. Nowadays, a median sternotomy or a variation on this approach is used most frequently. It is fortunate for the surgeon that the area

of the mediastinum immediately behind the sternum is devoid of vital structures. Separate incisions can be made in the suprasternal notch and beneath the xiphoid process, the two being joined by blunt dissection. Splitting of the sternum exposes the pericardial sac lying between the pleural cavities. An important structure in this area is the thymus gland, particularly well developed in infants, which wraps itself over the pericardium in the area of the arterial pole. In dividing or excising the gland, the surgeon must take care of both the arterial supply, from the internal thoracic and inferior thyroid arteries, and the venous drainage through the thymic veins. The latter structures are fragile and often empty via a common trunk to the left brachiocephalic vein, which may be inadvertently damaged by undue traction.

Having exposed the pericardium, the surgeon should then remember that the vagus and phrenic nerves traverse its length, albeit well clear of the operative field (Fig. 59-1). The phrenic nerves, nonetheless, can be damaged should the pericardium be harvested for use as an intracardiac patch or baffle. Excessive traction on the pericardial cavity should be avoided, since it is easy to avulse the origin of the pericardiophrenic arteries, which accompany the phrenic nerves.

Lateral thoracotomies are made most frequently in the fourth intercostal space, using the posterior bloodless triangle between the edges of the latissimus dorsi, trapezius, and teres major muscles. An incision midway between the ribs avoids the intercostal neurovascular bundle, protected beneath the lower margin of the fourth rib. Such an incision takes the surgeon into the pleural space.

On the left side, posterior retraction of the lung exposes the middle mediastinum, revealing the left lobe of the thymus overlying the pericardium and the aortic arch, with its associated nerves and vessels. The aortic isthmus and descending aorta are readily approached in this fashion, dividing the parietal pleura posterior to the vagus nerve. Care must be taken to avoid the left recurrent laryngeal nerve, which takes its origin from the vagus and curves around the inferior border of the arterial ligament or, if this structure is still patent, the arterial duct (Fig. 59-2). The thoracic duct should also be avoided; this vessel drains at the junction of the left subclavian and internal jugular veins.

A right thoracotomy provides access to the right pulmonary artery and adjacent structures. On the right side, the right recurrent laryngeal nerve passes around the subclavian artery as it runs superiorly from the vagus toward the larynx. The stellate ganglion from the sympathetic trunk is also at potential danger in this region, inappropriate damage to this structure resulting in Horner syndrome.

## SURFACE ANATOMY OF THE HEART

The nature of the cardiac chambers is readily determined by external inspection. The morphology of the appendages best distinguishes the right from the left atrium. These outpouchings usually clasp the arterial pedicle, with one appendage to each side (Fig. 59-3). The arrangement in which both appendages are on the same side of the pedicle

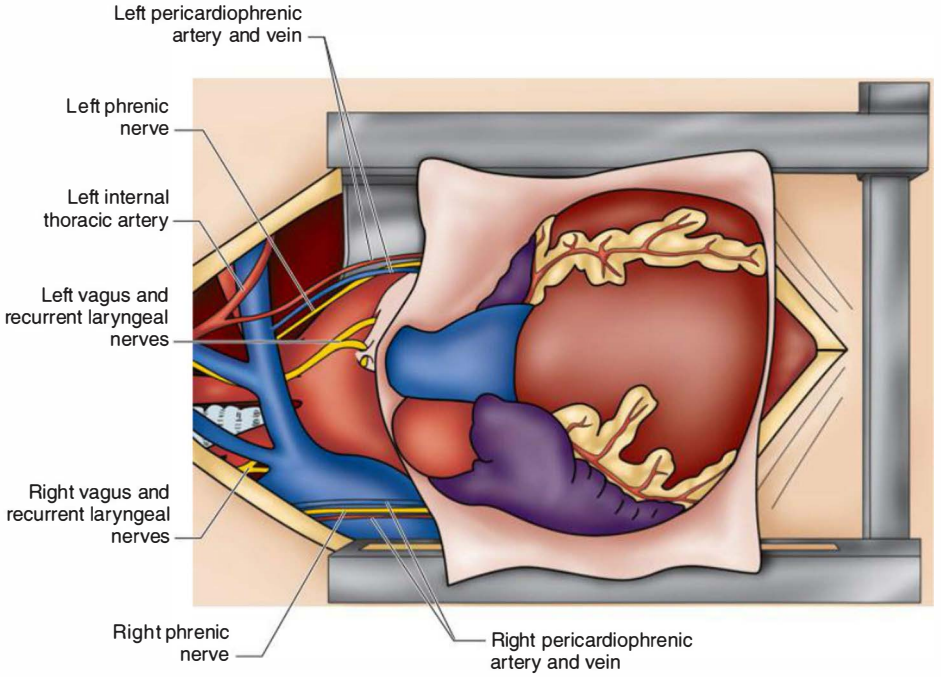

**FIGURE 59-1** The diagram shows the relationships between the vagus and phrenic nerves and the heart contained within its pericardial sac as seen by the surgeon approaching the heart through a median sternotomy.

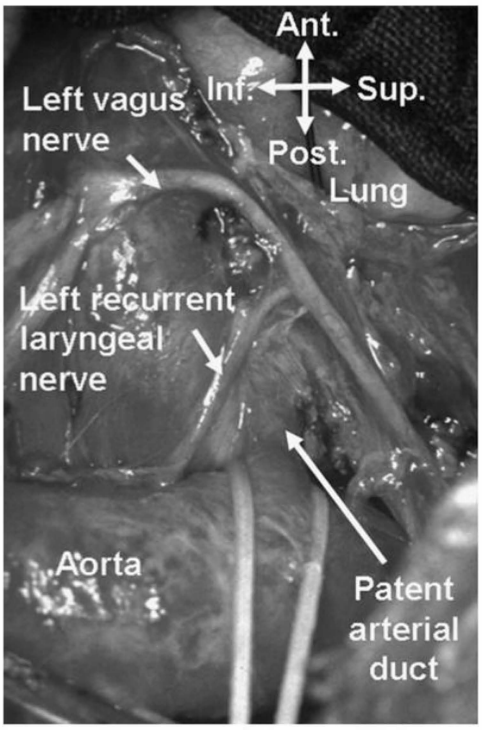

**FIGURE 59-2** This operative view through a left thoracotomy shows the relationships of the recurrent laryngeal nerve relative to the arterial duct. (Courtesy of Benson Wilcox, MD, with permission.)

is called juxtaposition of the atrial appendages. Should the two appendages both be left-sided, then the cardiac chambers and arterial trunks are almost always abnormally joined together. If both appendages are to the right, however, this being a much rarer finding, the heart is again likely to be malformed, but in much simpler fashion, sometimes with no more that an atrial septal defect. Juxtaposition of the appendages also distorts the internal atrial architecture, particularly the atrial septum—a situation that can produce problems unless properly recognized.

In this chapter, we use the terms "right" and "left" to indicate morphology rather than position, this being one of the basic rules of congenital cardiac morphology. If position is also abnormal, this should be described separately. The appendages are the best structures with which to distinguish the morphologically right and left atriums. The right appendage has an obviously triangular shape, in contrast to the tubular left appendage. Shape, however, can be modified by abnormal hemodynamics. In situations of uncertainty therefore, the surgeon should examine carefully the junctions between the appendages and the remainder of the atrial chambers.[2] The essential feature of the right atrium is that the pectinate muscles extend all around the atrioventricular junction to the back of the heart. In the left atrium, in contrast, the posterior wall is entirely smooth, the pectinate muscles being confined within the tubular appendage. When the triangular appendage is right-sided and the tubular appendage left-sided, this usual arrangement is frequently called "situs solitus." Our preference, as already stated, is to use words which have currency in normal language, so we prefer simply to describe it as "the usual arrangement." On rare occasion, the tubular appendage will be right-sided, with the triangular one on the left side. This is best described as "the mirror-image arrangement." Although often called "situs inversus," the appendages in this setting are truly mirror-imaged rather than being turned upside down. Mirror imagery is rare. In the setting of complex malformations, it is more frequent to find the arrangements in which both the appendages have comparable morphology. Both appendages can then be either broad and triangular, with pectinate muscles extending all around the atrioventricular vestibules, or

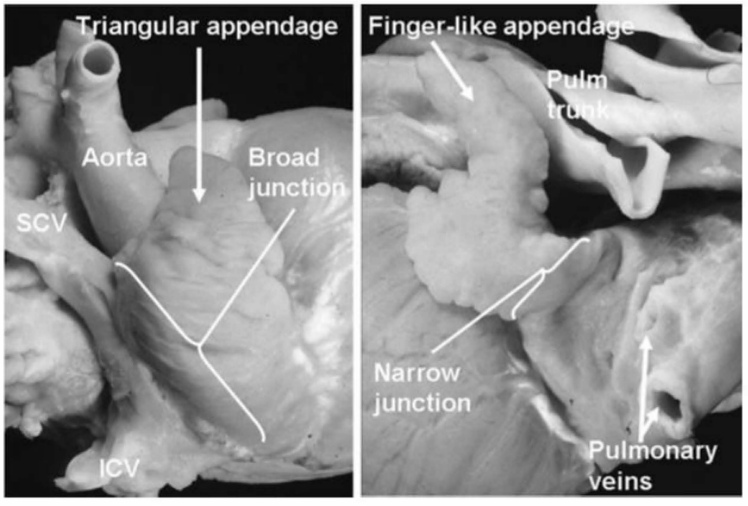

**FIGURE 59-3** These lateral views of the heart, taken in anatomic position, show the different shapes of the right and left atrial appendages.

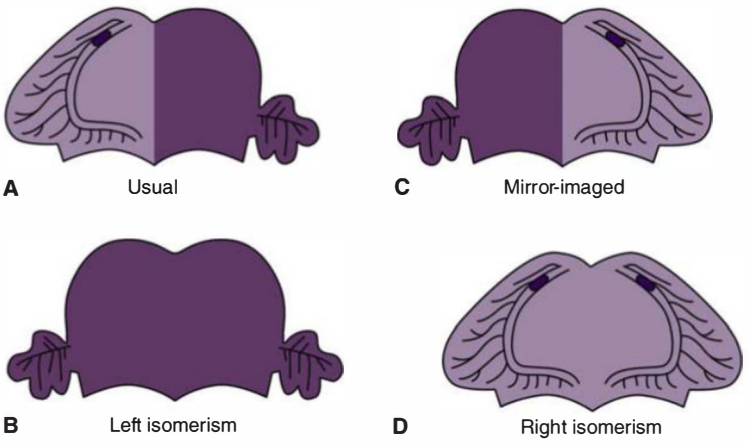

**FIGURE 59-4** The potential arrangement of the atrial appendages. Note the location of the sinus node (hatched commas or dots; see text for further discussion).

else both can be tubular and narrow, with smooth posterior atrial walls on both sides (Fig. 59-4). These arrangements are accurately described as isomerism of the right or left atrial appendages, respectively. Patients with such arrangements of the appendages also typically have malposed abdominal organs, along with an isomeric arrangement of the lungs and bronchial tree.[1,2] The overall arrangement is called visceral heterotaxy and, in the past, was often categorized on the basis of splenic morphology. These syndromes are the harbingers of the most complex combinations of intracardiac lesions, but it is now unusual for such patients to be denied attempted surgical correction. By the simple expedient of inspecting the appendages, the surgeon now has the means of diagnosing these entities directly in the operating room, should the conditions not have been recognized during the diagnostic workup. Indeed, recognition of the appendages is the more important to the surgeon, since sometimes there is discordance between splenic anatomy and the arrangement of the appendages.[3] It is accurate recognition of the appendages that guides the surgeon to an appreciation of the likely location of the sinus node.[4]

Thus, the surgeon should examine carefully the junctions between the appendages and the atrial venous components. If the junction is morphologically right, there will be an extensive terminal groove, marking the site of the terminal crest internally (Fig. 59-5). The sinus node is always located in the immediately subendocardial position within this groove, positioned lateral to the crest of the atrial appendage (Fig. 59-6). The morphologically left junction is never marked by any such prominent groove and similarly lacks a sinus node. Should both junctions be morphologically right, the sinus node will be duplicated and the surgeon should respect both junctions. In the setting of isomeric left appendages, in contrast, the sinus node will be hypoplastic or even absent, and the surgeon should be aware that the nodal remnant can be positioned in the smooth atrial wall close to the atrioventricular junctions.[4]

Having inspected the appendages, the surgeon should turn attention to the venoatrial connections, ensuring that all the pulmonary veins, along with the caval veins and the coronary sinus, are in their appropriate positions. Search should always be made for a persistent left superior caval vein. This will be found between the left appendage and the left pulmonary veins. If the surgeon has already established that there is isomerism of the left atrial appendages, then attention should be directed to the inferior caval vein, which is often interrupted in this setting, venous flow from the abdomen being returned through the azygos venous system, which will be correspondingly enlarged.

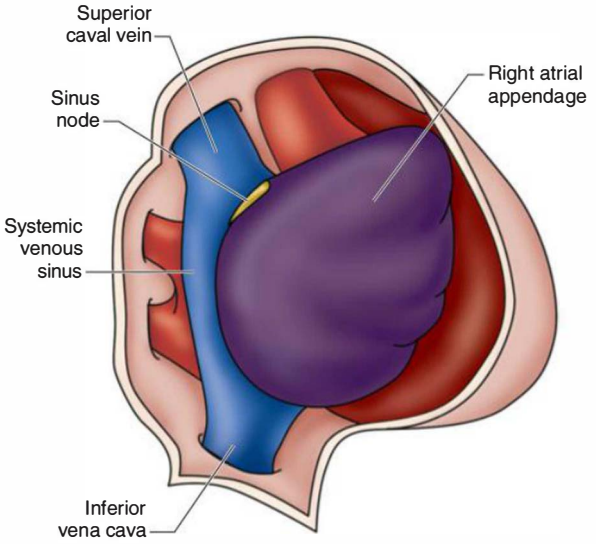

**FIGURE 59-5** The drawing shows how the terminal groove interposes between the right atrial appendage and the systemic venous component. The heart is shown in anatomic orientation, with the subepicardial position of the sinus node marked.

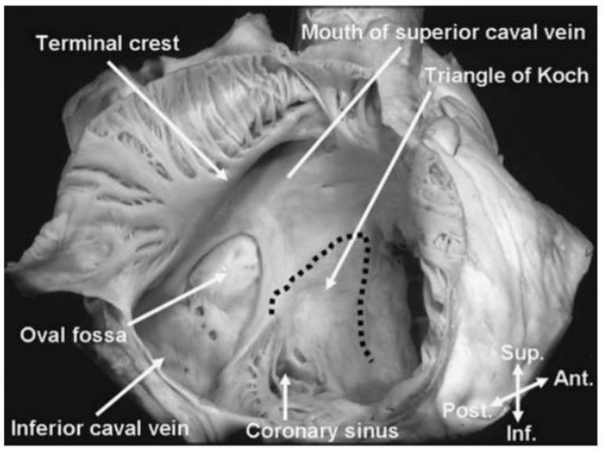

**FIGURE 59-6** The right atrium has been opened with the heart in anatomic position to show the terminal crest and the location of the triangle of Koch. Note the apparent extensive area occupied by the septal surface.

External inspection also provides significant information concerning the structure of the ventricular mass. It is the positions of the interventricular branches of the coronary arteries that are the guide.[5] In the usual situation, the anterior interventricular coronary artery is a branch of the main stem of the left coronary artery, descending close to the obtuse margin of the ventricular mass. Should this artery take its origin from a coronary artery arising in right-sided position from the aortic root, the aorta itself being anterior to the pulmonary trunk, then almost always the ventricles themselves will be arranged in mirror-imaged fashion (so-called left-hand ventricular topology) with the morphologically left ventricle then positioned on the right. Identification of such a coronary arterial pattern should alert the surgeon to the likely presence of congenitally corrected transposition, the combination of discordant atrioventricular and ventriculoarterial connections (see below). Equally obvious should be the arrangement in which two arteries of comparable size take origin from an anteriorly positioned aorta, delimiting the position of a small ventricle on the anterior surface of the ventricular mass. Such a finding is indicative of disproportion between the sizes of the ventricles. The most frequent disproportion is seen when the left ventricle is dominant and the right ventricle is small, as in double-inlet left ventricle or tricuspid atresia. Should prominent interventricular arteries not be evident on the anterior ventricular surface, suspicion should be raised that there is a solitary ventricle of indeterminate morphology. This pattern, however, is exceedingly rare. Much more frequently in this setting, the right ventricle will be dominant, with the small left ventricle hidden on the diaphragmatic surface of the ventricular mass. This is the typical pattern seen in hypoplasia of the left heart.

In examining the ventricular mass, note should also be taken of the relationship of the arterial trunks, confirming first that there are separate aortic and pulmonary trunks as opposed to a common or solitary trunk. There will usually be separate trunks, and typically the aortic trunk is then posterior- and right-sided, with the pulmonary trunk spiraling around the aorta as it divides into right and left pulmonary arteries. This is the "normal relationship."

Abnormal relationships of the great arterial trunks are indicative of intracardiac malformations, albeit that the positions and connections of the cardiac chambers themselves cannot be inferred from such knowledge. Abnormal arterial positions, nonetheless, give important clues to the presence of particular lesions, which nowadays will almost certainly have been accurately diagnosed before the patient reaches the operating room. An anterior and right-sided aorta is the typical feature of discordant ventriculoarterial connections, usually known as "transposition," but is also seen when both arterial trunks arise from the right ventricle. When the aorta is anterior and left-sided, most frequently the transposition will be congenitally corrected as discussed above, but this pattern can also be seen with double outlet from the right ventricle. The aorta can also be anterior and left sided when the connections are concordant across both the atrioventricular and ventriculoarterial junctions, a rare situation sometimes called "anatomically corrected malposition."[6] A left-sided and anterior aorta can also be found with regular transposition. All this variation serves to emphasize that relationships of the arterial trunks are at best a guide to the specific connections of the cardiac segments.

## ANATOMY OF THE CARDIAC CHAMBERS

The perceptive reader will have ascertained from our descriptions thus far that one of the major features of the congenitally malformed heart is that the cardiac chambers are not always in their usual position, nor are they joined as expected to their neighbors. The most important rule of congenital cardiac anatomy, nonetheless, is that each chamber has a relatively constant anatomy irrespective of its position or its connections, albeit that a subtle change in morphology is found when the chambers are connected in abnormal fashion or when the junctions between the cardiac segments are themselves malformed. In this section, therefore, we concentrate our attention on the expected normal morphology, emphasizing when the surgeon should expect to find abnormal arrangements.

### The Right Atrium

As already discussed, the most distinctive feature of the right atrium is its extensive triangular appendage, which is separated from the venous component of the atrium by the terminal groove (Fig. 59-5). When viewed by the surgeon, the superior caval vein enters the left-hand side of the venous component, with the inferior caval vein to the right-hand side. The venous component itself is then seen by the surgeon as a sleeve, being separated inferiorly from the right pulmonary veins by the extensive interatrial groove. This

groove, also known as Waterston's or Sondergaard's groove, is a deep infolding between the right and left atrial walls.

Opening of the right atrium reveals the extensive terminal crest (Fig. 59-6). This muscular bundle underlies the terminal groove, encasing the orifices of both the superior and inferior caval veins, and extending anteriorly toward the atrial septum. In the region of the septum, it becomes a muscular ridge, the eustachian ridge, which separates the orifice of the inferior caval vein from the mouth of the coronary sinus. The mouths of these venous structures are often guarded by sickle-shaped fibrous folds of varying dimensions, the eustachian and thebesian valves. The fibrous commissure of these two valves buries itself in the musculature between the coronary sinus and the oval fossa; as viewed by the surgeon, it runs toward the left-hand margin of the tricuspid vestibule. This important structure, the tendon of Todaro, forms one boundary of the crucial triangle of Koch (Fig. 59-6). When seen in the operating room, the tendon forms the most distant border of the triangle, while the site of annular attachment of the septal leaflet of the tricuspid valve is closer to the surgeon. The atrioventricular node is found at the apex of this triangle, with the atrioventricular bundle penetrating from the apex to pass into the left ventricular outflow tract.

When the right atrium is viewed as shown in Figure 59-6, the impression is gained of an extensive septal surface between the right and left atriums. Sectioning shows that this is not the case (Fig. 59-7). The atrial septum, defined as the tissue that can be removed without encroaching on the pericardial cavity,[7] is confined to the floor of the oval fossa and its anteroinferior margins.[7,8] The left-hand side of the fossa, as viewed by the surgeon, is the atrial wall overlying the aortic root. The septum secundum, between the fossa and the orifice of the superior caval vein, positioned superiorly with the heart in anatomic location but seen as an inferior structure by the surgeon, is no more than the deeply infolded walls of the interatrial groove.

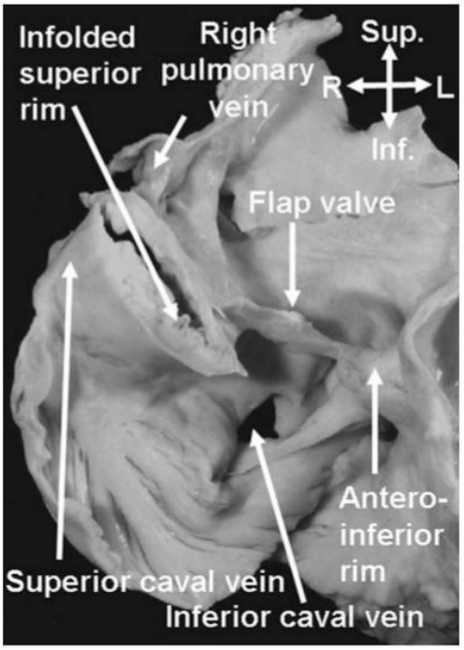

**FIGURE 59-7** Sectioning of the heart reveals that only the oval fossa and its inferoanterior rim are true septal structures. The other borders are infoldings of the atrial walls.

## The Left Atrium

Overall, the left atrium (Fig. 59-8) has a much simpler structure than the right atrium but also possesses an extensive body, which is lacking in the right atrium. The appendage accounts for less of the chamber than on the right side. The venous component, located posteriorly and superiorly, receives the four pulmonary veins, one at each corner. When seen by the surgeon entering through the atrial roof, the narrow opening of the tubular appendage is to the left hand, while the septal surface is to the right. The smooth inferior and posterior margin of the mitral vestibule overlies the coronary sinus as it runs round from the obtuse margin of the ventricular mass. The septal surface of the left atrium is much simpler than that of the right, being formed by the flap valve of the oval fossa (Fig. 59-8).

## The Atrioventricular and Ventriculoarterial Junctions

Knowledge of the structure of the junctions between the cardiac components is fundamental to the proper understanding of several congenital anomalies, particularly

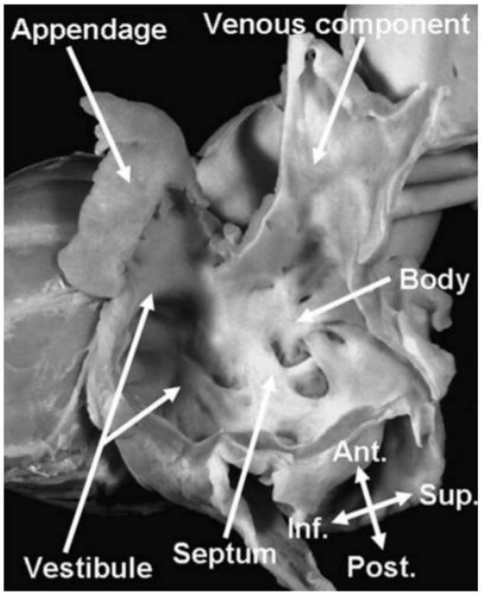

**FIGURE 59-8** The components of the left atrium are shown in anatomic orientation as seen in left lateral position.

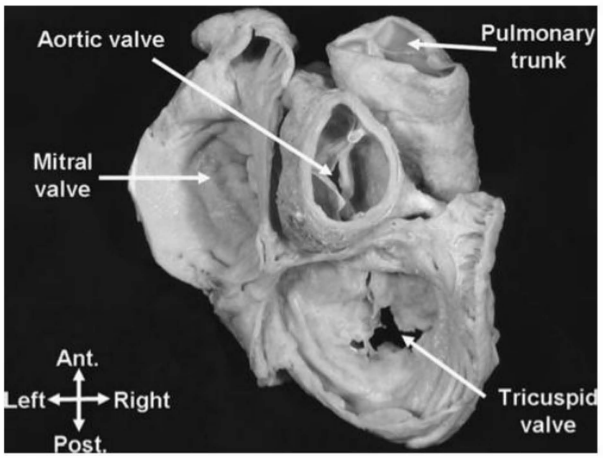

**FIGURE 59-9** The atrial myocardium has been removed from the base of the heart, which is photographed from above and from the right to show the arrangement of the atrioventricular junctions relative to the ventriculoarterial junctions.

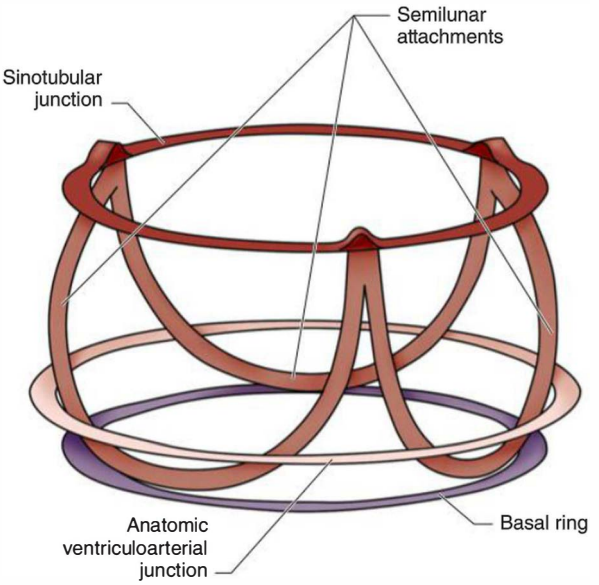

**FIGURE 59-10** The drawing shows how the arterial roots are formed in the style of a coronet, with the semilunar attachments of the valvar leaflets crossing the anatomic ventriculoarterial junction. The basal ring is a virtual ring, made by joining together the basal attachments of the leaflets. The sinotubular junction, in contrast, is a true annular structure and marks the distal boundary of the arterial root.

atrioventricular septal defects in the setting of common atrioventricular junctions.[9] The salient anatomy of both these junctions, and the relationship between the valves guarding them, is well seen when the musculature of the atrial chambers and the arterial trunks is dissected away from the ventricular base, which can then be viewed from its superior aspect (Fig. 59-9). Although each of the four cardiac valves is usually described as possessing an annulus, in reality none has a true and complete fibrous ring supporting its leaflets. It is the mitral annulus that approximates most closely to the concept of a ring, albeit that it is more akin to an oval saddle, and parietally there is often very little collagenous tissue supporting the mural leaflet of the valve. In the tricuspid orifice, it is very rare to find a collagenous annulus. Instead, it is the fibro fatty tissues of the atrioventricular groove that separate the atrial muscle from the ventricular mass. In the case of the arterial valves, the concept of a "ring" is totally deficient. For both the aortic and pulmonary valves, each of the three leaflets is attached to the underlying ventricular structures in semilunar fashion. Although encased in a circular tube, the attachments of the arterial valvar leaflets, when considered as a whole, take the form of a coronet, with the hinge lines of the leaflets tenting up to reach the sinotubular junction and sweeping down to the nadir of the attachments at the ventricular bases (Fig. 59-10).[16] In the right ventricle, these basal attachments are exclusively supported by ventricular muscle, specifically by the free-standing subpulmonary infundibulum. For the aortic valve, in contrast, a good half of the valvar circumference is supported by fibrous and collagenous tissues. This is because the leaflets of the aortic valve usually have extensive fibrous continuity with those of the mitral valve and, via the membranous septum, also with the leaflets of the tricuspid valve (Fig. 59-11). The two ends of the region of aortio-mitral valvar continuity are thickened to form the right and left fibrous trigones, with the right trigone itself forming an integral part of the fibrous mass where the aortic root is continuous with the leaflets of the tricuspid valve (Fig. 59-12). This whole area is called the central fibrous body, incorporating the so-called membranous septum, which forms the medial wall of the subaortic outflow tract beneath the zone of apposition between the right coronary and noncoronary leaflets of the aortic valve.

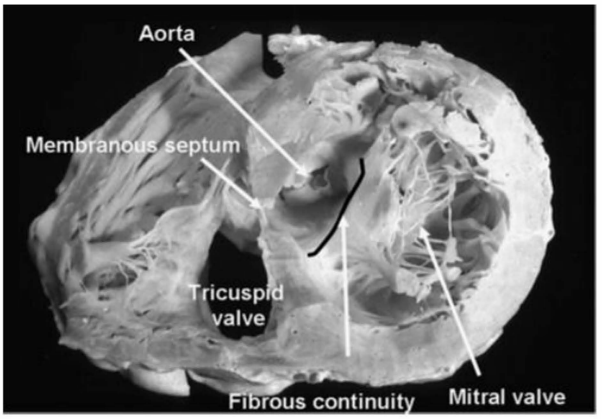

**FIGURE 59-11** The short axis of the ventricular mass is photographed from beneath in left anterior oblique orientation, showing the relationship between the leaflets of the aortic and mitral valves. Note also the fibrous continuity with the tricuspid valve through the substance of the membranous septum.

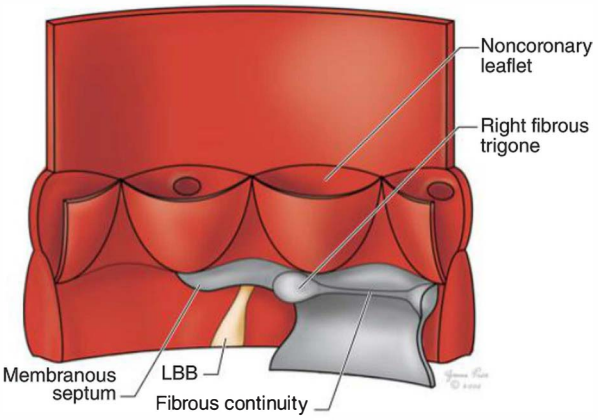

**FIGURE 59-12** The drawing shows how the right trigone and the membranous septum form the so-called central fibrous body.

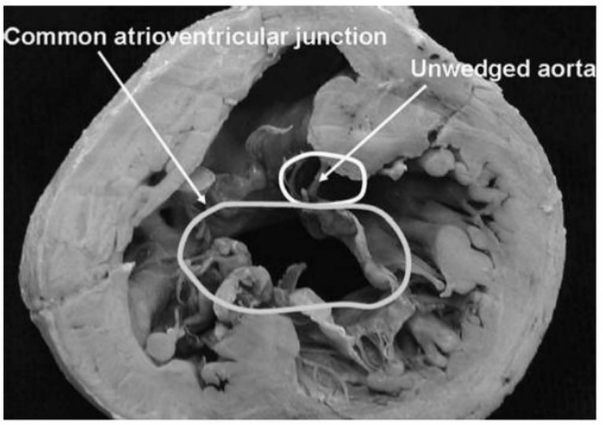

**FIGURE 59-13** An atrioventricular septal defect with the common atrioventricular junction has been sectioned in the short axis of the ventricular mass and photographed from beneath (compare with Fig. 59-11). The essence of the lesion is the common atrioventricular junction.

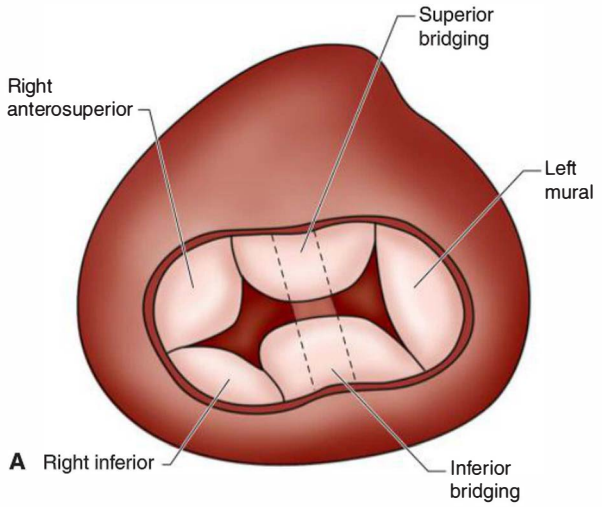


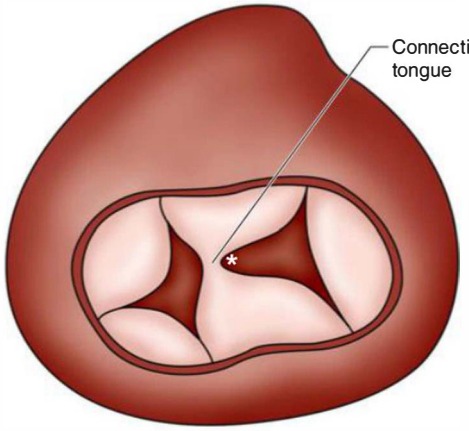
The attachment of the septal leaflet of the tricuspid valve divides this membranous septum into its atrioventricular and interventricular components.

Viewing the atrioventricular junctions from their ventricular aspect (Fig. 59-11) shows how the subaortic outflow tract "lifts" the aortic leaflet of the mitral valve away from the muscular ventricular septum. Because of this, the two atrioventricular valves are attached to opposite sides of the septum over a remarkably short distance. In this short area, the tricuspid valve is attached to the septum more toward the ventricular apex than is the mitral valve, producing the well-recognized echocardiographic feature of valvar off setting. In times gone by, we considered this area to be the "atrioventricular muscular septum."[9] We now know that, in this area, an extension of the inferior atrioventricular groove interposes between the atrial and ventricular musculatures. The area is better likened to a sandwich rather than a septum.[10] It is into the atrial aspect of the sandwich that the coronary sinus opens to the right atrium, having traversed the posterior and inferior aspect of the left atrioventricular junction. The atrial components of the "atrioventricular muscular sandwich" contain the atrioventricular node, which lies on the sloping atrial aspect of the junction. From this position, the atrioventricular bundle is able to penetrate the central fibrous body and reach the crest of the muscular ventricular septum in the left ventricular outflow tract. The surgical landmark to this point of penetration is the zone of apposition between the right and noncoronary aortic valvar leaflets. As seen from the right atrium, it is the landmarks of the triangle of Koch that delineate the site of the specialized atrioventricular conduction tissues. Seen from the left atrium, the septal end of the zone of apposition between the leaflets of the mitral valve demarcates the area of danger. In approaching from the right ventricle, so as to protect the conduction tissue, the surgeon must avoid the area immediately adjacent to the medial papillary muscle and the zone of apposition between the septal and anterosuperior leaflets of the tricuspid valve.

It is the atrioventricular muscular sandwich together with the atrioventricular component of the membranous septum that are lacking in the group of lesions known as atrioventricular canal malformations, or more recently as atrioventricular septal defects.[9] Attention to the junctional morphology of these lesions shows that the phenotypic feature is a common atrioventricular junction (Fig. 59-13). The valve guarding the common junction closes in the fashion of a pentafoliate structure, irrespective of whether there is a common valvar orifice, or separate orifices for the right and left ventricles, the latter morphology being the phenotypic feature of the so-called ostium primum defect.[9] Attention to the pattern of closure of the left ventricular component of this common valve shows that it possesses three leaflets, one being exclusive to the left ventricle and the other two being the left ventricular components of leaflets that bridge the ventricular septum (Fig. 59-14). Analysis in this fashion shows that the "cleft" in the left atrioventricular valve, a source of appreciable confusion over the years, is no more than the zone of apposition between the left ventricular components of these two leaflets bridging the ventricular septum.

## The Right Ventricle

Traditionally, it has been customary to divide ventricles into sinus and conus. This convention is adequate for the normal heart, although less than ideal. In our opinion, it is better to consider ventricles as possessing three rather than two components, namely, the inlet, apical trabecular, and outlet portions (Fig. 59-15). All ventricles, no matter how deformed, are readily described using this tripartite convention. For instance, the small ventricles in functionally univentricular hearts with a dominant left ventricle, whether produced by double-inlet- or tricuspid atresia, possess apical trabecular and outlet components. As such they are logically described as ventricles, and



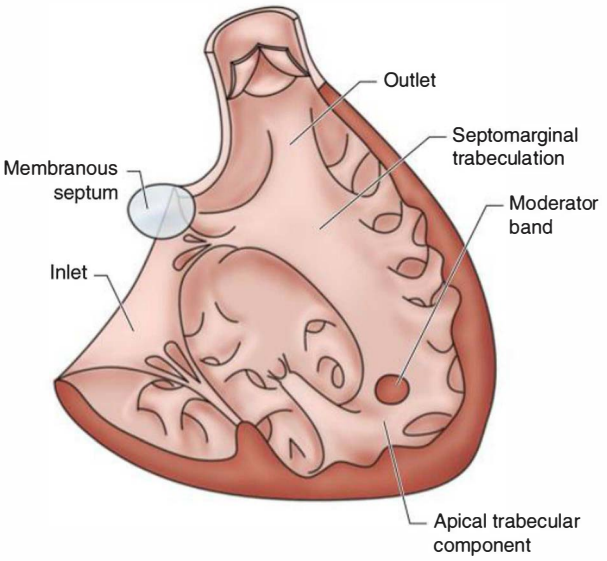


**FIGURE 59-14** The drawing shows the arrangement of the leaflets of the common valve that guards the common atrioventricular junction, as shown in Figure 59-13, when (**A**) there is a common atrioventricular junction and (**B**) there are separate valvar orifices for the right and left ventricles. Note that the left atrioventricular valve possesses three leaflets and that the so-called cleft (asterisk) is the zone of apposition between the left ventricular components of the leaflets, which bridge the ventricular septum.

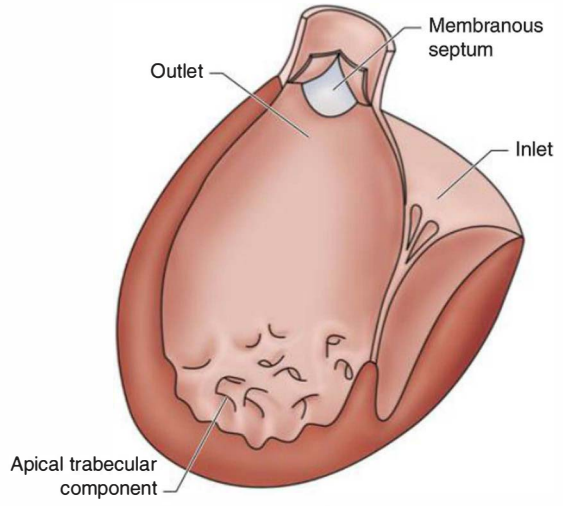

**FIGURE 59-15** The drawing shows how both right and left ventricles can be described as possessing inlet, apical trabecular, and outlet components.

the hole between them and the dominant left ventricle appropriately described as a ventricular septal defect.[11]

In describing the atrioventricular valves, integral components of most ventricles, we must be able to distinguish their leaflets. This is best done by viewing the valves in their closed rather than open positions. It is then an easy matter to recognize the number of zones of apposition within the components of the skirt of leaflet tissue. Such an approach is much better than taking the "commissural cords" as the criterion of division between leaflets. In using the criterion of commissural cords, it is difficult to determine whether the mitral valve has two or four leaflets.[12] When viewed from the stance of the closed valve, there is no question but that the mitral valve possesses two leaflets with a solitary zone of apposition between them.[13] In similar fashion, viewing the closed tricuspid valve shows that it truly possesses three leaflets.[14] And, when seen in attitudinally appropriate orientation, these leaflets are located septally, anterosuperiorly, and inferiorly within the valvar orifice.

The right ventricle, when normally constituted, possesses the tricuspid valve in its inlet portion. The zone of apposition between its septal and anterosuperior leaflets, supported by the medial papillary muscle, is intimately related to the site of penetration of the atrioventricular bundle. The feature of the apical trabecular component is its typically coarse

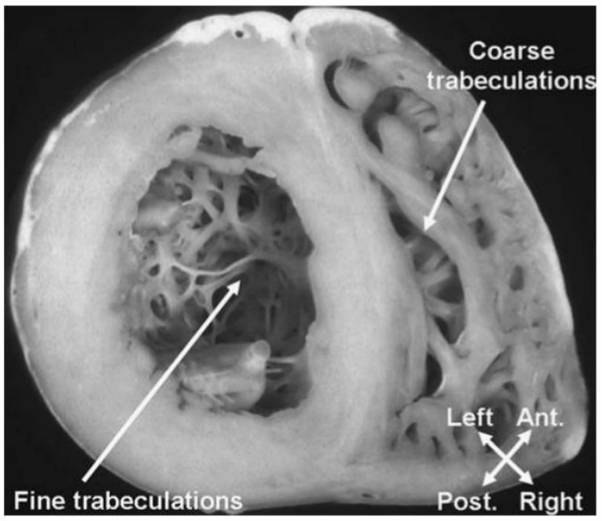

**FIGURE 59-16** The view of the apical part of the ventricular mass, seen from above, shows the difference in apical trabeculations between the right and left ventricles.

trabeculations. Indeed, it is on this basis that the ventricle is most reliably differentiated from the finely trabeculated left ventricle (Fig. 59-16).

In the normal right ventricle, the outlet component is a free-standing muscular sleeve, the infundibulum (Fig. 59-17). The apparently "septal" aspect of this infundibulum is part of the supraventricular crest, which interposes between the attachments of the leaflets of the tricuspid and pulmonary valves. Dissection shows that this structure is no more than the parietal wall of the heart, its removal emphasizing the important relationship to the right coronary artery

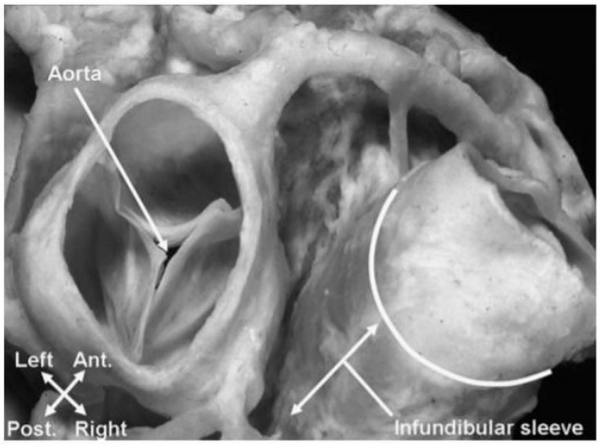

**FIGURE 59-17** The free-standing muscular infundibulum of the right ventricle has been swung away from the aortic root, showing the deep tissue plane that separates the two arterial roots. The white line shows the circular junction between the infundibular musculature of the right ventricle and the wall of the pulmonary trunk.

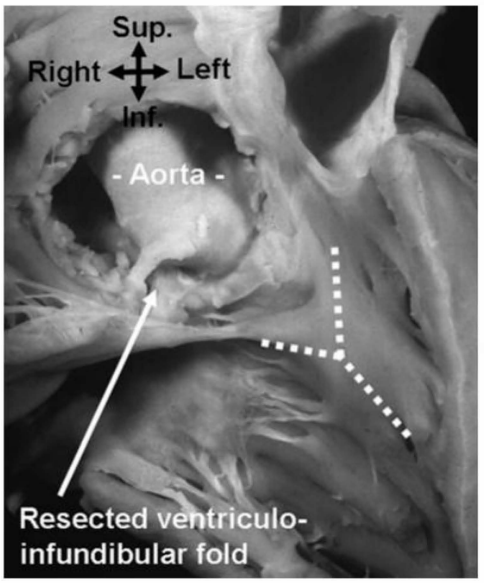

**FIGURE 59-18** The larger part of the supraventricular crest has been cut away, showing that it is no more than a fold in the parietal ventricular wall. Note the aorta giving rise to the right coronary artery. The dissection also shows how the crest inserts between the limbs of the septomarginal trabeculation (Y-dotted lines). This extensive trabeculation extends to the apex of the right ventricle, with multiple septoparietal trabeculations taking origin from its anterior aspect.

(Fig. 59-18). The crest inserts between the limbs of the extensive septal muscle bundle, which runs down into the apical trabecular component, splitting into various trabeculations including the moderator band, the anterior papillary muscle, and various septoparietal trabeculations (Fig. 59-18). In the past, this extensive bundle was often viewed as part of the supraventricular crest, and it still retains the designation of "septal band." Logic dictates that this structure cannot, at the same time, be both septal and supraventricular. It is better to distinguish this important structure as the septomarginal trabeculation, separating it in this way from both the ventriculoinfundibular fold, which forms the supraventricular crest, and the outlet component of the ventricular septum.[15] In the normal heart, however, it is not possible to distinguish with certainty that small part of the muscular septum between the subaortic and subpulmonary outlets. This part of the septum is better seen when the ventricular septum itself is deficient and is most obvious when both arterial trunks take their origin predominantly or completely from the right ventricle, as in tetralogy of Fallot (Fig. 59-19A) or double-outlet right ventricle (Fig. 59-19B).

## The Left Ventricle

As with the right ventricle, we find it best to analyze the left ventricle as possessing inlet, apical trabecular, and outlet components (Fig. 59-13). The inlet component contains the

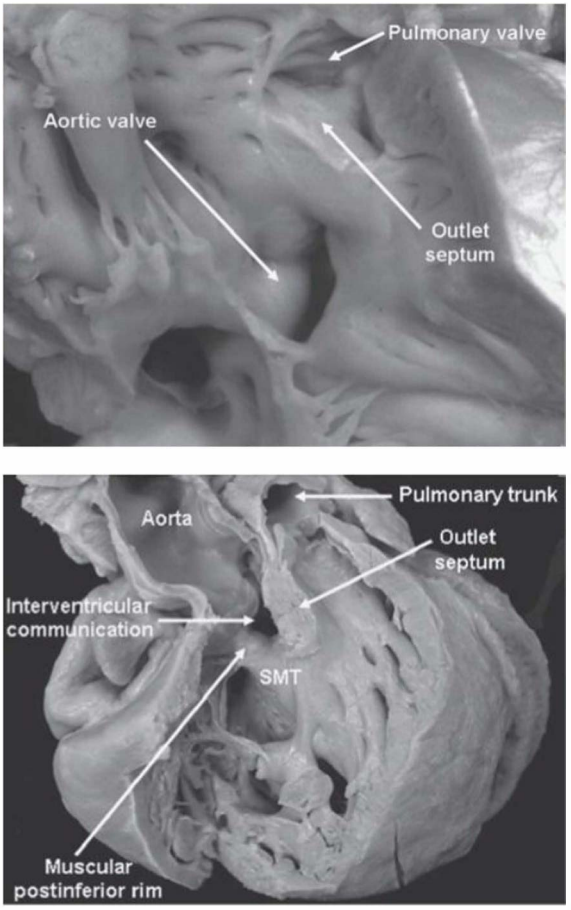

**FIGURE 59-19** These illustrations show the extensive outlet septum, seen in the setting (**A**) of tetralogy of Fallot and (**B**) double-outlet right ventricle.

mitral valve, which has a solitary zone of apposition between its aortic and mural leaflets (Fig. 59-20). The aortic leaflet is relatively short, guarding only about one-third of the valvar circumference, albeit that it has considerable depth.[13] The mural leaflet, although having a much more extensive annular attachment, has much less depth. In most hearts, this leaflet is divided into a series of "scallops," usually three, but five or even six may be seen on occasion. Although guarding different lengths of the junction, the two leaflets have more or less equal surface area. The left ventricle is characterized by its particularly fine trabeculations. Unlike the right ventricle, however, the trabecular component of the left ventricle has a smooth septal surface, down which cascades the fan-like left bundle branch of the ventricular conduction tissues. The outlet portion is well formed in the left ventricle but does not have completely muscular walls because of the fibrous continuity between the leaflets of the aortic and mitral valves. As we have already emphasized, because of the coronet-like attachment of the valvar leaflets (Fig. 59-10), it is inappropriate to describe either

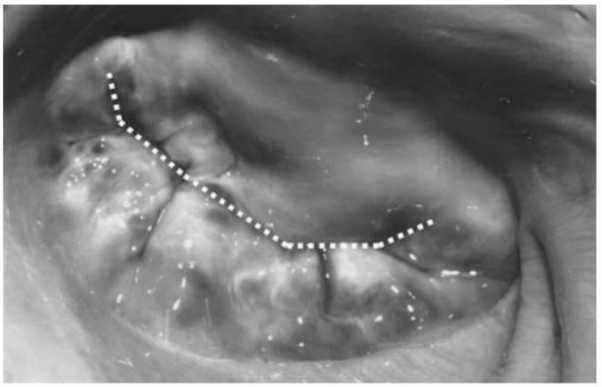

**FIGURE 59-20** The mitral valve is photographed from above with the leaflets in their closed position. Note the solitary zone of apposition of the leaflets (dotted line), which guard markedly dissimilar proportions of the atrioventricular junction. The anterior leaflet is also known as the aortic leaflet of the valve.

arterial valve as possessing an "annulus." It is the semilunar attachments of the valvar leaflets that constitute the surgical "annulus," and it is these structures that the surgeon typically uses as an anchorage for sutures in replacing the aortic valve. We should emphasize again, therefore, that the leaflets are attached within the arterial root in crown-like rather than circular fashion.

## SEQUENTIAL SEGMENTAL ANALYSIS OF CONGENITAL HEART DISEASE

In the preceding paragraphs, we have discussed the basic morphology of the cardiac chambers and emphasized the features of surgical note. Thus far, this has been considered mostly in the setting of the normal heart, albeit with emphasis being placed on the differences seen in the setting of a common atrioventricular junction (Figs. 59-14 and 59-15) or when the ventricular septum itself is deficient (Fig. 59-19). The majority of patients undergoing surgery will have their intracardiac lesions in the setting of the normal heart. Persistent patency of the arterial duct, for example, or a simple aortic coarctation, does not alter the basic cardiac morphology. Similarly, the presence of a simple atrial septal defect does not distort the basic arrangement to such an extent that the heart is not readily recognized as being normal. In a few cases, nonetheless, the anatomy can be exceedingly bizarre, often with the heart itself abnormally positioned. Even in these complex cases, description is straightforward if the surgeon follows the logical approach we have tried to establish in the previous paragraphs. This is because, as we have already discussed, the atrial appendages, the markers of atrial identity, can be arranged in only one of four patterns (Fig. 59-4). Irrespective of these patterns, the ways in which the atrial chambers can connect to the ventricles are also strictly limited, as are the possibilities for the ventricles

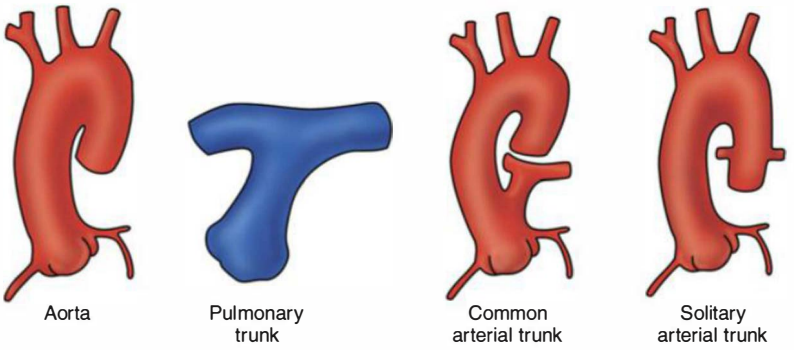

**FIGURE 59-21** The features permitting distinction of an aorta from a pulmonary trunk and a common from a solitary arterial trunk.

to make connection with the arterial trunks. We conclude our discussion of cardiac morphology, therefore, with a brief account of the principles and philosophy of sequential segmental analysis.[1,17]

## Philosophy of Sequential Segmental Analysis

To provide an unambiguous account of any abnormally formed heart, it is necessary to separate, for the purposes of description, the morphology of the individual cardiac segments, the way that the segments are joined one to the other, and the interrelationships of the components within each segment.[17] Provided that each of these features is described using mutually exclusive terms, the specific words themselves are less important, although it surely makes sense to use words in the fashion that they are also employed in day-to-day activities. We have used a multiplicity of terms during the evolution of our own approach. It is these experiences that have convinced us of the value of using simple everyday words in description rather than retaining a lexicon deeply rooted in classic etymology. One of our rules, therefore, is to eschew Latin and Greek words, since American English has now become the scientific "lingua franca." Another of our rules is to follow the "morphologic method." This requires that cardiac components, however deformed or abnormal, should always be identifiable in terms of their own intrinsic characteristics.[18,19] Venous connections, therefore, cannot, for example, be used to identify an atrium, since the veins themselves may connect anomalously. In similar fashion, the structure of an atrioventricular valve cannot always be used as the final arbiter of the morphology of a ventricle, simply because some ventricles do not possess atrioventricular valves. Thus, as we have already discussed, it is the morphology of the atrial appendages that provides the most reliable feature for atrial recognition, and it is the nature of the apical trabeculations that is most useful for distinguishing between the ventricles. Although the arterial trunks have no intrinsic distinguishing features, almost always their pattern of branching is sufficiently discrete to permit distinction of an aorta from a pulmonary trunk and both of these from a common or solitary trunk (Fig. 59-21). On the basis of the philosophy outlined above, it also follows that we always account separately for the way that the cardiac chambers are joined as opposed to their relationships in space. It could be argued that each of these features should then have equal weight in description. There is little doubt, however, that the surgeon is most concerned with the way that the cardiac components are joined or not joined. In our system, therefore, we delegate primary importance to the connections between the cardiac components, relegating relationships to a secondary role.

## Atrial Arrangement

Recognition of the arrangement of the appendages is the starting point of diagnosis. We depicted the four possible arrangements for the appendages in Fig. 59-4. When both morphologically right and left appendages are present, as in the usual and mirror-imaged patterns, the arrangements can be said to be lateralized. The other two patterns are isomeric. As we discussed, it is the morphology of the atrial appendages that dictates the disposition of the sinus node, hence the importance to the surgeon of recognizing the position of the morphologically right appendage.

## Variations at Atrioventricular Junctions

Once the atrial arrangement is known, the other information needed to analyze the structure of the atrioventricular junctions is the morphology of the ventricular chambers. Separate attention should then be paid to the fashion in which the atria are joined to the ventricles and the morphology of the atrioventricular valve or valves, which guard the junctions. The commonest patterns are found when each atrium is joined to its own separate ventricle. Such biventricular atrioventricular connections can be found with either lateralized or isomeric atrial appendages. With lateralized appendages, there are two possible patterns of connection across the atrioventricular junctions (Fig. 59-22). The first gives the concordant pattern and is seen when the right atrium is joined to the right ventricle and the left atrium to

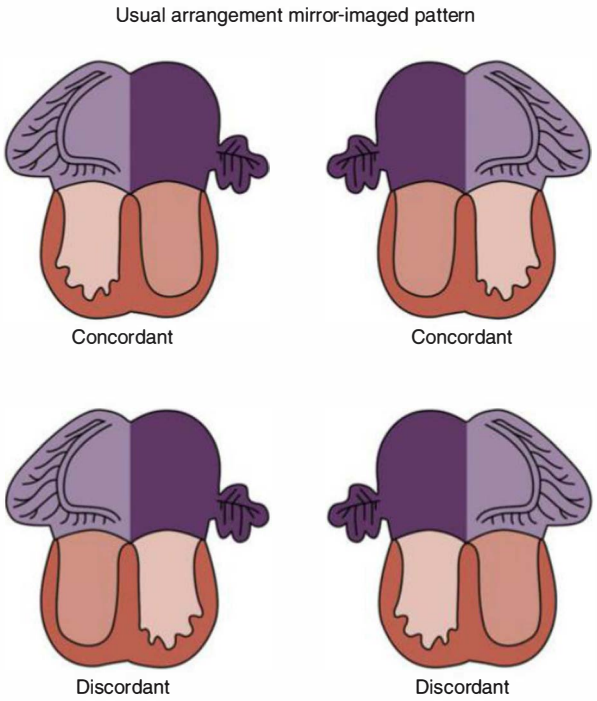

**FIGURE 59-22** The diagram shows the essence of concordant and discordant atrioventricular connections, which can both exist in either usually arranged or mirror-imaged variants.

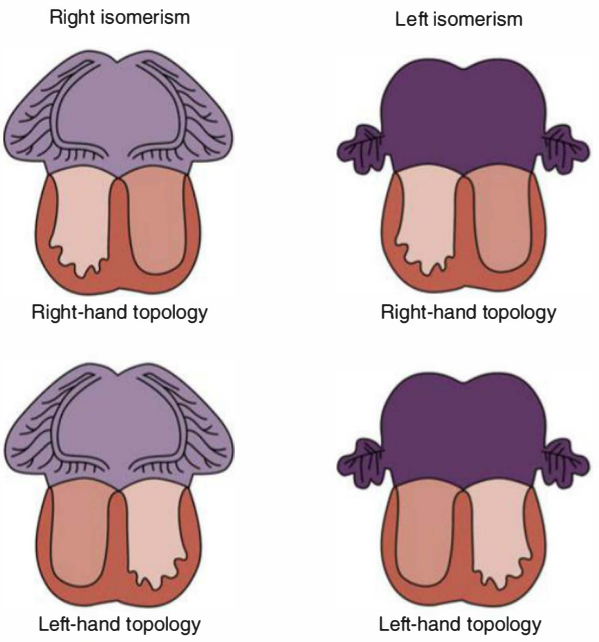

**FIGURE 59-23** When the atrial appendages are isomeric, the atrioventricular connections are perforce ambiguous. Description of ventricular topology is then essential so as fully to characterize the anatomic arrangement.

the left ventricle. In the second pattern, producing discordant connections, the right atrium is connected to the left ventricle and the left atrium to the right ventricle. Should the appendages be isomeric, then irrespective of the arrangement of the ventricles, the atrioventricular connections are biventricular but ambiguous (Fig. 59-23). It is also important in this situation, therefore, to take note of the topologic arrangement of the ventricular mass. There are two basic patterns (Fig. 59-24). In the usual pattern, as seen in the normal heart with usual atrial arrangement and concordant atrioventricular connections, the right ventricle is related to the left ventricle, so that, figuratively speaking, it is the palmar surface of the right hand of the observer that can be placed on the septal surface of the ventricle, with the thumb in the inlet, the wrist in the apex, and the fingers in the outlet. It is appropriate, therefore, to describe this as right-hand topology (Fig. 59-24, left panel). In the mirror-imaged variant, as seen typically in the patient with congenitally corrected transposition, it is the left hand that can be placed on the septal surface of the morphologically right ventricle, hence its designation as left-hand topology (Fig. 59-24, right panel). Either of these two arrangements can be found when hearts with isomeric atrial appendages have biventricular atrioventricular connections (Fig. 59-23). It follows, therefore, that complete description requires an account of atrial arrangement and ventricular topology. The topologic arrangement is also important to the surgeon, since this feature dictates the disposition of the conduction tissues.[4]

There is then a much smaller second group of hearts that do not exhibit biventricular atrioventricular connections, having as their unifying feature the fact that the atria are joined to only one ventricle. Thus, the hearts have univentricular atrioventricular connections.[20] In this group, all variants can exist irrespective of whether the atrial appendages are lateralized or isomeric. The junctional morphologies making up the group are double-inlet ventricle and absence of either the right or the left atrioventricular connection (Fig. 59-25). With any of these patterns,[21] the atria can be connected to a dominant left ventricle, a dominant right ventricle, or a solitary and indeterminate ventricle. When the atria are connected to either a dominant left or a right ventricle, the complementary ventricle is incomplete and hypoplastic, since of necessity it will lack at least the greater part of its inlet portion. Incomplete right ventricles, as found with the atria, are connected to a dominant left ventricle and are always positioned anterosuperiorly relative to the ventricular mass, although they may be either right- or left-sided (Fig. 59-26, right). Incomplete left ventricles, as seen in the presence of univentricular connection to a dominant right ventricle, are always positioned posteroinferiorly, but again may be either right- or left-sided (Fig. 59-26, left). The feature of solitary and indeterminate ventricles is that they do not possess second ventricles.

The arrangement of the atrioventricular valves depends on the number of atrioventricular junctions. In the setting of concordant, discordant, ambiguous, and double-inlet connections, the atria are joined across two atrioventricular

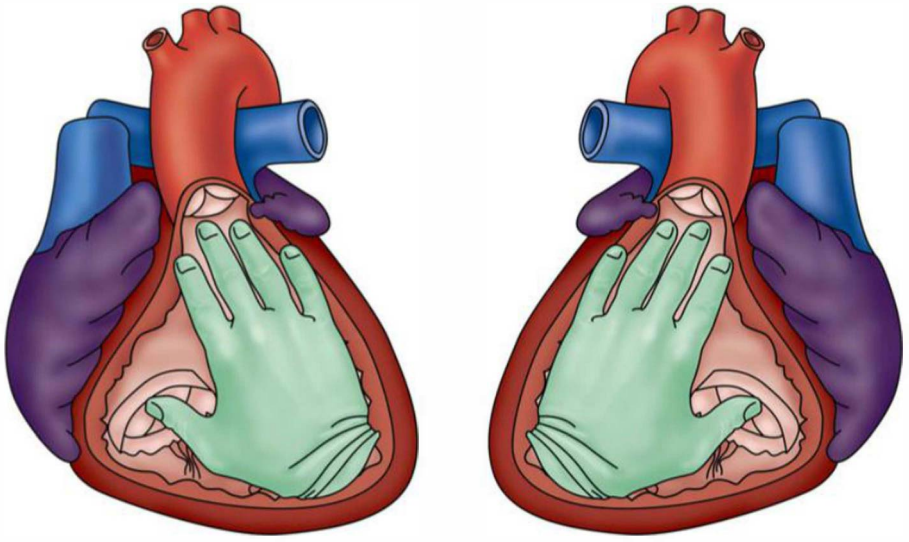

**FIGURE 59-24** The two patterns of ventricular topology, which can be likened to the palms of the hands placed on the septal surfaces of the right ventricles.

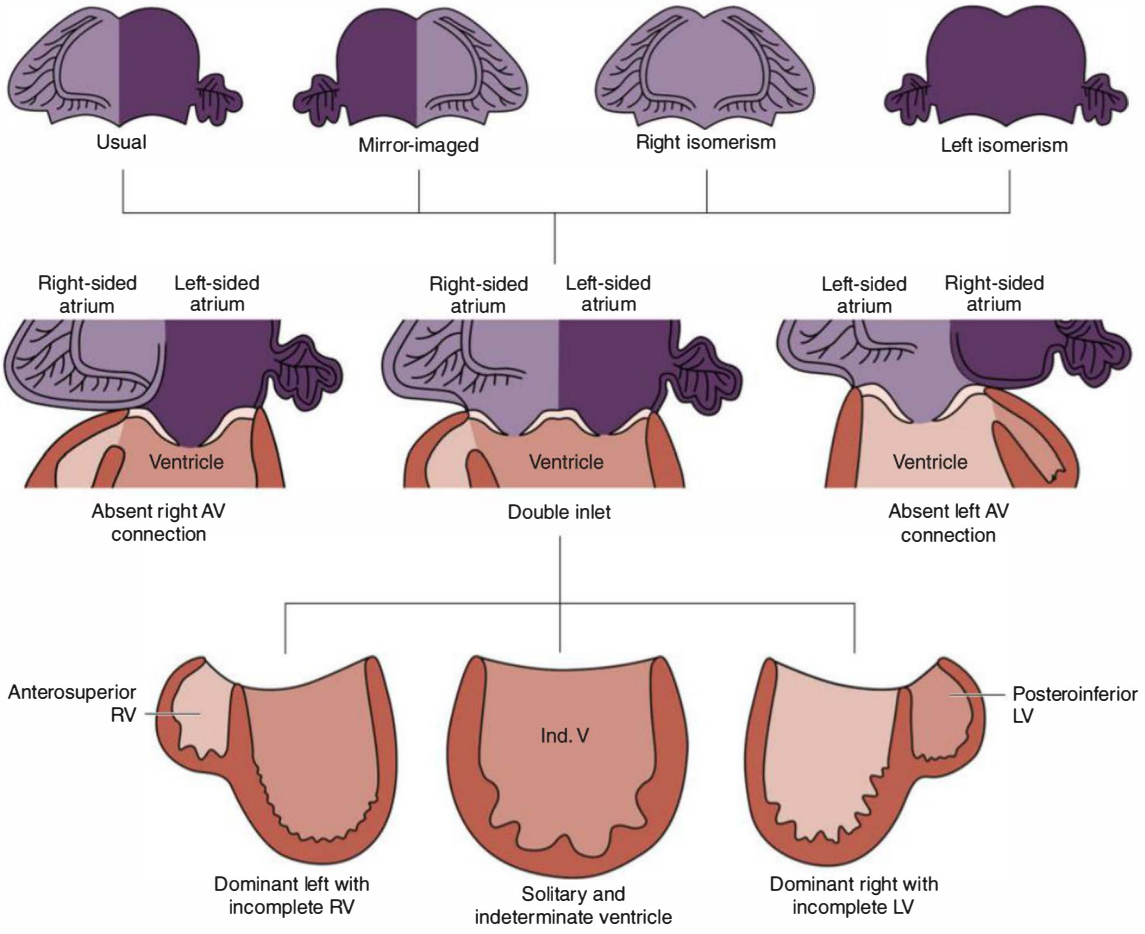

**FIGURE 59-25** The arrangements that produce univentricular atrioventricular connections.

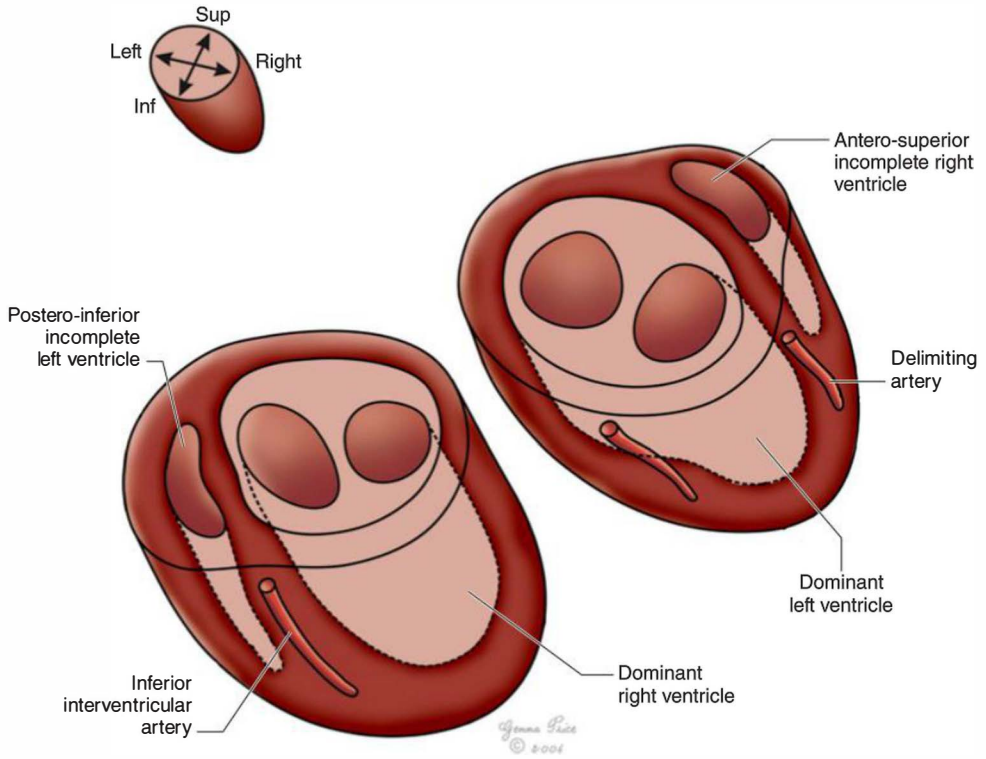

**FIGURE 59-26** The drawing shows how incomplete right ventricles are always found anterosuperiorly relative to a dominant left ventricle, albeit in right- or left-sided position (upper panels), whereas incomplete left ventricles a re positioned inferoposteriorly relative to dominant right ventricles, but again can be left- or right-sided (lower panels).

junctions to the ventricular mass. The dual atrioventricular junctions, however, can be guarded by two separate valves (Fig. 59-11) or by a common atrioventricular valve (Fig. 59-14). One of two valves, or rarely both, may straddle the ventricular septum when the tension apparatus is attached on both sides of the septum. When a valve straddles, usually its junction also overrides the septum. The degree of this override determines the commitment of the valve to the two ventricles. For the purposes of categorization of the precise connection present in such hearts, the overriding valve is assigned to the ventricle connected to its greater part. Common valves usually straddle, but not always. A common valve, nonetheless, always guards two atrioventricular junctions (Fig. 59-13), so note must be taken of this feature in assessing the degree of override. When there are two valves, it is also possible for one of the valves to be imperforate. This morphology must be distinguished from absence of an atrioventricular connection, since both patterns produce atrioventricular valve atresia.[22] When one atrioventricular connection is absent, the modes of connection of the persisting junction are strictly limited. The atrioventricular valve may either be exclusively connected to one ventricle or alternatively straddle or override.[23] The latter arrangement gives a connection that is uniatrial but biventricular (Fig. 59-27).

## Variations at the Ventriculoarterial Junctions

In analyzing the ventriculoarterial junctions, it is again necessary to distinguish between the specific junctional morphology and the structure of the arterial valve or valves guarding the junctions. At this level, attention should also be paid to

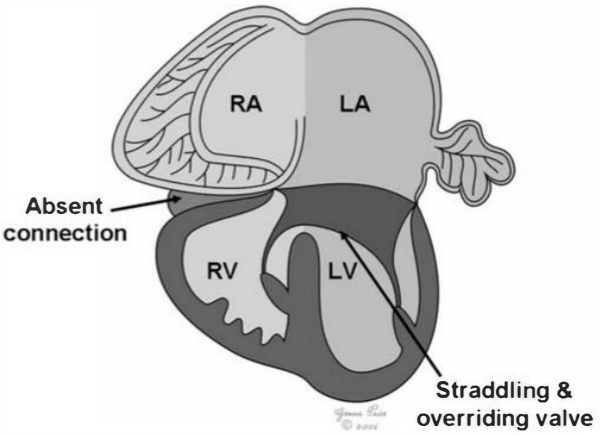

**FIGURE 59-27** The drawing illustrates the uniatrial but biventricular atrioventricular connection.

arterial relationships as well as the morphology of the ventricular outflow tracts (so-called infundibular or conal anatomy).

The ventriculoarterial connections are concordant when the aorta takes origin from the left ventricle and the pulmonary trunk from the right ventricle. When the aorta arises from the right ventricle and the pulmonary trunk from the left ventricle, the ventriculoarterial connections are discordant. These descriptions hold good irrespective of whether the ventricles themselves are complete or incomplete. Double outlet exists when the larger parts of both ventriculoarterial junctions take origin from the same ventricle, which can be of right, left, or solitary and indeterminate morphology. Single outlet from the heart describes the situation in which only one patent arterial trunk can be traced from the ventricular mass. The trunk may be common or solitary (Fig. 59-21) or, alternatively, it may be an aortic trunk with pulmonary atresia or a pulmonary trunk with aortic atresia. Because arterial valves lack tension apparatus, they cannot straddle. Thus, variations in valvar morphology are more limited than for the atrioventricular valves. Furthermore, a common arterial valve exists only when there is a common arterial trunk. When there are two arterial valves, however, one of them may be imperforate. One or both may also override the septum. As with overriding atrioventricular valves, the precise connection of an overriding arterial valve is determined by using the "50 percent" rule.

Arterial interrelationships are of no significance in determining the fashion in which the trunks take their origin from the ventricular mass. Indeed, it is impossible to infer the ventricular connection of the intrapericardial arterial trunks from their relationships. Relationships can be of help in predicting connections. For example, a right-sided and anterior aorta is seen most frequently with concordant atrioventricular and discordant ventriculoarterial connections. At best, however, such associations are no more than a guide to the possibility of abnormal connections. In describing the abnormal relationships, it is also necessary to account for both the positions of the arterial valves and for the orientation of the ascending portions of the arterial trunks. Relationships can be described by accounting for the position of the aortic valve relative to the pulmonary valve, taking note of right/left and anterior/posterior coordinates. For the arterial trunks, the possibilities are for the pulmonary trunk to spiral around the aorta toward its bifurcation, or else for the trunks to ascend in parallel fashion. Combining these two variables makes it an easy matter to describe all anticipated patterns of arterial interrelationships.

In the past, great emphasis was placed on the role of the bilateral conus, or bilateral infundibulum, in diagnosis. Again, however, there is no specificity in these findings. Each arterial valve can potentially be supported by a complete muscular infundibulum irrespective of the ventriculoarterial connection. It is more important, therefore, to analyze the infundibular components. There are three parts of significance.[15] The first separates the arterial valves and their subvalvar outflow tracts from each other. This structure is the muscular outlet—the infundibular or conal septum. The second part is the free parietal component of the ventricular wall. The third part is the inner heart curvature of the ventricles between the atrium and the great arterial trunks. This muscular fold separates the arterial valves from the atrioventricular valves and is well described as the ventriculoinfundibular fold. The most frequent variability in infundibular morphology depends on the integrity of this fold. When it is intact, then there is discontinuity between the atrioventricular and arterial valvar leaflets; in other words there is usually a complete muscular infundibulum or indeed bilateral infundibula (Fig. 59-19B). When the fold is deficient, there is continuity between the leaflets of the atrioventricular and arterial valves, and part of the infundibulum is deficient (Fig. 59-19B). We purposely use the term "usually," since it is rarely possible for the ventriculoinfundibular fold to be intact, producing arterial–atrioventricular discontinuity, and yet for the outlet septum to be deficient, permitting valvar continuity between the leaflets of the aortic and pulmonary valves. In this setting, the muscular infundibula would be incomplete. The integrity of the ventricular outflow tracts, therefore, depends on the morphology of both the ventriculoinfundibular fold and the outlet septum. The interrelationship between these structures is well demonstrated in the "supracristal ventricular septal defect." In the past, such defects were held to be "supracristal" because they were positioned superiorly relative to the so-called septal band (Fig. 59-28A). But the allegedly infracristal defects (Fig. 59-28A) are also positioned superiorly relative to this "band." It is because of such difficulties than we believe it is better to describe the septal band as the septomarginal trabeculation, this being an integral component of the muscular ventricular septum. Nowadays, fortunately, ventricular septal defects are more usually described as being perimembranous, muscular, or doubly committed and subarterial.[24] It is failure of muscularization of the outlet septum, combined with failure of formation of the subpulmonary infundibulum, which is the phenotypic feature of the doubly committed, or supracristal, defect (Fig. 59-28B). There is a common ventriculoarterial junction, albeit guarded by separate aortic and pulmonary valves. The lesion is closely related, therefore, to a common arterial trunk (Fig. 59-29), albeit that the doubly committed defect can be found when both arterial trunks arise from the right ventricle or even when they take their origin predominantly from the left ventricle. Because of this variation, it has been suggested that the lesion would best be described as "double outlet both ventricles."[25]

## Subsequent Steps in Sequential Analysis

The analysis described thus far accounts only for the segmental combination of the heart. In most instances, this will be normal. But it will have cost the surgeon nothing to prove this normality. Indeed, it is essential to do so. Having established the segmental pattern, analysis is concluded by assessing all the associated defects present. This is also best done in segmental fashion, commencing by confirming the normality of the venoatrial connections. Attention can then be

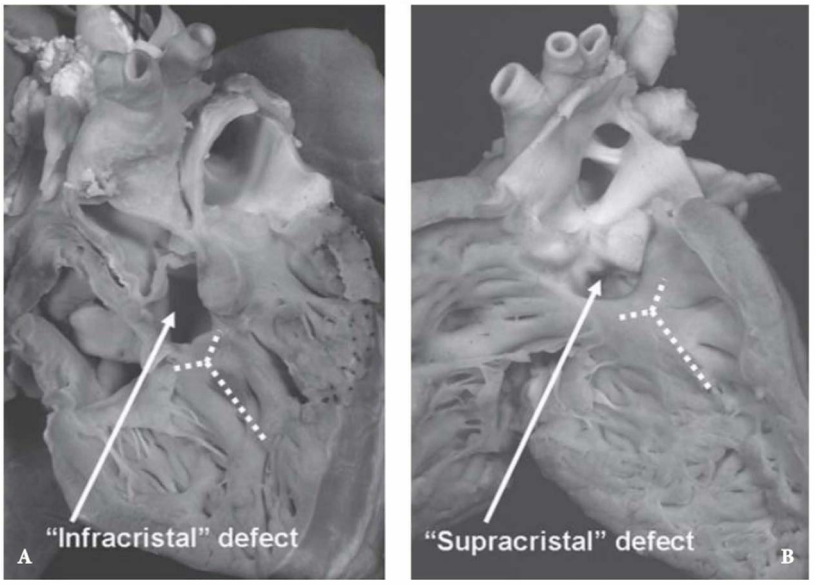

**FIGURE 59-28** The "supracristal" defect (**B**) is compared with the allegedly "infracristal" variant (**A**); in reality both defects are located within the limbs of the "septal band" or septomarginal trabeculation (dotted Y). The phenotypic feature of the supracristal defect, which is doubly committed and juxta-arterial, is failure of muscularization of the outlet septum and failure to form the subpulmonary infundibulum. Because of this, there is a common ventriculoarterial junction.

directed to the atrial segment, the ventricular segment, and the arterial segment in turn, at the same time looking for any junctional malformations that may not have been accounted for during the analysis of the connections. Then the anatomy of the aortic and pulmonary pathways is assessed. In this way, any congenital cardiac lesion or combination of lesions, however simple or complex, is accounted for and understood in the segmental setting of the heart itself. Separate description is then provided for the location of the heart, the direction of its apex, and the arrangement of the thoracic and abdominal organs, taking care to describe each system separately when discrepancies from the anticipated patterns are encountered. To the best of our knowledge, it has proved possible to describe and categorize in unambiguous fashion all lesions thus far known and encountered.

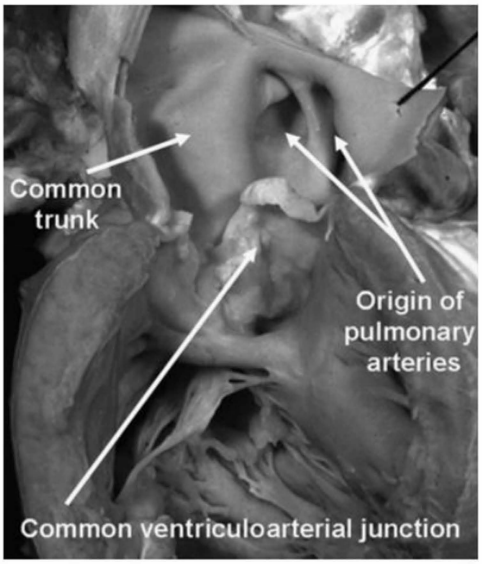

**FIGURE 59-29** The picture shows the doubly committed ventricular septal defect seen in the setting of a common arterial trunk. Note the similarity to the defect shown in Figure 59-28B. The phenotypic feature of both hearts is the common ventriculoarterial junction, albeit guarded by separate aortic and tricuspid valves in the heart shown in Figure 59-28B.

## ACKNOWLEDGMENT

The research on which our account is based has been supported over a period of 30 years by the British Heart Foundation together with the Joseph Levy Foundation. Research at the Institute of Child Health and Great Ormond Street Hospital for Children NHS Trust benefits from R&D funding received from the NHS Executive. The text of this chapter is based upon a comparable account written for the textbook edited by Gardner and Spray.[26] The illustrations are adapted from the third edition of *Surgical Anatomy of the Heart*.[27]

# Perioperative Critical Care of the Pediatric Cardiac Surgical Patient

*Stacie B. Peddy*
*Marissa A. Brunetti*
*Jamie McElrath Schwartz*

## INTRODUCTION

Perioperative care of the pediatric cardiac surgical patient requires a multidisciplinary team that includes cardiologists, cardiothoracic surgeons, anesthesiologists, and intensivists as well as multiple other support staff. A well-functioning system requires coordinated effort and communication. This chapter focuses on common perioperative critical care challenges encountered in the care of pediatric cardiac surgical patients, with emphasis on physiologic basis, diagnosis, and treatment.

## PEDIATRIC CARDIOPULMONARY PHYSIOLOGY

Management of children with congenital heart disease (CHD) requires an understanding of neonatal/pediatric cardiopulmonary physiology and how this differs from the adult. First, neonatal and pediatric cardiac output (CO) is significantly more reliant on heart rate (vs stroke volume) than in the adult patient. As such, these patients will maintain a "normal" blood pressure despite impending shock by increasing heart rate to maintain CO. The neonatal and pediatric myocardium is less compliant (compared to an older child or adult) and is less tolerant of changes in preload and afterload. Oxygen consumption is also increased compared with adult patients, and lung volumes are obviously smaller. In order to maintain oxygen supply in the face of increased consumption with smaller lung volumes, minute ventilation is increased with higher respiratory rates. In addition, infants breathe below their functional residual capacity (FRC), and lung units are collapsed and reopened with each breath. This unique physiology results in low tolerance to apnea and very rapid desaturation.

Neonates also have potential for labile pulmonary vascular resistance (PVR) as they transition from fetal to newborn circulation in the first few days of life. Furthermore, neonatal pulmonary physiology differs from that of an older child because of the increased chest wall compliance, reliance on the diaphragm for optimal mechanics, and increased propensity for atelectasis. The preoperative management of neonates with significant unrepaired CHD requires an understanding of both general neonatal cardiopulmonary physiology as well as the specific impact of the particular lesion(s).

## PREOPERATIVE CARE

Although the majority of preoperative care of the pediatric patient with CHD is in the outpatient setting, the neonate with significant unrepaired CHD may require intensive care assessment and monitoring. Goals of preoperative care include optimization of hemodynamics to ensure adequate CO and normal end-organ function while awaiting corrective or palliative neonatal surgery.

In general, infants requiring neonatal surgery can usually be classified into three preoperative "states": single ventricle (SV) physiology, transposition physiology, and ductal-dependent pulmonary or systemic blood flow.

1. Many complex congenital heart lesions have **SV physiology,** where there is complete mixing of systemic and pulmonary venous return and thus aortic (AO) saturation equals pulmonary artery (PA) saturation. The total ventricular output is divided between two competing parallel circuits whose flow (pulmonary/systemic) is determined by the resistances of each system. Hypoplastic left heart syndrome (HLHS) typifies SV physiology. Acceptable balance between pulmonary and systemic outputs will provide enough pulmonary blood flow for adequate oxygen delivery without excessive volume load on the SV as

well as adequate systemic output and end-organ function. However, since the two circuits are in parallel, too much blood flow to one system occurs at the expense of the other. The neonate with HLHS requires an unrestrictive atrial-level communication to unload the left atrium and ductal patency [via prostaglandin ($PGE_1$) infusion] to maintain systemic outflow. Too much pulmonary blood flow, manifested as "high saturations," will occur at the expense of systemic output; these infants are at risk for renal insufficiency (due to decreased renal perfusion) and necrotizing enterocolitis (due to decreased splanchnic perfusion).

2. Transposition of the great arteries (TGA), where the aorta arises from the right ventricle (RV) and the PA arises from the left ventricle (LV) (PA saturation is greater than the AO saturation) mandates mixing. This intercirculatory mixing can occur at any of the following levels: intracardiac (via a patent foramen ovale, atrial septal defect or ventricular septal defect) and/or extracardiac (via patent ductus arteriosus). Effective pulmonary blood flow (net volume of blood flow passing from systemic circulation to pulmonary circulation, the anatomic right-to-left shunt) and effective systemic blood flow (net volume of blood flow passing from pulmonary circulation to systemic circulation, the anatomic left-to-right shunt) is the intercirculatory mixing upon which survival depends. Extracardiac intercirculatory mixing is maintained by ductal patency with a $PGE_1$ infusion, while inadequate intracardiac mixing is palliated with a balloon atrial septostomy (BAS) when needed.
3. Finally, **lesions where either pulmonary or systemic blood flow depends on ductal patency** require a $PGE_1$ infusion until palliative or corrective neonatal surgery takes place. Ductal-dependent pulmonary blood flow lesions include tetralogy of Fallot with severe right ventricular outflow obstruction, tetralogy of Fallot with pulmonary atresia, and critical pulmonary stenosis. Critical coarctation of the aorta is another example of a lesion associated with ductal-dependent systemic blood flow.

Indications for preoperative mechanical ventilation in the neonate with unrepaired CHD are commonly due to pulmonary and/or cardiac issues. Causes of respiratory failure are many and may include prematurity with respiratory distress syndrome, meconium aspiration, or infectious etiologies. Cardiac indications are less common, but may include severe hypoxemia due to inadequate intracardiac mixing (neonate with TGA in need of a BAS) or low CO due to increased pulmonary blood flow at the expense of systemic output in the SV patient.

In addition to optimizing pulmonary and cardiac systems, preoperative care of the neonate with CHD should include evaluation of other associated anomalies, including a genetic evaluation as well as head, abdominal, and renal ultrasound where indicated. Blood analysis for genetic abnormalities (including fluorescence in situ hybridization – FISH test) is best performed prior to blood transfusion associated with cardiopulmonary bypass (CPB).

# POSTOPERATIVE CARE

## Admission to the ICU

All children undergoing surgical repair for CHD are admitted to an intensive care unit (ICU) postoperatively. Upon admission, the patient will be quickly assessed by an intensivist for hemodynamic stability including heart rate, heart rhythm, clinical CO, perfusion, adequacy of sedation and/or pain control, and respiratory dynamics. Blood work is sent on admission to assess ventilation and oxygenation, electrolytes, hematocrit, platelet count, and coagulation. A chest x-ray is taken to ensure adequate lung inflation, normal heart size and to confirm proper placement of all lines, tubes, and wires.

Verbal report is given by cardiac surgeons and anesthesiologists to the ICU team upon transfer of care. Report should include the patient's preoperative cardiac anatomy; other significant medical problems; preoperative medications; intraoperative findings and procedure done, including duration of CPB, cross-clamp and deep hypothermic circulatory arrest (DHCA); location of arterial and venous lines; medications required intraoperatively; complications; occurrence of arrhythmias; transesophageal echocardiographic findings; plan, including vital sign goals and anticoagulation plans when applicable (see Table 60-1, sign out components). Patient handover systems and checklists have been studied during transfer of care of cardiac patients and are encouraged to enhance quality of communication and patient safety.[1]

**TABLE 60-1: Components of Postoperative Report**

**Patient name**
**Age**
**Weight**
**Allergies**
**Surgical procedure**

| Preoperative data | Intraoperative Data | Postoperative Data and Plans |
|---|---|---|
| Preoperative diagnosis and anatomy<br>Previous surgeries | Induction and intubation<br>Lines/catheters/chest tubes | Post-CPB rhythm/pacing need<br>Postoperative TEE findings—LV and RV function, residual lesions, others |
| Past medical history<br>Comorbidities<br>Preoperative medications and symptoms | Intraoperative medications<br>Surgical findings/details/complications<br>CPB/XC/CA/MUFF<br>Lowest temperature | Vital sign goals (HR, BP, CVP, $Spo_2$)<br>Anticoagulation plans<br>Anticipated problems<br>Extubation plans |

BP, blood pressure; CA, circulatory arrest; CPB, cardiopulmonary bypass; CVP, central venous pressure; HR, heart rate; LV, left ventricle; MUFF, modified ultrafiltration; RV, right ventricle; $Spo_2$, oxygen saturation; TEE, transesophogeal echocardiogram; XC, cross-clamp.

## Hemodynamic Monitoring and Cardiac Support

Intensive care of neonatal and pediatric patients relies on both indirect assessments of CO and oxygen delivery as well as direct hemodynamic monitoring. Continuous monitoring of heart rate, respiratory rate, blood pressure, and pulse oximetry is standard. Depending on patient age and anatomy, peripheral (radial, ulnar) or central (umbilical artery or femoral artery) arterial blood pressure monitoring is performed. Central lines are usually placed in the internal jugular, subclavian, or femoral vein after induction of anesthesia, while direct atrial lines may be placed intraoperatively. In neonates, umbilical venous lines are often placed postnatally. Central lines are used for administration of vasoactive infusions, fluids, parenteral nutrition and for measurement of central venous pressures. If the central line tip is positioned at the superior cavo–atrial junction, it can be used to sample mixed venous saturation as well.

### POSTOPERATIVE HYPOTENSION

Hypotension in the postoperative period is common and multifactorial. The more common causes are listed in Table 60-2, along with changes in hemodynamics that are unique to each etiology.

### LOW CARDIAC OUTPUT SYNDROME

Low cardiac output syndrome (LCOS) is one of the most important predictors of poor outcome after surgery for CHD.[2] LCOS is a fall in CO with a commensurate increase in systemic vascular resistance (SVR) and PVR, typically occurring between 6 and 18 h after surgery.[3] Clinical signs of LCOS include tachycardia, oliguria, delayed capillary refill, metabolic acidosis, hypotension, and low mixed venous oxygen saturation. The mainstay of treatment of LCOS is anticipation and early identification. With predictable decrease in CO and increased PVR and SVR, afterload reduction (milrinone) and inotropic support oppose this trend.[4]

**TABLE 60-2: Diagnosis of Postoperative Hypotension**

| Clinical Condition | BP | HR | RA/CVP | LA |
|---|---|---|---|---|
| Tamponade | ↓ | ↑[a] | ↑ | ↑ |
| LCOS (with euvolemia) | ↓ | ↑[a] | ↑ | ↑ |
| Hypovolemia | ↔↓ | ↑[a] | ↓ | ↓ |
| AV dissociation | ↓ | AV dissociation | ↑ | ↑ |

AV, atrioventricular; BP, blood pressure; CVP, central venous pressure; HR, heart rate; LA, left atrial pressure; LCOS, low cardiac output syndrome; RA, right atrial pressure.

[a]Sinus tachycardia.

### POSTOPERATIVE VASOACTIVE MEDICATIONS

Inotropic support is a mainstay of postoperative care. Table 60-3 lists the most common vasoactive medications used for the postoperative pediatric cardiac surgical patient.

## Arrhythmias

Arrhythmias are a common complication after surgical repair of CHD, with a reported incidence of 15 to 30 percent.[5–7] Postoperative arrhythmia prolongs ICU stay and increases morbidity and mortality. Various studies have looked at risk factors for arrhythmias and found age, underlying anatomy and type of repair, duration of CPB, and cross-clamp time to be possible risk factors.[5–7] The most common postoperative arrhythmias are junctional ectopic tachycardia (JET), complete heart block, ventricular tachycardia (VT), and supraventricular tachycardia.

The first step in managing a patient thought to have an arrhythmia is to obtain a 12-lead electrocardiogram (EKG). This should be reviewed by a pediatric intensivist or cardiologist to determine the precise type of rhythm present. If the rhythm is complex, a pediatric electrophysiologist may be consulted. If the patient is hemodynamically unstable as evidenced by poor perfusion on exam, low blood pressure, change in mental status, and metabolic acidosis, prompt diagnosis should be made so that correct treatment may be immediately initiated.

### JUNCTIONAL ECTOPIC TACHYCARDIA

JET is one of the most prevalent postoperative arrhythmias. It is an automatic tachycardia that should be suspected when a patient has a gradual increase to heart rates out of range for age, usually greater than 170 beats/min, over minutes to hours. It typically occurs in the first 24 postoperative hours, but may have a later onset. The exact cause is unknown but it is thought to be due to direct or indirect atrioventricular (AV) node injury, including shear forces and edema. Surgery near the AV node is not required as evidenced by the fact that JET may occur after repair of total anomalous pulmonary venous return, Blalock-Taussig shunts, and Glenn and Fontan procedures.

The EKG shows a narrow complex tachycardia with AV dissociation as evidenced by a ventricular rate faster than atrial rate. P waves may or may not be visualized on the EKG depending upon the speed of ventricular rate. If a central venous line is present, cannon A waves are noted on waveform analysis, representing atrial contraction against a closed tricuspid valve. Differential diagnosis of this narrow complex tachycardia includes sinus tachycardia and supraventricular tachycardia. If the diagnosis is unclear and temporary pacing wires are present, an atrial EKG often aids in the diagnosis. The key pathophysiologic finding in JET is loss of AV synchrony. Postoperative patients have decreased CO secondary to cardioplegia, inflammatory response to CPB, and ischemia-reperfusion injury. Loss of atrial synchrony

**TABLE 60-3: Commonly Used Vasoactive Medications**

| Drug | Mechanism | Inotropy | Chronotropy | SVR | PVR | Dose | Side Effects |
|---|---|---|---|---|---|---|---|
| Amiodarone | Class III antiarrhythmic, but with class IB, II and IV effects | ↔↓ | ↔ | ↔ | ↔ | Load: 1–15 mg/kg<br>Infusion: 5–10 μg/kg/min | Slows repolarization and AV conduction, prolongs QTc |
| Epinephrine | $\alpha_1$- and $\beta_{1,2}$-agonist | + | + | | ↑ | Bolus: 1–10 μg/kg<br>Infusion: 0.05–2 μg/kg/min | Hypertension, tachycardia, arrhythmias, myocardial necrosis |
| Dopamine | Dopaminergic$_1$-, $\alpha_1$- and $\beta_1$-agonist | ↔ | ↔ | ↑ | ↑ | Infusion: 0.5–20 μg/kg/min | Arrhythmias |
| Dobutamine | $\beta_1$-agonist | + | ↔ | ↔ | ↔ | Infusion: 0.5–10 μg/kg/min | Arrhythmias |
| Isoproterenol | $\beta_{1,2}$-agonist | + | + | ↑ | ↓ | Infusion: 0.05–1 μg/kg/min | Arrhythmias |
| Milrinone | Phosphodiesterase-3 inhibitor | + | ↔ | ↓ | ↓ | Load:50 μg/kg<br>Infusion: 0.25–1 μg/kg/min | Hypotension |
| Norepinephrine | $\alpha_1$- >>> $\beta_1$-agonist | + | + | ↑ | ↑ | Infusion: 0.05–0.1 μg/kg/min | Arrhythmias, hypertension |
| Sildenafil | Phosphodiesterase-5 inhibitor | ↔ | ↔ | ↔ | ↓ | PO/NG, starting dose 0.25/mg/kg Q6 h and titrate | Hypotension |
| Vasopression | V 1a agonist | ↔ | ↔ | ↑ | ↔ | Infusion: 0.5–2 mU/kg/min | Bradycardia, hyponatremia |

AV, atrioventricular; QTc, corrected QT interval.

Adapted from Everett AD, Lim DS: *Illustrated Field Guide to Congenital Heart Disease and Repair*. Scientific Software Solutions, 2004–2013.

will further decrease CO and may lead to hypotension. Treatment focuses on decreasing catecholamine infusion, as JET is catecholamine-sensitive. Sympathomimetic drugs, such as epinephrine and dopamine, should be quickly discontinued as they may sustain arrhythmia and cause further hypotension. Patients should be sedated and hyperthermia should be aggressively treated. Active cooling may be necessary in refractory and symptomatic cases. Medical therapy includes amiodarone or procainamide to decrease conduction and control ventricular rate. Both drugs should be administered carefully as hypotension may occur. Atrial pacing may also be used to restore AV synchrony. JET is usually self-limited, resolving within the first postoperative week.

## HEART BLOCK

Heart block is another common postoperative arrhythmia, with complete AV block being the most significant. It results from damage at or below the level of the AV node. EKG shows complete dissociation of the atrial rate from the ventricular rate. The QRS complex may be narrow or wide depending upon where in the ventricular conduction system the injury occurs; injury at the AV node itself will lead to a narrow complex QRS whereas injury to the bundle of His will lead to a wide-complex QRS. Symptoms depend on ventricular rate since this controls CO in these patients. If ventricular rate is sufficient, patients may be asymptomatic. If ventricular rate is low for age, the patient may have signs and symptoms of low CO. For symptomatic patients, AV pacing is the mainstay of treatment. Pharmacologic therapy with sympathomimetics or anticholinergics may increase the atrial rate but will not restore AV synchrony and is therefore not indicated. Most cases of postoperative complete AV block are temporary, and resolve within the first 1 to 2 postoperative weeks. For those that do not resolve, placement of a permanent pacemaker may be necessary.

## VENTRICULAR TACHYCARDIA

VT is another form of arrhythmia seen postoperatively. It is a wide-complex tachycardia and may be nonsustained (resolving spontaneously) or sustained. It may be stable VT with no effects on the patient's hemodynamic status or unstable with complete cardiovascular collapse. Stable VT is treated with lidocaine and/or amiodarone. Correction of electrolyte abnormalities and acid–base status is strongly encouraged. Unstable VT is treated according to Pediatric Advanced Life Support (PALS) guidelines, including rapid defibrillation and chest compressions followed by epinephrine, amiodarone, and/or lidocaine.

## PACING

Many patients have temporary pacing wires placed during cardiac surgery. In particular, patients at risk for postoperative arrhythmias or heart block benefit from pacing. Pacing

wires can be diagnostic (for atrial EKG to determine origin of tachycardias) or therapeutic (pacing during heart block or overdrive pacing for tachycardias). Consultation with a cardiologist or intensivist may be warranted for analysis and management of arrhythmias or complex cardiac pacing.

## Pulmonary Management and Mechanical Ventilation

Ventilation and respiratory mechanics exert strong influences on the hemodynamics of children with CHD, especially after palliative or reparative operations. The effect of positive-pressure ventilation on cardiac performance represents the concept of cardiopulmonary interaction. Increased intrathoracic pressure increases right atrial (RA) pressure, which in turn decreases venous return to the RA, RV preload, and RV output. Effects on the left side of the heart are different. Increased intrathoracic pressure decreases LV transmural pressure, which decreases LV afterload and increases LV output. The impact of positive pressure is accentuated in the heart with compromised or failing function, such as in postoperative LCOS. In the palliated univentricular heart, the effects are somewhat different. For example, increased intrathoracic pressure increases the common atrial pressure, which increases the transpulmonary gradient, which will lead to decreased passive pulmonary blood flow in the postoperative cavopulmonary anastomosis/Glenn or hemi-Fontan patients.

PVR is defined as resistance to blood flow within the lungs, which is influenced by the anatomy of the vascular bed, vascular tone, pulmonary blood flow, and left atrial pressure. Understanding how the manipulation of PVR can influence CO is crucial to the perioperative management of children with complex CHD. Conditions that increase PVR include hypoxia, hypercarbia/acidosis, polycythemia, atelectasis, hyperinflation, CPB, and agitation. Conditions that decrease PVR include oxygen, alkalosis, normal FRC, low hematocrit, and pulmonary vasodilators (inhaled nitric oxide, sildenafil, etc.). Patients at risk for postoperative pulmonary hypertension include patients with increased PVR preoperatively, infants in the first several days of life, patients with pulmonary venous hypertension (e.g., total anomalous pulmonary venous return), older children with uncorrected CHD leading to increased PVR, patients with systemic PA pressure, and infants with Down syndrome. Treatment and prevention of pulmonary hypertension include adequate analgesia and sedation, oxygen, appropriate amount of PEEP to maintain FRC, serum alkalinization, inhaled nitric oxide, milrinone, and avoidance of unnecessary endotracheal tube suctioning. Lung volumes above or below FRC lead to increased PVR, which increases RV afterload and can lead to decreased RV function. In the palliated univentricular heart, the effects are somewhat more complex. For example, lung volumes above or below FRC increase PVR, which decreases shunt flow in postoperative stage I Norwood patients and passive PBF in postoperative cavopulmonary anastomosis/Glenn or hemi-Fontan patients.

## Neurologic Monitoring and Sequelae

As surgical techniques have improved over the past decades, mortality associated with CHD has decreased significantly. Comorbidities and long-term outcomes of these patients have now become areas of great interest. Neurologic protection and cognitive development are two such areas, as follow-up of these patients has revealed a high prevalence of neurologic injury. Studies have shown that approximately 50 percent of school-age children who have undergone cardiac surgery as infants have abnormalities on formal testing.[8] Long-term follow-up studies have revealed deficits with speech and language, inattention and hyperactivity, motor skills, memory, problem-solving, learning disorders, and impaired executive functioning, all affecting quality of life.

In 2002, Mahle et al. published a study in which infants with CHD underwent preoperative and postoperative magnetic resonance imaging (MRI).[9] Twenty-five percent of the infants had preoperative abnormalities; early postoperative MRI showed, however, new periventricular leucomalacia in 48 percent, new infarct in 19 percent, and new parenchymal hemorrhage in 33 percent. In summary, new lesions or worsening of preoperative lesions occurred in 67 percent of patients. The causes of neurologic injury in this population are thought to be multifactorial. Preoperative factors include genetics, disturbed cerebral blood flow secondary to cardiac disease and abnormal brain development in utero. Intraoperative factors include exposure to anesthesia, CPB and, in some cases, DHCA, altered cerebral autoregulation/perfusion, and embolism. Postoperative factors include low CO, sedation, possible infection, and emboli. CPB is an extremely important factor when considering intraoperative brain injury. Conditions encountered on bypass include induced hypothermia, transfusion of blood products, hemodilution, altered blood flow characteristics, hypoxia-ischemia, inflammatory response, and reperfusion injury.

Given that neurologic injury is now widely acknowledged in this population, neuroprotection in the perioperative period has become an important focus of study.[10] Detection of injury remains difficult, however. Patients are sedated and often hemodynamically unstable, making clinical and radiographic assessment difficult. Although a head ultrasound can be performed at the bedside, it remains only as a viable option in infants with an open fontanelle. Computed tomography provides more detail than head ultrasound, but MRI is nevertheless the gold standard, with clear elucidation of gray and white matter injury in both cerebral cortex and brain stem. MRI, however, requires transport to a scanner and anesthesia in an often unstable patient. It also does not allow real-time detection of changes during perioperative management.

Near-infrared spectroscopy (NIRS) is one method being used to monitor perioperative brain perfusion. NIRS uses wavelengths of light to measure oxyhemoglobin saturation of tissue approximately two centimeters beneath the probe. It is a local marker of brain oxygenation and is used intra- and postoperatively at many institutions to give information on

cerebral perfusion. It is thought to be an early warning sign of neurologic injury. Electroencephalograms (EEG) have been widely studied for the detection of brain injury as evidenced by seizures; however, the results are varied. In addition, there is concern that brain injury is detected once cellular damage has already occurred. Therefore, EEG is not routinely used for the acute detection of brain injury. Biomarkers are another area of intense study as they may be rapid surrogates of injury that can easily be obtained from serum and indicate the presence and extent of injury as well as the response to potential therapies. Biomarkers such as neuron-specific enolase and S100β have been studied and found not to be specific for brain injury. Newer biomarkers such as glial fibrillary acidic protein (G-FAP), ubiquitin C-terminal hydrolase 1, and phosphorylated axonal neurofilament heavy chain show promise as brain-specific biomarkers.

## Hemostasis and Coagulopathy

Cardiac surgery and CPB both require and cause coagulopathy. The impact of CPB on hemostasis is greater in the pediatric patient than in adults and postoperative bleeding is a significant problem. Risk factors for postoperative bleeding and transfusion include younger age, higher preoperative hematocrit, complexity of surgery, duration of DHCA, low core body temperature, and platelet count during CPB.[11] Causes include activation and consumption of clotting factors, hemodilution, platelet dysfunction, inflammatory mediators, and effects of medications.

CPB has been shown to activate the clotting cascade via intrinsic (contact) and extrinsic pathways, causing thrombin formation and decreases in fibrinogen and platelet number and function. Hypofibrinogenemia and thrombocytopenia have been associated with increased intraoperative and postoperative blood loss in children undergoing cardiac surgery.[12] Platelets are impacted in multiple ways during pediatric cardiac surgery. Platelets are significantly decreased by the trauma of CPB and hemodilution. Platelet function is decreased in children by CPB, hypothermia, heparin, and protamine. In addition, CPB-stimulated proinflammatory mediators such as interleukin-1, tumor necrosis factor, and endotoxin activate and impair the coagulation cascade.[13]

Younger age, and smaller weight and body surface area have been shown in multiple studies to be risk factors for postoperative bleeding and transfusion.[11,14] This is presumably due to the greater magnitude of hemodilution and CPB effect on smaller children as well as intrinsic coagulation abnormalities in neonates and small infants.

Diagnosis and management of postoperative coagulopathy in neonates and children begin with a thorough evaluation of laboratory data immediately on admission to the ICU. Hemoglobin, platelet count, prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen concentration should be obtained. Thromboelastography (TEG) can provide an evaluation of the comprehensive system of clot formation and breakdown. In anticipation of laboratory data, immediate drainage from chest tubes should be replaced empirically, typically with packed red blood cells and fresh frozen plasma (FFP) or fresh whole blood. In the patient with severe or persistent bleeding, early platelet administration may be prudent considering their importance in clot formation and the high likelihood of thrombocytopenia in the infant and child with significant bleeding after CPB. Similarly, fibrinogen may need repletion with either FFP or cryoprecipitate.

Multiple small case series report off-label use of Factor VIIa for severe bleeding in postoperative cardiac patients. Although most report decreased chest tube output and decrease in PT/PTT without increase in thrombotic complications, caution must be used in administration of this agent to patients with shunts or conduits. Data to support safety of this agent in patients following congenital heart surgery are insufficient.

If severe or persistent bleeding is present after correction of coagulopathy and repletion of platelets and fibrinogen, reexploration may be warranted.

## Fluid Imbalance/Electrolyte and Renal Management

Despite routine use of modified ultrafiltration after CPB, fluid overload and renal dysfunction are major contributors to morbidity after neonatal and infant surgery.[15] Total body water accumulation is directly proportional to duration of CPB.[3] Use of diuretics is routine in the postoperative period.

Need for renal replacement modalities in the postoperative pediatric patient is not uncommon. Indications include fluid overload, electrolyte abnormalities, and uremia. Renal replacement modalities include peritoneal dialysis, hemodialysis, and continuous arteriovenous or venovenous hemofiltration with or without dialysis. Selection of a renal replacement therapy depends on volume and/or solute to be cleared, patient's age and vascular access, weight, and comorbidities.

The postoperative myocardium is extremely sensitive to electrolyte imbalances. Postoperative care should be attentive to the maintenance of normal serum electrolytes. Hypocalcemia, hypomagnesemia, and hypokalemia should be quickly remedied, as these imbalances may lead to arrhythmias. Use of steroids on CPB can cause postoperative hyperglycemia with a concomitant high output diuresis leading to hypovolemia. Fluid replacement is the treatment. Hyperglycemia is common early after neonatal and pediatric cardiac surgery, particularly after glucocorticoid administration, but will generally resolve without treatment. The significance of hyperglycemia and need for treatment in this patient population is controversial. In a large retrospective review of infants and children undergoing cardiac surgery, hyperglycemia was associated with increased risk of complications such as infection, need for extracorporeal membrane oxygenation (ECMO), lactic acidosis, organ system failure, and death, but this risk was modified by younger age and residual cardiac lesions.[16,17] However, other studies have found that postoperative hyperglycemia is not associated with increased

morbidity or mortality, or does not have a deleterious effect on neurodevelopmental outcomes at 1 year of age.[18–20]

## Infectious Issues

Pediatric cardiac surgical patients are at high risk for infections in the postoperative period. Many surgical patients are neonates with immature immune systems. In addition, postoperative patients may experience immunosuppression secondary to critical illness. These patients also have wounds, central lines, and prosthetic materials used in their repair, which may become colonized with bacteria. One recent study found the prevalence of nosocomial infections in pediatric cardiac surgery patients to be approximately 25 percent.[21] Postoperative infections prolong ICU length of stay and increase morbidity and mortality.

Patients routinely receive perioperative antibiotic coverage to prophylax against skin flora; however, this is discontinued within 24 hours, and longer treatment is not supported. It is common for patients to have fever in the immediately postoperative phase as part of a systemic inflammatory response to bypass; this should resolve within 24 hours. Infection should be considered in any patient who experiences profound hypotension. In addition, if fever continues for greater than 24 hours or resolves and then recurs, an infectious workup should be performed including complete blood count, blood culture, urinalysis and urine culture, and gram stain and culture of respiratory secretions in intubated patients, as well as a complete physical exam. Differential diagnosis of fever in a postoperative patient includes superficial wound infection, mediastinitis, osteomyelitis of the sternum, bacteremia, urinary tract infection, and ventilator-associated pneumonia, or tracheitis in ventilated patients. In addition, during the winter season, viral infections such as respiratory syncytial virus and influenza should be considered. These may be community-acquired in patients presenting for surgery from home or nosocomial. Secretions should be sent for rapid assay and viral culture as part of the infectious workup to rule out viral infection.

Given the prominent use of central lines in this population and the prevalence, morbidity, and mortality associated with catheter-related bloodstream infections in ICU patients, prevention of this nosocomial infection has become an area of interest for those caring for these patients. One recent study looked at risk factors for bloodstream infection in pediatric cardiac ICU patients and found that, in surgical patients, lower admission weight, higher Pediatric Risk of Mortality (PRISM) and Risk Adjustment in Congenital Heart Surgery (RACHS) scores, greater blood product exposure, prolonged mechanical ventilation, and noncardiac comorbidities were risk factors for catheter-related bloodstream infections.[22]

Treatment of postoperative infection depends upon etiology. If bacterial infection is suspected, empiric broad-spectrum antibiotics should be started while the workup is being done. If a bacterial source is found on culture, specific treatment is based on the type of bacteria and the location of infection.

The most important aspect of infections in postoperative patients is prevention. Devices such as central lines and urinary catheters should be placed in a sterile manner. Access to central lines for intermittent medication administration and blood draws should be minimized and all devices should be removed as soon as possible.

Special mention should be given to patients with the DiGeorge syndrome. This is caused by a deletion of the long arm of chromosome 22 and is associated with cono-truncal abnormalities, such as truncus arteriosus and interrupted aortic arch, as well as tetralogy of Fallot. An additional component of the syndrome is T-cell immunodeficiency due to hypoplasia or agenesis of the thymus. Humoral deficiency may also be present. This further predisposes this group of patients to perioperative infections as well as risk of graft versus host disease associated with blood transfusion. If DiGeorge syndrome is confirmed, an immunologist should be consulted for further testing and management.

## Postoperative Cardiopulmonary Arrest

Cardiac arrest (CA) is more common in the patient with cardiac disease than in patients without heart disease but outcomes are better. In a large review of pediatric perioperative CA, the incidence of CA for patients undergoing cardiac procedures was 127 per 10,000 versus 2.9 per 10,000 for noncardiac procedures.[23] Children with CHD are more likely to arrest from cardiovascular causes than children without heart disease, whose CA etiology is primarily respiratory. In the postoperative period, LOCS, arrhythmias, bleeding, and mechanical problems such as shunt occlusion are risks for CA in cardiac patients. In a dedicated pediatric cardiac ICU, survival for cardiac patients receiving cardiopulmonary resuscitation (CPR) following cardiac surgery was reported to be 46 percent, increasing to 53 percent for patients receiving CPR following cardiac surgery.[24]

Treatment of CA requires prompt recognition and CPR of excellent quality. The 2005 American Heart Association (AHA) CPR guidelines stress minimizing chest compression interruption and avoidance of hyperventilation to improve flow to critical organs during CPR. After sternotomy, reopening of the chest provides for evaluation and treatment of tamponade as well as direct cardiac compressions.

Consideration of the patient anatomy, physiology, and surgical procedure must factor in to resuscitation plan during CA following cardiac surgery. In patients with shunt-dependent pulmonary blood flow, shunt occlusion should be entertained, particularly in patients with low end-tidal carbon dioxide despite quality CPR. In addition to standard AHA guidelines, heparin should be considered for treatment of urgent shunt occlusion.

An additional adjunct is mechanical support in the form of rapid deployment ECMO for rescue from CPR (eCPR). eCPR can provide restoration of oxygenation and perfusion to vital organs while the cause of CA is investigated and treated. When CA is recognized promptly and quality CPR initiated, eCPR can lead to very good outcomes, even

**TABLE 60-4: Approaches to Clinical Scenarios in Stages of Single Ventricle Heart Disease Palliation**

| | Stage I—Norwood Procedure | Stage II—Cavopulmonary Anastomosis Glenn or Hemi-Fontan Procedure | Fontan Completion |

in patients who have had CPR for over 30 min and would have otherwise died. A retrospective review of a large single-center experience with eCPR in cardiac patients reported survival to discharge of 51 percent, despite CPR durations of over 30 min in some cases; 75 percent of those had mild-to-no neurologic impairment (see Chapter 87).[25]

## Special Considerations for the Postoperative Single Ventricle Patient

SV physiology encompasses a wide variety of anatomic lesions that have parallel circulations and complete mixing of systemic and pulmonary venous return. Palliation for SV anatomy in most centers is performed via two to three stages, with variability in the initial procedure depending on degree of left ventricular outflow tract obstruction and amount of pulmonary blood flow. The goal of the stage 1 palliation with modified Blalock–Taussig shunt or Sano modification is 3-fold: creation of unobstructed systemic blood flow by construction of a neo-aorta, unobstructed pulmonary venous return by an atrial septectomy, and controlled pulmonary blood flow without PA distortion. The goals of second stage or cavopulmonary anastomosis Glenn/hemi-Fontan procedure are two: volume unloading the SV and creation of passive pulmonary blood flow. The final stage or Fontan completion provides in-series pulmonary and systemic circulations (see Chapter 77). Table 60-4 shows the three stages with their unique postoperative considerations, as well as our approach to low CO and hypoxemia.

## PERIOPERATIVE CRITICAL CARE OF THE PEDIATRIC CARDIAC SURGICAL PATIENT BOARD REVIEW QUESTIONS (CHAPTER 60)

1. Which is correct regarding postoperative arrhythmias?
   A. The incidence is 5 to 10 percent
   B. JET typically occurs after the first 24 h
   C. Most cases of postoperative complete AV block are temporary
   D. VT is a narrow complex tachycardia
   E. Prolonged AO cross-clamp time is not a risk factor
2. Which of the following decreases PVR?
   A. Hypoxia
   B. Acidosis
   C. Polycythemia
   D. Agitation
   E. Sildenafil
3. Which is not a risk factor for postoperative pulmonary hypertension?
   A. Neonatal repair
   B. Total anomalous pulmonary venous return
   C. Older child with uncorrected congenital defect
   D. Patients with normal preoperative PA pressures
   E. Down syndrome
4. Which of the following is not a risk factor for neurologic injury?
   A. Anesthesia
   B. Hypothermic circulatory arrest
   C. Blood transfusion
   D. Hemoconcentration
   E. Reperfusion
5. Which is not a risk factor for bloodstream infection in the pediatric ICU?
   A. Lower admission weight
   B. Lower PRISM score
   C. Blood product exposure
   D. Prolonged mechanical ventilation
   E. Renal dysfunction

## ANSWERS

1. **Answer: C.** Most cases of postoperative complete AV block are temporary. The overall incidence of arrhythmia is 15 to 30 percent. JET typically occurs during the first 24 h after surgery. VT is a wide complex tachycardia. Prolonged AO cross-clamp and CPB times are associated with increased incidence of postoperative arrhythmias.
2. **Answer: E.** Sildenafil is a pulmonary vasodilator. The other conditions increase PVR.
3. **Answer: D.** Patients with normal PA pressures prior to operation are not at increased risk for postoperative pulmonary hypertension. The remaining conditions are associated with increased risk.
4. **Answer: D.** Hemodilution from CPB, not hemoconcentration, is associated with neurologic injury. The remaining conditions are all associated with the development of neurologic injury during repair of CHD.
5. **Answer: B.** A higher PRISM or RACHS score is associated with an increased risk of bloodstream infection. Lower admission weight, greater blood product exposure, prolonged mechanical ventilation, and other comorbidities are all established risk factors as well.

# Cardiopulmonary Bypass in the Pediatric Patient

*Jacob Ostrowsky*
*Ross Ungerleider*

The development of cardiopulmonary bypass (CPB) has enabled operative treatment for countless numbers of patients with a multitude of acquired and congenital cardiac and vascular anomalies. The CPB circuit is a unique device designed to divert a patient's circulation around the area that requires surgical repair so that surgeons can operate in a virtually bloodless field. The typical CPB circuit consists of a series of blood pumps that provide cardiopulmonary support through disposable components consisting primarily of tubing, a blood collection reservoir, and an oxygenator (Fig. 61-1). The deoxygenated venous blood is pumped through the oxygenator and is returned to the arterial system of the patient. The first successful open heart surgical procedure using an extracorporeal CPB machine was performed in 1953 by John Gibbon.[1] Since then, there have been dramatic improvements to the device itself, to the components required for its application and to the techniques and strategies used to apply it, and to the monitoring, while safety systems have been designed to enable safe and consistent results, with steadily improving patient outcomes. This chapter will provide a general overview of the CPB circuit components [extracorporeal circuit (ECC)] and a brief discussion of strategies used to apply this technology in the field of pediatric cardiac surgery.

## CIRCUIT COMPONENTS

### Venous Cannulae

Deoxygenated blood is diverted from the systemic atrium to the collection reservoir via a venous cannula. Although CPB can be simply established using a single venous cannula placed in the right atrium, most pediatric operations require direct or indirect (via the right atrium) systemic (or bicaval) venous cannulation. As the situation warrants, venous drainage may be achieved through peripheral cannulation of one or more of the large peripheral veins. This is particularly true for larger children, in which femoral vessels might be sizeable. For smaller children and infants presternotomy cannulation of the internal jugular vein in the case of a truly hostile mediastinum might be an option for venous drainage. The diameter of the venous cannula/e depends on the size of the patient, the number of cannulae, and the desired CPB blood flow rates for the particular child and operation. Venous drainage is normally facilitated by gravity, but may be assisted by adding low-level vacuum, allowing in turn for the use of smaller venous cannulae. The vacuum is applied to the venous reservoir in the circuit, and should not exceed a negative pressure of 40 mm Hg. The potential drawback for vacuum assisted venous drainage is air entrainment and hemolysis through excess negative pressure; when applied appropriately, this risk of such complications is nevertheless minimal.[2,3]

### Tubing

The venous cannulae are connected to tubing that provides a path for blood volume to be diverted to a reservoir. The tubing is made of polyvinyl chloride, causing foreign surface activation of blood components that requires systemic anticoagulation with heparin to avoid clotting of the CPB circuit. Coated tubing, lined with heparin or a biologically active surface, is currently available and is used by many centers in an attempt to mimic the vascular endothelium and minimize the activation of clotting and inflammatory pathways. Tubing is available in many sizes, ranging from ⅛″ to ½″ inner diameter. Selecting the proper size is based on the requirements for calculated CPB blood flow rates.

### Blood Pumps

There are two common types of blood pumps available: roller pumps and centrifugal pumps. Roller pumps consist of two roller heads placed 180 degrees apart inside a raceway. Tubing is placed between the roller heads and the raceway and, as the rollers spin, blood is propelled forward in the same direction as the rotation of the roller head. Roller pumps require partial occlusion of the tubing to ensure blood flow in the proper direction. Pump output is measured by the speed of rotation and the diameter of the tubing. Centrifugal pumps

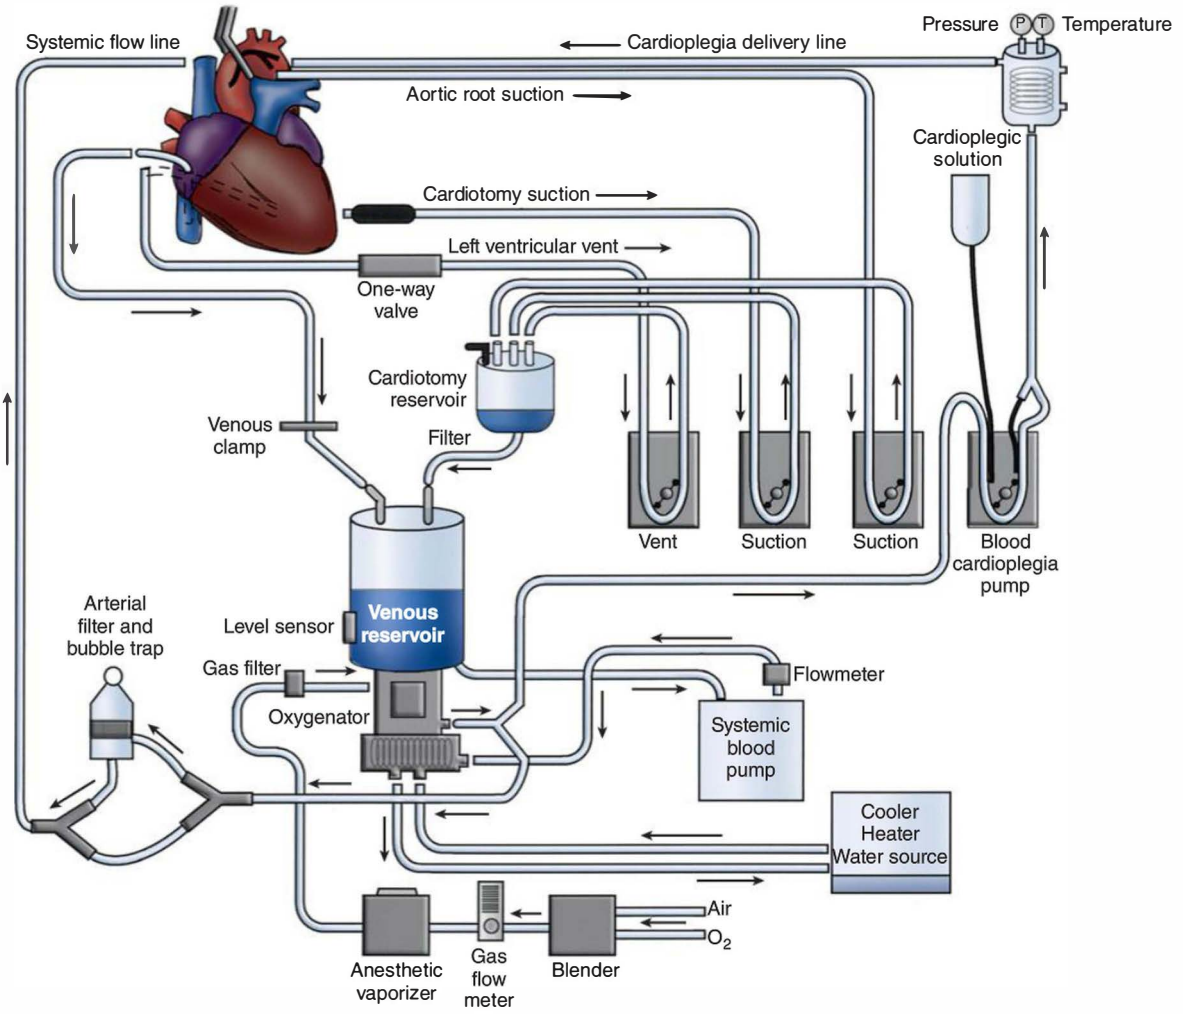

**FIGURE 61-1** The typical CPB circuit consists of a series of blood pumps that provide cardiopulmonary support through disposable components consisting primarily of tubing, a blood collection reservoir, and an oxygenator.

have a rotating impeller in the blood compartment that propels blood forward. Centrifugal pumps are nonocclusive, and are therefore dependent on the amount of volume available on the inflow side and the resistance on the outflow side. Pump output is measured by a flow probe placed distal to the outlet of the pump. Both pump systems can be monitored and regulated with integrated safety devices to avoid air emboli and overpressurization of the ECC.

## Oxygenator

The oxygenator is the component of the circuit that allows for blood to upload oxygen and unload carbon dioxide. In modern circuits, the blood chamber or surface is separated from gas surface by a polypropylene or silicone membrane (see also Chapter 87). The gas flow is regulated by a blender that enables manipulation of oxygen content, and the speed at which the gas passes through the membrane is known as "sweep speed." This creates a pressure gradient for both oxygen and carbon dioxide that facilitates gas exchange via diffusion across the membrane, similar to the alveolar capillary interface within the lung. Inhalational anesthetic can be delivered to the patient by including a vaporizer, inserted inline with the ventilation gas.

## Heat Exchanger

Most oxygenators have an integral heat exchanger that enables manipulation of the patient's core temperature. This is particularly important in neonates and small children, in which hypothermia is still widely utilized. Water lines are attached from a heating and cooling device that allow for precise and efficient temperature control. Maintaining proper temperature gradients during cooling and warming

is important to avoid bubble formation. Overheating blood beyond 40°C carries the risks of severe deleterious effects, such as enzyme and protein inactivation.

## Blood Filters and Arterial Cannula

Most venous reservoirs contain a depth filter to remove gross particles and facilitate air bubble purging. Once the blood has passed through the oxygenator, the inclusion of an arterial line filter is common. The arterial line filter is a screen with a defined pore size to remove particulate and gaseous emboli before the blood is returned to the patient via the arterial cannula. The arterial cannula is typically placed in the ascending aorta, but can be placed in a multitude of sites depending on the pathology and type of repair planned. Other common sites include the axillary or subclavian or right brachiocephalic artery (sometimes through a Goretex© graft), or the femoral artery (also occasionally through a graft). In particular cases (interrupted aortic arch or certain variants of hypoplastic left heart syndrome), the aortic return line may be split, to allow simultaneous proximal and duct-dependent perfusion or selective antegrade cerebral perfusion during aortic arch reconstruction. Proper selection of the arterial cannula size is based on patient size, calculated CPB blood flow rates, and number of cannulae required.

## Cardioplegia Delivery System

To allow surgical repair, it is usually necessary to induce diastolic chemical arrest by using a high potassium solution (cardioplegia). This solution can be crystalloid-based, blood-based, or a combination of the two, for instance, given at 4:1 blood to crystalloid ratio. Although institutional variance is great, most pediatric cardiac centers utilize cold cardioplegia, which maximizes suppression of myocardial metabolism. Typical cardioplegia delivery systems consist of a bubble trap, a heat exchanger, and a pressure monitor. When the heart is isolated from the systemic perfusion by placement of the aortic cross clamp, cardioplegia can be delivered directly within the aortic root with a separate catheter (antegrade). Alternatively, in cases with aortic valve regurgitation, cardioplegia can be infused directly within the coronary ostia. Experience with retrograde (via the coronary sinus) delivery of cardioplegia in pediatric patients is not ubiquitous, but reported. There is also great variability between centers in the timing of redosing of cardioplegia during cardioplegic arrest. This interval ranges from redosing every 30 min (with a lower volume) to the performance of long and complex repairs with a single upfront dose of cardioplegia. This is particularly applicable with crystalloid or very diluted (1:4 blood to crystalloid ratio) solutions.[4,5]

## Vents, Cardiotomy Suction, and Cell Saver

The left ventricle (LV) receives blood throughout CPB from the bronchial circulation via the pulmonary veins and vents placed in the left side of the heart can keep the heart empty and the surgical field more "bloodless." This is particularly true for patients with profound and persistent cyanosis, in whom development of aortopulmonary collaterals is prominent. In order to keep the heart empty, vents are occasionally placed into the left atrium or LV, most commonly through the right superior pulmonary vein (SPV). In very small neonates and infants, insertion of a vent in the right SPV might result in stenosis, or might be unfeasible because of the size of the vessel. Venting can be accomplished through the left atrial appendage, in a retrograde fashion via the pulmonary artery or through a patent foramen ovale, or atrial septal defect (ASD). The surgeon must individualize the venting strategy according to the specific lesion and clinical situation. For example, in the correction of transposition of the great arteries (see Chapter 74) venting through the SPV during cooling or cardioplegic arrest might be unnecessary if an ASD is present or if the neonate has undergone a preoperative balloon atrial septostomy. When the heart is reperfused, venting becomes necessary when the atrial communication has been closed. Occasionally, venting is accomplished through the pulmonary artery or the LV apex.

Vents are connected to the CPB circuit using one of the cardiotomy suction tubes. The cardiotomy suction tubes are small lengths of tubing that are designed to return blood, via a roller pump, back to the CPB circuit. Once the patient is heparinized, blood loss in the surgical field can be removed and returned to the venous reservoir. This diminishes blood loss by returning "shed blood" to the circuit where it can recirculate. Some centers will also return shed blood using a "cell-saver" device, which does not return the blood to the venous reservoir, but functions instead as a suction device. Blood is collected in a chamber from which it can be processed to eliminate the serous component. Blood from the cell-saver often has a hematocrit in excess of 70 percent or greater and is reinfused to minimize the need for blood transfusion. The cell saver can be used regardless of whether the patient is anticoagulated or not, and is often used prior to heparinization and then after administration of protamine. Minimizing the length of tubing and miniaturization of the CPB circuit, as well as priming the circuit with patient's own blood prior to instituting CPB have enabled many centers to avoid blood transfusion altogether, even in small patients.

# CARDIOPULMONARY BYPASS MANAGEMENT TECHNIQUES

## Priming the Circuit

For adults and adolescents, the ECC is primed with a balanced and buffered electrolyte solution. Blood is rarely necessary unless the patient is anemic before surgery. Priming the ECC for neonates and small infants represents a challenge because the volume required may exceed the patient's blood volume, causing excess hemodilution. The average priming volume for most neonatal circuits, including all

components, is 300 to 400 mL. Even at this small volume, blood is often required to maintain adequate oxygen carrying capacity. With the addition of bank blood, other additives are often necessary to normalize the prime.

## Anticoagulation

Exposure of blood to the ECC surface activates the clotting cascade. Without systemic anticoagulation, the patient's blood will clot and obstruct the oxygenator. Unfractionated heparin is the most common drug used to achieve anticoagulation due to simple monitoring with activated clotting time (ACT) and reversal with protamine sulfate. Initial heparin dose of 300 to 400 u/kg is given intravenously or directly into the right atrium prior to cannulation, with a target ACT of greater than 400 s, monitored every 30 to 60 min on CPB. Heparin works by increasing the action of antithrombin III (ATIII). Inadequate anticoagulation with proper heparin dose may be a result of ATIII deficiency. This situation may be corrected by giving exogenous ATIII or fresh frozen plasma.

After separation from CPB, protamine sulfate is infused to bind and inactivate heparin, reversing anticoagulation, and facilitating postoperative hemostasis. Empirical protamine dose of 1 mg for every 100 u of heparin may be used if a direct heparin content assay is unavailable. The protamine/heparin complex can activate complement and stimulate mast cells to release histamine and both can cause cardiac dysfunction and transient hypotension. In neonates and infants, this is usually reversible with simultaneous intravenous administration of calcium. Protamine alone can, however, also stimulate secretion of thromboxane $A_2$ from platelets, causing severe pulmonary vasoconstriction and systemic circulatory collapse. During protamine administration, the surgical team must be prepared to reheparinize and reinstitute CPB in the event of dangerous hemodynamic instability.

## Flow Rate and Pressure

An adult anesthetized and normothermic patient requires a CPB blood flow rate of 2.2 to 2.4 L/min/$m^2$ body surface area for adequate oxygen delivery to the tissues. Neonates and infants require higher flow rates (150–200 mL/min/kg) to meet metabolic demands. Combined with adequate flow rates, maintaining minimal perfusion pressure is crucial to protect vital organ systems. For adults, a mean arterial pressure (MAP) of 50 to 70 mm Hg is considered safe at normal body temperature. MAP below 45 mm Hg for prolonged periods at normothermia is associated with increased neurologic impairment postoperatively. Neonates and infants have compliant vascular beds, making them more flow than pressure-dependent. Perfusion pressure greater than 30 mm Hg is considered adequate in newborns, rising to adult levels only once adolescence is reached. Perfusion pressures can be manipulated by changing CPB blood flow rates or by administering vasoconstricting or vasodilating medications.

## Hematocrit

Appropriate levels of hemoglobin must be maintained to provide adequate oxygen-carrying capacity. Individual tolerance levels dictate the need for transfusion and can be monitored by several methods, including saturation of venous blood ($SVo_2$), cerebral and regional oximetry, CPB blood flow rates, and MAP. As blood viscosity increases with cooling, blood flow through the microcirculation may be impaired, a phenomenon known as "sludging." Matching core temperature to hematocrit (20 percent hematocrit at 20°C as an example) is an accepted practice to avoid sludging. Data in children suggest that sludging does not occur, and that a higher hematocrit of approximately 30 percent carries more benefit during deep hypothermia.[6]

## Temperature

Systemic cooling during cardiac operations while on CPB decreases metabolic activity and suppresses the oxygen demand, allowing reduction of CPB blood flow rates without compromising oxygen delivery to the tissues. Decreased flow may improve visualization of the operative field, enabling a safe and precise surgical repair. Systemic cooling also affords a safety margin in the event of an unanticipated intraoperative catastrophic event. With deep hypothermic conditions, total cessation of blood flow for short periods of time is possible, and the resulting bloodless field may allow the surgeon to deal with a difficult portion of the repair. During aortic cross-clamping, hypothermia also minimizes the rewarming of the myocardium, providing additional myiocardial protection during the ischemic period. Hypothermia in neonates and infants does, however, have postulated disadvantages (capillary leak, prolonged mechanical ventilation, and renal impairment), and some prominent centers have advocated complex cardiac intervention at near-normothermia, with high flow and high hematocrits.

## Neuroprotection

Organ protection is a vital component to proper performance of CPB. Cerebral tissue has high metabolic oxygen demand. At core temperatures below 22°C, cerebral autoregulation (the maintenance of cerebral blood flow across a wide range of perfusion pressures) is impaired.[7–10] Cerebral monitoring is a useful tool to ensure adequate perfusion delivery. Cerebral metabolism is a direct function of brain temperature. Monitoring cooling at multiple sites (including nasopharyngeal, bladder, rectal, and blood) provides information that is useful in determining flow rates on CPB in children. Indirect monitoring of cerebral metabolism during systemic cooling may be achieved via internal

jugular venous saturation with values greater than 95 percent signifying minimal oxygen extraction and adequate cerebral oxygen delivery for the metabolic state of the brain. Electroencephalographic (EEG) monitoring may be used to measure adequate depth of anesthesia, but using EEG as an end point for cooling is unreliable because EEG activity does not always become silent at a consistent body temperature. Near-infrared spectroscopy (NIRS) has become a useful noninvasive tool to monitor cerebral and regional oxygen saturation. The NIRS probe is placed over the tissue of interest, and using optical reflectance a beam of light passes through the area and oxygen saturation is calculated and displayed. Placed over cerebral tissue, NIRS provides an accurate trend of brain oxygen saturation levels which allow real-time interventions to avoid cerebral ischemia.[11]

## Circulatory Arrest and Low-Flow Perfusion in Pediatric Patients

Deep hypothermic circulatory arrest (DHCA) is a useful method to allow surgical repair in a motionless, bloodless field. The patient's temperature is gradually lowered to 18 to 20°C using CPB over several minutes. Perfusion is stopped and the patient's blood volume is drained into the venous reservoir; the cannulae may be removed to improve visualization of the surgical field. Indications for DHCA may include correction of complex congenital systemic or pulmonary venous return anomalies or repairs on the distal pulmonary arteries, aortic arch, or management without clamping of a heavily calcified aorta. The brain has the lowest tolerance to ischemia during DHCA. Inadequate cooling may lead to cerebral rewarming during DHCA, which may result in neurologic injury. Cooling for 20 min or greater is prudent to ensure adequate and homogeneous suppression of cerebral metabolic activity; in addition, packing the head in ice during cooling has the theoretical advantages of rapid and uniform cooling to prevent rewarming during DHCA.[12] Since long duration of the circulatory arrest period is clearly associated with increased frequency of brain injury, it is therefore crucial to limit the arrest period to the absolute shortest time required to achieve the surgical objective. The duration of "safe" DHCA is dependent on numerous factors, including degree and homogeneity of brain cooling, hematocrit, acid–base strategy used during cooling (with pH Stat being best) and the patient's inflammatory state, among other factors. In general, at 18°C, it is not recommended to extend the uninterrupted period of DHCA beyond 40 min.[13,14] Some authors believe the "safe" period at 18°C to actually be no longer than 30 min. Strategies of intermittent, or continuous regional cerebral perfusion have replaced the use of extended, uninterrupted periods of DHCA at many centers.[15–17] The benefits of continuous or intermittent cerebral perfusion compared to limited uninterrupted DHCA (<40 min) have not been proven.[18] Since systemic inflammation (which affects brain response to CPB) is increased at hypothermic temperatures, some centers are limiting systemic cooling to 25°C, by using very limited (<10 min) periods of circulatory arrest, alternating with periods of perfusion, with the patient's head packed in ice, with excellent results. The strategies for neuroprotection have gradually moved to shorter durations of circulatory arrest, more application of continuous cerebral perfusion, decreased levels of systemic cooling (at centers that use continuous or intermittent perfusion), and more routine application of perioperative neurological monitoring with NIRS. Institutional variation and experience dictates the management strategy. The ideal temperature, flow rates, hematocrit and duration of low-flow, and intermittent periods need to be studied further to develop an evidence-based approach to optimize outcomes.

## Weaning from Cardiopulmonary Bypass

Several criteria must be fulfilled before weaning the pediatric patient from CPB. The heart must regain sufficient function to provide adequate cardiac output and the lungs must have satisfactory gas exchange prior to separation from CPB. Factors that have an impact on cardiac and pulmonary function must be assessed and abnormalities corrected before weaning. Temporary pacing may be used to increase a slow heart rate and nonsinus rhythm may benefit from electric cardioversion. Inadequate cardiac contractility should be treated with inotropic agents. If hypothermia was used during CPB, the patient should be fully rewarmed to a core temperature of greater than 35.5°C. Inadequate rewarming, especially in infants, can lead to "rebound" hypothermia with deterioration of myocardial function. Adequate rewarming is vital to hemostasis because the coagulation system functions optimally at normal body temperature.

Blood gas analysis should be performed to normalize blood pH and correct any electrolyte imbalance. Acidosis can negatively influence cardiac contractility. Hyperkalemia is uncommon in patients with normal renal function, but hypokalemia may need correction due to diuresis while on CPB. Ionized calcium may be low due to hemodilution or transfusion of citrate-containing blood products and may be easily corrected while still on CPB. Hyperglycemia can be treated with insulin, mild anemia is usually not a problem with normal LV function, but is not well tolerated with minimal cardiac reserve or in pediatric patients with significant left-to-right shunting and abnormal arterial oxygen saturation.

Anesthetic requirements are decreased during hypothermic CPB due to suppressed metabolism of these agents. Increased levels of anesthetics and muscle relaxants are required during rewarming to prevent patient awareness and shivering. The lungs are inflated before separation from CPB to treat atelectasis. Impaired lung expansion suggests either bronchospasm (which can be treated with bronchodilators) or mucous plug obstruction (which should be cleared with endotracheal suctioning). Care must be taken when passing a suction catheter to avoid mucosal trauma and bleeding in a fully anticoagulated patient. If the pleural space was violated

during surgery, any residual fluid volume should be aspirated to facilitate lung expansion.

Weaning from CPB is performed by partially occluding the venous line to leave volume in the heart. The increase in preload encourages ejection and transition from mechanical to physiologic cardiac output. As more volume is left in the heart, the support is simultaneously decreased from the ECC while assessing hemodynamic parameters. The process is continued until the totality of cardiac output is being entirely provided by the patient's own heart. After assessing adequate hemodynamic stability, the cannulae may be removed and heparin reversed to achieve hemostasis.

Prior to decannulation and reversal of anticoagulation, adequacy of the repair is confirmed in most centers by transesophageal echocardiography, and sometimes requires direct assessment of cavitary pressures or shunt calculation by saturation measurements.

## Postcardiopulmonary Bypass Adjuncts

Once separated from CPB, there is often residual blood volume left in the ECC. There are several methods employed to utilize this volume, including modified ultrafiltration (MUF), cell saver, and whole blood collection systems. MUF is performed using a hemoconcentrator, or artificial kidney, to remove excess volume while reinfusing blood volume left in the ECC. Benefits of MUF include increasing the hematocrit, removing inflammatory mediators, and reducing organ edema. The efficacy of MUF has been shown in pediatric patients, especially neonates and infants, but the time required to remove enough volume to demonstrate clinical significance for larger patients has hampered its utilization in larger patients.[19–24] Autologous blood salvage, commonly known as "cell saver," allows processing of collected shed blood and residual pump blood. Collected red blood cells are separated and washed, removing waste, medications, and damaged cells, and allowing reinfusion to the patient. Cell saver's product consists of red blood cells suspended in saline, and does not contain clotting factors or significant amounts of heparin. Care must be taken when returning large volumes of cell saver due to dilution of clotting factors and the subsequent potential for bleeding. Returning whole pump blood to the patient, either directly or to a collection system, is another way to decrease waste volume in the ECC. Pump blood still contains heparin; therefore, additional protamine may be needed when utilizing this volume.

# COMPLICATIONS OF CARDIOPULMONARY BYPASS

All major organ systems can be adversely affected by a period of CPB. Excess hemodilution combined with hypothermia may cause coagulopathy and platelet dysfunction, leading to postoperative bleeding requiring transfusion of clotting factors and platelets. Foreign surface activation stimulates the systemic inflammatory response syndrome (SIRS) that may result in capillary leak and increased tissue and organ edema. Pulmonary, renal, and hepatic dysfunction may prolong the recovery period, although these issues typically resolve shortly after cessation of CPB support. Brain tissue carries the largest risk for injury following CPB, and this is especially true following excessive periods of DHCA. Neurologic symptoms are usually related to global cerebral ischemia or inadequate perfusion. Seizures, although rare, are usually temporary and do not require long-term medical management. Seizures may be related to embolic events rather than ischemia. Choreoathetosis, thought to be due to basal ganglia ischemia, may occur after periods of DHCA. This very rare event may occur 2 to 6 days after surgery and permanent hypotonia may occur in the most severe cases. By utilizing temperature-corrected blood gas management techniques and limiting duration of hypothermic circulatory arrest with low flow and intermittent reperfusion, many of the clinically significant complications of CPB with DHCA have been reduced.[25]

The evolution of our understanding of the negative sequelae associated with CPB has driven research to reduce the risk of exposure. SIRS was thought to be a product of CPB, but off-pump data have identified it as a mechanism that manifests even without CPB related to incision and surgical exposure. The severity of SIRS can be exacerbated by CPB due to foreign surface activation, and this can be ameliorated by decreasing the surface area and using biologically active surface coatings to decrease blood reactivity. The current-generation CPB machines focus on mast-mounted remote-controlled blood pumps that allow dramatically shorter tubing length to reduce surface area of the ECC. Another benefit of decreasing the size of the ECC is reduced need for blood products, reducing the risks associated with banked blood such as disease transmission, anaphylactic reactions and an overall correlation with blood transfusion and poor outcomes. Avoiding blood prime may also be aided by autologous priming techniques, utilizing the patient's blood volume to prime the ECC will decrease hemodilution and the need for blood transfusion. Autologous priming must be done carefully to avoid hypotension and a subsequent catecholamine response that may compromise global perfusion, particularly in small patients that may not tolerate a large fluid shift. Ultrafiltration techniques allow mechanical fluid manipulation to decrease tissue edema, improve oxygen carrying capacity by increasing hemoglobin concentration, and remove inflammatory mediators.

Cardiopulmonary bypass has been used for more than 50 years to allow cardiac surgical repair for a myriad of people worldwide. Improved surgical techniques, ECC miniaturization, coated tubing, and perfusion management techniques have all contributed to making CPB safer, yielding consistent results. The addition of monitoring systems, such as transesophageal echocardiography and NIRS, has been invaluable in facilitating real-time response in the surgical correction of congenital heart disease.[25]

# 62 Palliative Operations for Congenital Heart Disease

*Tara Karamlou*
*Gordon A. Cohen*

## INTRODUCTION

Alfred Blalock and Helen Taussig ushered in the surgical treatment of congenital heart disease with the introduction in clinical practice of a systemic artery-to-pulmonary artery (PA) shunt in 1944. In the current era of early complete correction of congenital heart disease, the Blalock–Taussig shunt still plays an important role in the surgical management of newborns and infants with inadequate pulmonary blood flow.[1–3] The paradigm shift emphasizing early complete repair is based on contemporary data demonstrating the deleterious effects of palliative physiology, coupled with the realization that most infants can tolerate operative correction. However, some malformations still require a staged approach toward eventual correction, while others may necessitate a palliative procedure when anatomic or patient factors preclude complete repair. A staged repair is often favored when there are extenuating technical issues that stem from morphologic complexity or severe extracardiac pathology that would make one-stage correction prohibitive. The functionally single ventricle (Chapter 77) is an example of this strategy, by which a staged palliative approach eventually achieves the goal of separating the pulmonary and systemic circulations.

Palliative or staged procedures are primarily designed to modify pulmonary blood flow, enhance intracardiac mixing, or rehabilitate a ventricle prior to definitive surgery. For example, aortopulmonary shunts will increase pulmonary blood flow, while a pulmonary artery band (PAB) will limit pulmonary perfusion. Although conceptually simple, palliative operations pose several unique challenges. Intraoperatively, the infants are often low birth-weight or even preterm, and might have other extracardiac factors that have mitigated against complete repair. Postoperatively, the palliated state complicates patient management, as equipoise must be achieved between the pulmonary and systemic circulations (Chapter 60), also inviting the opportunity for interstage attrition.

## SYSTEMIC-TO-PULMONARY SHUNTS

As early complete repair has become increasingly more common, indications for systemic-to-PA shunts are in some respects controversial. However, a shunt still remains the initial procedure for duct-dependent single-ventricle lesions and also specific lesions with inadequate pulmonary blood flow in the presence of two adequate ventricles. In those instances, a systemic-to-PA shunt may be necessary for early survival, at the expense of further surgical procedures.

A systemic-to-PA shunt could be indicated in any anomaly that presents with obstruction of blood flow either entering or exiting the right heart (in specific types of tricuspid atresia, or pulmonary stenosis or atresia not amenable to percutaneous intervention, for example). Other indications include anomalies with unbalanced pulmonary blood flow where a systemic-to-PA shunt (alone or, rarely, with a PAB) can be used to provide a controlled source of pulmonary blood flow.

### Classic Blalock–Taussig Shunt

The development of palliative procedures began at the Johns Hopkins Hospital with the goal of providing improved blood flow to the pulmonary vascular bed in cyanotic children; the subclavian-to-right PA shunt was introduced clinically in 1944.[3] This method of systemic-to-PA shunt followed the pioneering experimental work by Alfred Blalock and Vivien Thomas, who created a canine model of PA hypertension by anastomosing the subclavian artery to the transected end of the PA; this concept was adopted as a palliative attempt to augment pulmonary blood flow in patients with tetralogy of Fallot. In the 2 years following the first successful case, hundreds of cyanotic children traveled to Baltimore to undergo a classic Blalock–Taussig shunt. The reported early mortality was 16 percent, and only 6 percent of the patients were refused surgery.

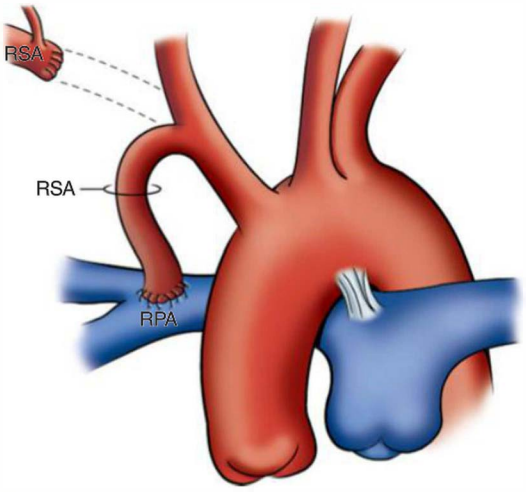

FIGURE 62-1 Classic Blalock–Taussig shunt. RPA, right pulmonary artery; RSA, right subclavian artery.

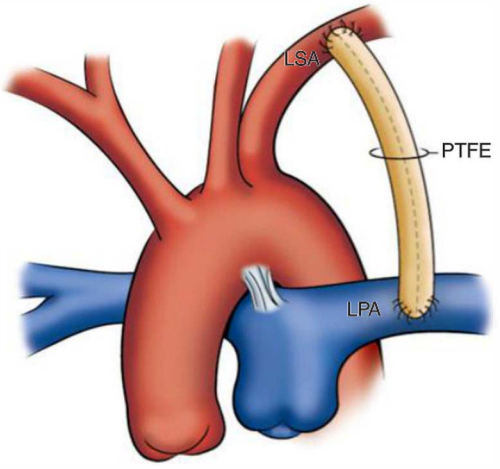

FIGURE 62-2 Modified Blalock–Taussig shunt. LPA, left pulmonary artery; LSA, left subclavian artery; PTFE, polytetrafluoreethylene shunt.

The shunt is performed on the side opposite the aortic arch, by anastomosing the subclavian artery to the ipsilateral PA in an end-to-side fashion. There is usually an innominate artery on the side opposite the aortic arch, and it provides adequate length and orientation to allow for the subclavian to form a gentle curve inferiorly toward the PA. Access to the subclavian artery is typically obtained via an anterolateral thoracotomy (Fig. 62-1). The branches of the subclavian artery are also ligated. Additional mobilization can be obtained by freeing the proximal carotid artery from surrounding tissues. The subclavian artery is then brought through the loop of the recurrent laryngeal nerve, oriented down toward the PA, and sewn to the main PA. Division of the inferior pulmonary ligament will often help in facilitating this anastomosis.

Even though the classic Blalock–Taussig shunt has the distinct advantage of avoiding the use of prosthetic material, this procedure has been largely abandoned because of concerns regarding ipsilateral arm or hand ischemia. Although an asset in the era preceding the advent of open cardiac surgical intervention, the growth potential of this shunt may provide excessive pulmonary blood flow and therefore additional volume-load to the ventricle, which can be extremely detrimental in single ventricle patients. At the time of corrective surgery, the shunt may be taken down via median sternotomy by entering the plane posterior to the superior vena cava (SVC).

## Modified Blalock–Taussig Shunt

A significant modification of the classic Blalock–Taussig shunt, first performed by Redo and Ecker in 1963, involved the interposition of a prosthetic graft to connect the systemic circulation to the PA (Fig. 62-2).[4–6] This procedure was later reported by Gazzaniga in 1976 and termed the "modified" Blalock–Taussig shunt by deLeval in 1975.[7] This modification provides several advantages over the standard Blalock–Taussig shunt: less tendency to deform hypoplastic PAs, less need for mediastinal dissection, preservation of upper extremity blood flow, consistent shunt flow (regulated by the internal diameter of the ostia of the innominate or subclavian arteries), and adequate length. Disadvantages include a 10 to 15 percent incidence of seroma formation and the rare possibility of endocarditis or thrombosis (3–5 percent). Because of these significant advantages, the modified Blalock–Taussig shunt remains the most widely used systemic-to-PA shunt today. Initial concerns that there may be a risk of impaired growth of the contralateral PA have been discredited by current literature, which demonstrates that equivalent growth without distortion can be accomplished with the modified shunt.[5] Compared to the classic Blalock–Taussig shunt, the modified Blalock–Taussig shunt has a more predictable life span, which is limited by the lack of growth potential. These shunts are destined for short-interval use and generally require some other surgical intervention to provide a reliable source of pulmonary blood flow as the child grows.

The modified Blalock–Taussig shunt can be performed through either right or left thoracotomy, or via a median sternotomy. The decision to perform a sternotomy versus a thoracotomy is usually dictated by surgeon preference. However, in some circumstances the approach is dependent on the vascular anatomy and on the location of the ductus arteriosus. For instance, the shunt should be placed on the side of the dominant SVC (so as to facilitate pulmonary arterioplasty at the time of bidirectional cavopulmonary shunt placement) and opposite to the ductus arteriosus. The three different approaches have subtle advantages and disadvantages. Some authors have suggested that a right-sided shunt is easier to take down, while others suggest that a thoracotomy is preferred because, at the time of the next operation, the

pericardium will be relatively free of adhesions. A median sternotomy prevents post-thoracotomy scoliosis, allows for duct ligation, a shorter and more centrally located shunt with less distortion and eventual loss of the upper lobe PA branch, and affords the ability to initiate cardiopulmonary bypass in case of hemodynamic instability or intolerable levels of hypoxemia. Currently, the sternotomy approach is favored by most centers in the United States.

In performing the procedure via thoracotomy, the chest is usually entered through the fourth intercostal space. The lung is retracted inferiorly and medially and the mediastinal pleura opened posterior to the SVC. The innominate and/or subclavian arteries are dissected free from the surrounding tissues and controlled with vessel loops. During this portion of the dissection, great care is taken to avoid the recurrent laryngeal nerve, which, on the right side, courses around the distal innominate artery at its bifurcation into subclavian and common carotid arteries. Next, the PA is mobilized, first proximally toward the pericardial reflection and then distally to the first bifurcation. The vessels are controlled with vascular tapes. An expanded polytetrafluoroethylene (ePTFE, Gore-Tex) graft is then beveled with scissors to conform to the natural curve of the systemic artery. A Cooley or Castaneda vascular clamp is applied to the innominate artery, encompassing the origin of the right subclavian artery and an arteriotomy is made on the inferior aspect of the artery. The anastomosis is performed with a 7-0 monofilament suture in a running fashion. Some authors prefer systemic heparinization prior to systemic vessel clamping; we prefer to heparinize the patient after the first anastomosis is complete. The clamp is then repositioned on the graft to minimize systemic arterial trauma. If at this point the azygos vein lies in the direct path of the shunt, it is ligated and divided. The distal anastomosis is performed by first placing a stay suture in the direct center of the superior margin of the unmanipulated PA to make sure that there will be no torsion or kinking during occlusion. Prior to initiating the anastomosis, vascular tapes are used for a test-occlusion of the PA. Once the surgeon is assured that the patient will tolerate single-lung perfusion, the pulmonary arteriotomy is made by excising a circular portion of the PA. The excised portion should be larger than the diameter of the graft so as to avoid proximal stenosis. The graft is then cut to length, attempting to avoid any redundancy. The anastomosis is again performed with a 7-0 monofilament suture in a running fashion. Clamps and tapes are then released, hemostasis is assured, and the chest closed with a pleural drain. There should be a nearly instantaneous increase in the patient's oxygen saturation and a drop in the diastolic blood pressure, with a palpable thrill in both shunt and PA.

If a sternotomy is chosen, the sequence remains the same. Following sternotomy and thymectomy, the pericardium is left undisturbed and the innominate artery is mobilized to the bifurcation. A limited pericardial incision is then made in order to mobilize the PA between the aorta and SVC. The anastomosis is performed as described above. Ligation of the ductus arteriosus or additional sources of pulmonary blood flow are dependent upon individual patient anatomy as well as surgeon's preference.

The size and the length of the shunt are important factors in controlling the amount of pulmonary blood flow. Decisions regarding shunt dimensions should consider both the size of the patient as well as whether additional sources of pulmonary blood flow exist. Most infants of normal birth weight require a 3.5-mm shunt. Infants weighing less than 3.5 kg should be treated with a shunt of no less than 3 mm, and the distal anastomosis should be constructed almost entirely to the subclavian artery rather than to the innominate artery. Larger infants may receive shunts as large as 4 or 5 mm. Ideal shunt characteristics may be achieved by indexing shunt diameter to the patient's body size or surface area.[8,9]

Regardless of the approach used to create the shunt, it is usually relatively straightforward to take down a modified Blalock–Taussig shunt through a median sternotomy at the time of the next procedure. A right-sided shunt can be found by dissecting the plane between the aorta and SVC. A left-sided shunt presents more difficulty at the time of takedown and is usually identified by dissecting along the left PA, the inferior aspect of the aorta, or by entering the pleural space. The ePTFE graft can be interrupted with hemoclips and simply divided, usually with the proximal end oversewn. The distal (PA) end of the graft does not need to be removed unless access to the PA is required as part of the procedure (e.g., in case of a superior cavopulmonary anastomosis or a pulmonary arterioplasty).

## Right Ventricle-to-Pulmonary Artery Conduit

In selected diseases (hypoplastic left heart syndrome (HLHS) and pulmonary atresia with ventricular septal defect (VSD)),[10] a right ventricle-to-pulmonary artery (RV–PA) conduit can be utilized to provide pulmonary blood flow during initial palliation. The RV–PA PA conduit, first utilized in patients with HLHS by Norwood in 1981 in 4 consecutive patients, consisted of large nonvalved PTFE tubes (8 and 12 mm).[11] This was quickly abandoned due to uniformly fatal outcome of the 4 patients. Despite these initial failures, however, the concept of a RV–PA conduit has theoretical advantages over a standard systemic-to-PA shunt.[12–14] First, pulmonary blood flow occurs only during ventricular systole, and therefore diastolic runoff and "coronary steal" are eliminated. Second, because of the reduced pulmonary blood flow relative to a systemic-to-PA shunt, volume load on the ventricle is also reduced, which is critically important for single ventricle patients. Postoperative fluctuations in pulmonary and systemic vascular resistance in the single ventricle patients become less critical to control as myocardial perfusion is decoupled. However, there are also disadvantages to the RV–PA conduit. Construction of this shunt requires a ventriculotomy, which could predispose to ventricular dysfunction or enhance the substrate for late arrhythmias. Furthermore, the reduction in pulmonary blood flow could lead to reduced

growth of the branch PAs or lead to early cyanosis, necessitating earlier creation of additional sources of pulmonary blood flow (e.g., bidirectional cavopulmonary anastomosis).

Creation of the RV–PA conduit has been described by others.[11–14] Our current preference is as follows: After median sternotomy, a patch of autologous pericardium is harvested and fixed in glutaraldehyde. On the back table, a "skirt" of pericardium is created by punching a calibrated hole in the pericardial patch the exact size as the intended shunt diameter, and anastomosing the pericardium to the intended distal (PA) end of the ePTFE ringed graft using 6-0 Goretex suture. If the RV–PA shunt is performed as part of a modified Norwood operation, cardiopulmonary bypass is initiated and the pericardial skirt is created during systemic cooling. Otherwise, cardiopulmonary bypass is initiated following "skirt" creation. A 5-mm (for infants greater than 3.5 kg) or 6-mm ringed ePTFE graft is selected and the proximal end is beveled for later anastomosis to the right ventricle. Following cardiopulmonary bypass, the ductus arteriosus is ligated, the aorta is cross-clamped and the heart is arrested with a single dose of cardioplegia infused into the aortic root. The PA confluence and branch PAs are widely mobilized and encircled with vessel loops. The RV–PA shunt is most easily constructed slightly to the left side of the PA confluence. The PA is incised sharply and a small oval excised. In the case of a modified Norwood, the PA has been transected and thus a large defect already exists in which to construct the anastomosis. The cuffed PTFE graft is anastomosed to the PA with running 7-0 prolene. The vessel loops are released, and the graft is de-aired and controlled with a straight vascular clamp. Most rings are removed from the proximal aspect of the graft. A right ventriculotomy is created approximately 1.5 to 2.0 cm below the pulmonary valve using a calibrated punch. Care is taken to avoid any conal arterial branches that may be crossing the infundibulum. A small rim of endomyocardium is excised to prevent any late dynamic or muscular obstruction. The beveled end of the ePTFE graft is sutured to the edges of the ventriculotomy using interrupted pledgeted mattress sutures. Alternatively, we have utilized a running suture technique with two long homograft pledgets surrounding the ventriculotomy.

Outcomes of the RV–PA conduit have been extensively studied.[9,11,13] Many studies, including a large cohort of patients studied through Fontan completion from the Children's Hospital of Philadelphia[15] have found no difference in morbidity and mortality depending on whether a modified Blalock–Taussig or RV–PA conduit was utilized as part of first stage palliation. In the recently completed single ventricle reconstruction trial, prospectively randomized infants with HLHS received either a modified Blalock–Taussig shunt ($N = 275$) or an RV–PA conduit ($N = 274$). The trial demonstrated a 1-year transplantation free survival advantage in the RV–PA shunt group (74 percent) compared to the modified Blalock–Taussig shunt group (64 percent; $P = 0.01$).[14] However, transplantation-free survival was equivalent between both groups at a mean follow-up of 32 ± 11 months. The RV–PA conduit group had more unintended interventions and complications compared to the modified Blalock–Taussig shunt group. Importantly, pulmonary arterial size, as assessed by the Nakata Index, was lower for the RV–PA shunt group, but right ventricular size and function at the age of 14 months was similar among both groups.

## Waterston and Potts Shunts

The success of Blalock–Taussig procedure spawned a number of other systemic shunts. In 1946, Potts described an aortopulmonary shunt,[16] performed by creating an anastomosis between the descending aorta and the left PA through a left thoracotomy in patients with a right-sided aortic arch. To facilitate this procedure, a special partial occluding clamp was devised to minimize the risk of paraplegia. The Potts shunt was used throughout the 1940s and 1950s in patients thought to be too small for a classic Blalock–Taussig shunt. The Potts shunt was associated with several serious complications, including PA aneurysms and sizing difficulties, which often led to persistent cyanosis or chronic pulmonary hypertensive changes. In time, the Potts shunt was abandoned owing to its unnecessary difficulty and the risk associated with shunt takedown. Simple ligation of the shunt often leads to uncontrollable hemorrhage, requiring peripheral bypass and circulatory arrest to achieve control and repair.

In 1955 Davidson and colleagues first described a shunt between the ascending aorta and the PA. In 1962, Waterston reported a similar intrapericardial anastomosis between the posterior ascending aorta and the right PA (Fig. 62-3).[17] The procedure was performed through a right thoracotomy; the right PA and ascending aorta are both partially occluded

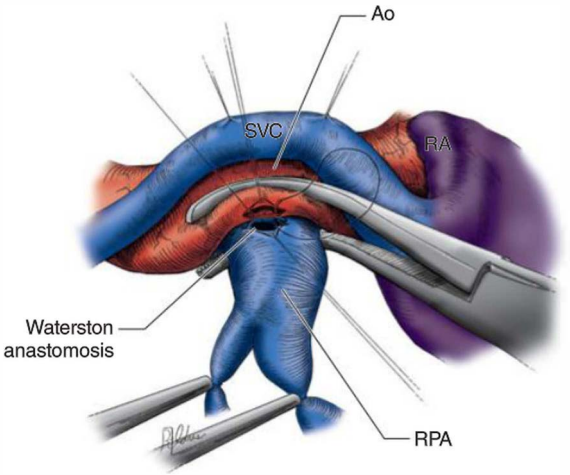

**FIGURE 62-3** Waterston shunt. Side-to-side anastomosis between the ascending aorta and right branch pulmonary artery. Ao, ascending aorta; RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava. (From Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

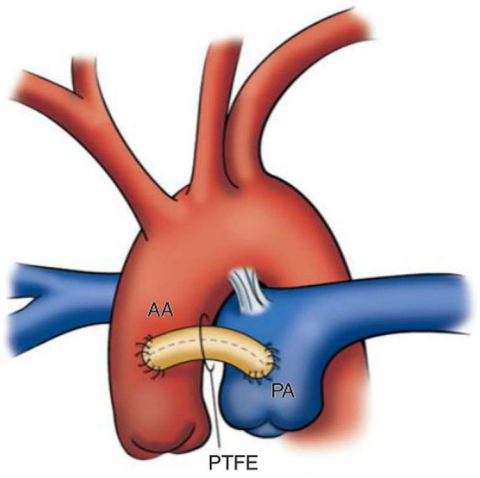

**FIGURE 62-4** Central shunt. AA, ascending aorta; PA, pulmonary artery; PTFE, polytetrafluoroethylene shunt.

with the same clamp. After making two opposing arteriotomies, the PA and ascending aorta were sewn side to side. This shunt was very effective in infants but was prone to PA kinking, with resultant unequal pulmonary blood flow and subsequent hypoplasia of the underperfused PA. The Waterston shunt is taken down intrapericardially at the time of definitive repair, the aorta is primarily closed, and the PA is patched.

In performing both the Waterston and Potts shunts, notorious difficulty was found in estimating the correct size that would prevent pulmonary hypertension or cyanosis. These shunts have been replaced by the central shunt (Fig. 62-4).

The central shunt is a modification of the Potts and Waterston shunts, created with an interposition ePTFE graft. These shunts are most often used when head vessel anatomy is unsuitable or when branch PAs are small, in the hope of encouraging pulmonary arterial growth. A small-caliber graft is preferable when creating a central shunt to avoid the potential for pulmonary overcirculation.

All systemic-to-PA shunts are designed to enhance pulmonary blood flow, but they also result in greater pulmonary venous return with subsequent left ventricular volume overload and increase in left ventricular end-diastolic dimension. In general, it is necessary to replace the systemic arterial inflow with a venous source at around 6 months of age in patients with single ventricle and by 2 years in patients with well-balanced ventricular chambers.

## PULMONARY ARTERY BANDING

First conceived by Muller and Dammann in 1952, PA banding (Fig. 62-5) was the only treatment for complex congenital heart disease with unrestricted pulmonary perfusion

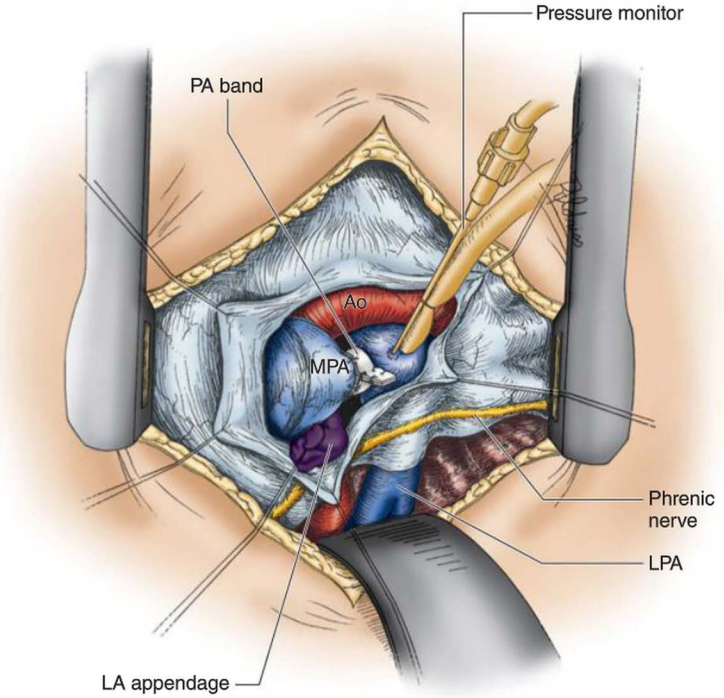

**FIGURE 62-5** Pulmonary artery band. Seen through a left thoracotomy, with a pressure monitoring line inserted in the distal main pulmonary artery. Ao, aorta; LA, left atrial artery; LPA, left pulmonary artery; MPA, main pulmonary artery; PA, pulmonary artery. (From Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

(large left-to-right shunt or single ventricle with unrestrictive pulmonary blood flow).[18] For many years, the PAB was the procedure of choice for large VSDs, atrioventricular canal, or truncus arteriosus. Though effective at limiting pulmonary blood flow, PAB has largely been abandoned in the aforementioned diagnoses except in the presence of specific circumstances (e.g., small, preterm infants) because of the success of early corrective surgery. However, the development of the Hybrid approach to HLHS,[19,20] in which the ductus arteriosus is stented and the bilateral branch PAs are banded, has created a new indication for this procedure.

In addition, a few congenital lesions still lend themselves to primary palliation with PAB.[21,22] Current indications for PA banding include "Swiss cheese" VSDs, multiple VSDs with coarctation, unbalanced atrioventricular septal defects in small patients, single-ventricle lesions, and to prepare the systemic ventricle for the arterial switch operation in cases with intact septum and late presentation or for patients who have undergone atrial switch and experience systemic ventricular dysfunction. In most cases, the goal of PAB is to protect the pulmonary vascular bed from systemic or near systemic pressures associated with these lesions and to facilitate future venoarterial shunts or delayed complete repair.

The presence of a concurrent illness in a patient with an otherwise correctable lesion would also be an acceptable reason for PAB placement. Patients with pulmonary overcirculation are more prone to respiratory illness and have less reserve to cope with viral illnesses such as pneumonia due to the respiratory syncytial virus (RSV). This disease state can last for weeks, often with the need for prolonged mechanical ventilation as the lungs recover; PAB in the short term may allow for the child to improve and have the lesion corrected in a better clinical condition.

Except in cases of aortic coarctation associated with a VSD not suitable for simultaneous repair, PAB is usually approached by most surgeons via a median sternotomy. After partial thymectomy, the pericardium is opened from the base of the innominate artery to the level of the pulmonary annulus. Pericardial stay sutures are placed to enhance exposure. The aorta and PA are carefully separated with cautery, and the PA is then encircled with careful blunt dissection. It is crucial to do as little vertical dissection between the aorta and PA as possible so as to minimize band migration. Although some authors recommend Teflon-impregnated Dacron, we use a 3.0-mm ePTFE conduit to create the band. We prefer this technique because the ePTFE band causes less of an inflammatory response and can usually be removed off bypass without any further intervention on the debanded PA if the PAB has been in place for less than 6 months. In addition, we have found that, when a VSD closes spontaneously during the period that the band is applied, the band can be removed in the cardiac catheterization laboratory by balloon dilatation, thus avoiding resternotomy. Bands constructed of either Teflon, silk or Dacron will often require a period of cardiopulmonary bypass with PA reconstruction in order to remove the band.

The banding material is advanced around the PA. The band is sequentially tightened using small Weck clips until the band is fixed to the desired circumference. In 1972, Mustard and Trusler introduced a formula to estimate the size of the band needed in patients with VSDs.[23] This formula suggested that the circumference of the band in millimeters should be equal to the child's weight in kilograms plus 20. This formula may be helpful as a guideline; however, intraoperative pressure measurements should be used to individualize the band size for each patient. The distal pulmonary arterial pressure should be reduced to somewhere between one-third and one-half of systemic, and systemic arterial saturations should remain between 75 and 85 percent on 50 percent inspired oxygen. The systemic pressure will usually increase by 10 to 15 mm Hg after proper banding.

Several complications are specific to PA banding. Improper band sizing can produce pulmonary under- or overcirculation with resulting congestive heart failure or cyanosis from excessive right-to-left shunting. However, this is an unusual problem if intraoperative pressures are taken correctly. Another possible complication is band migration. This problem may lead to impingement on the PA bifurcation, causing stenosis of one or both branch PAs. It is most common for the right PA to be compromised during banding, producing left PA hypertension and right PA ostial stenosis. Banding of the PA has been also associated with injury to the left phrenic nerve at the time of PAB placement or reentry. This is, of course, particularly detrimental in patients with functionally single ventricle staged toward Fontan-type physiology. Lastly, in palliating single-ventricle lesions with a posteriorly displaced conal septum, banding is thought to contribute to obstruction of left ventricular outflow tract.

## SYSTEMIC VENOUS–PULMONARY ARTERIAL SHUNTS

The goal of a systemic venous-to-PA shunt is to improve oxygenation by channeling the systemic venous return in part or in whole to the pulmonary vasculature. This procedure is commonly used in patients with a cyanotic defect who are staged to a Fontan circulation or total cavopulmonary connection (see Chapter 77). Although first performed experimentally and reported in 1950 by Carlon,[24] William Glenn is credited with the clinical application of a systemic venous-to-PA connection, effectively bypassing the right ventricle.[25] The initial ("classic") shunt developed by Glenn was an end-to-end anastomosis, in which the distal end of the transected SVC was sutured to the distal end of the right PA. The original Glenn shunt (Fig. 62-6) was later replaced by the bidirectional Glenn cavo-pulmonary anastomosis (Fig. 62-7), a modification in which an end-to-side PA anastomosis is created by suturing the distal end of the transected SVC to the intact right PA, thus providing a conduit for bidirectional flow to both branch PAs.[26] The bidirectional Glenn provides a reliable source of pulmonary blood flow and relieves the volume overload on the ventricle imposed by systemic-to-PA shunts. Furthermore, it unloads the right ventricle in cases of right ventricular hypoplasia and Ebstein's malformation

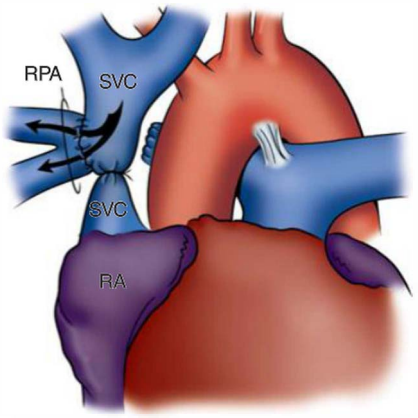

**FIGURE 62-6** Classic Glenn superior cavopulmonary connection. RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.

of the tricuspid valve (see Chapters 70 and 85). The major limitation to early palliation with a Glenn-type anastomosis is the need for low pressures in the pulmonary bed, which are usually not present until 3 or 4 months of age.

Although initially successful, the Glenn shunt fell out of favor as the final procedure when the Fontan or total caval pulmonary connection was popularized for patients with single-ventricle physiology. Conversion of the Glenn anastomosis to a total cavopulmonary connection allowed complete separation of the systemic and pulmonary circulations, completely obviated the volume load on the single ventricle, and also reduced the development of pulmonary arteriovenous malformations by providing inferior vena cava blood to the lungs. Results from the Kawashima operation for patients with interrupted inferior vena cava with azygous continuation, in which only the hepatic venous effluent is excluded from the cavopulmonary connection, suggested the presence of an incompletely defined "hepatic factor" within the IVC effluent that reduces development of pulmonary arteriovenous malformations.[27] Subsequent studies, in which the hepatic venous blood is redirected to the pulmonary circulation with resolution of the arteriovenous malformations, have supported this concept.[28,29] Although a trend toward early completion of a total cavopulmonary connection (at less than 2 years of age) has been established, not all children are ideal candidates for immediate bicaval connection to the PA. In these patients, a bidirectional Glenn became an intermediate step in management of the single ventricle. The usual palliative sequence for univentricular heart disease is therefore the creation of a systemic-to-pulmonary shunt (or placement of a PAB in cases with pulmonary overcirculation) for palliation in the neonatal period, followed by a Glenn or hemi-Fontan (see Chapters 76 and 77) connection at around 6 months of age and, eventually, by completion of the Fontan operation when the child reaches about 15 kg in size.

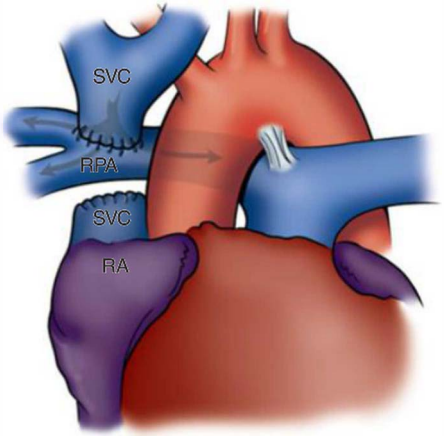

**FIGURE 62-7** Bidirectional Glenn cavopulmonary anastomosis. RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.

Following sternotomy, sharp dissection is undertaken to gain control of the systemic-to-pulmonary shunt, or, if present, the PAB is dealt with. Next, the right PA and SVC are fully mobilized. The azygous vein is also dissected free and is ligated and optionally divided for added mobility. Stay sutures are placed in the lateral extent of the SVC and the exact midpoint of the superior portion of the PA to avoid distortion during clamping. The patient is then systemically heparinized. Cardiopulmonary bypass is initiated with ascending aortic cannulation and venous cannulation. Two venous cannulae are required, one placed in the very proximal SVC or innominate vein and the other placed either at the inferior atriocaval junction (if a concomitant transatrial procedure is required) or through the right atrial appendage. Alternatively, a shunt can be utilized between SVC a nd right atrium, while in rare instances (when redundant blood flow to the pulmonary vasculature exists) the procedure can be performed by avoiding shunting or cardiopulmonary bypass altogether.

As bypass is instituted and the systemic-to-pulmonary shunt is ligated, the cardiac portion of the SVC is cross-clamped, divided, and oversewn with great care not to injure the sinus node. In the case of a previous Blalock–Taussig shunt, the graft-to-PA anastomosis is taken down and the arteriotomy widened so that the caliber is larger than that of the SVC. The anastomosis is performed in a running fashion using 7-0 monofilament suture, taking care to avoid purse-stringing of the suture line. In cases where purse-stringing appears likely, intermittent locking sutures or interrupted sutures may prove useful. This portion of the procedure is usually performed at normothermia with the heart beating. Cardioplegic or fibrillatory arrest may be necessary if an atrial septectomy or tricuspid valve repair is required. At the conclusion of bypass, it is important to monitor both SVC pressure and arterial oxygen saturation. In cases in which the arterial saturation is intolerably low or the SVC pressure is significantly elevated, a technical problem should be considered. If no technical error can be identified and the arterial saturation is unresponsive to ventilatory or pharmacologic manipulation, placement of a small additional systemic-to-pulmonary shunt may be considered. Postoperative

anticoagulation is a controversial subject, but most authors usually recommend at least the use of antiaggregant therapy.

The Glenn shunt has a reported operative mortality of 4 to 5 percent and can sustain palliation for 5 to 7 years.[30] Patients normally maintain saturations in the low to mid 80s, which generally persist to the fourth year of life, when cyanosis becomes symptomatic. A well-known complication of the superior cavopulmonary connection is the development of pulmonary arteriovenous malformations as discussed previously, or venovenous collaterals (superior-to-inferior vena cava) which result in shunting of the upper body venous return away from the PA to the right atrium and hence accelerated cyanosis. Once cyanosis progresses or the patient reaches approximately 2 years of age, the patient should undergo evaluation for completion of the total cavopulmonary connection.

## ATRIAL SEPTECTOMY AND SEPTOSTOMY

For some lesions, palliation can be provided by increasing the intracardiac mixing of venous and arterial blood. This can be accomplished either through a surgical atrial septectomy or a percutaneous balloon or blade septostomy. There are various ways of performing a surgical septectomy without cardiopulmonary bypass. The Blalock–Hanlon septectomy was first performed in 1950 through a right thoracotomy.[31] The right and left atrium are occluded with a single clamp. The atria are opened within the clamp with two parallel incisions (on either side of the septum); a portion of the atrial septum is then grasped and excised. The clamp is repositioned to allow the septum to fall back into the atria, and the resulting common atriotomy is then closed. With very few exceptions, this difficult and often high-risk procedure is no longer performed. Another technique for performing a surgical septectomy is that of inflow occlusion. This is usually performed through a median sternotomy. To perform this operation, the SVC and the inferior vena cava are both encircled with a heavy tie, which can be snared. A large purse-string suture is placed in the right atrial appendage and the patient is placed in the head-down position. Both cavae are then snared and the heart beats for about 5 to 10 seconds, at which time the aorta is cross-clamped. The right atrium is opened within the boundary of the large purse-string suture. The tissue in the fossa ovalis is then excised. With the purse-string suture still open, the cavae are unsnared and the right atrium fills with blood and de-airs the heart. The purse-string suture in the atrium is closed and the aorta is unclamped. The whole procedure should take less than 60 seconds of cross-clamping.

Most patients who now require creation of an atrial septal defect (e.g., transposition of the great arteries without VSD) undergo a Rashkind balloon septostomy. The procedure is usually performed under either fluoroscopic or echocardiographic guidance.[32] The septostomy itself is accomplished by passing a balloon-tipped catheter via the femoral vein across the restrictive foramen ovale. The balloon is inflated and rapidly pulled back. Because the procedure is performed with an imaging study, the effectiveness of the shunt can be assessed immediately, and the septostomy can be repeated if the result is suboptimal. In patients with a thick atrial septum recalcitrant to balloon septostomy, a blade septostomy or surgical atrial septectomy can be alternatively performed.[33,34]

## SUMMARY

Despite the current trend to perform early correction of most cardiac lesions, palliative procedures remain important tools in the armamentarium of the congenital heart surgeon. These operations are designed to alter pulmonary blood flow, augment intracardiac mixing, or rehabilitate a downregulated ventricle. In some cases, several procedures are performed in sequence as part of a multistage palliation strategy or with the aim of delaying complete intracardiac repair. Each of these procedures is associated with drawbacks and specific complications, making complete repair of malformed hearts with well-balanced ventricles ideal whenever possible.

## PALLIATIVE OPERATIONS FOR CONGENITAL HEART DISEASE BOARD REVIEW QUESTIONS (CHAPTER 62)

1. Palliative options for a 5-day-old neonate who weighs 3.5 kg with ductal-dependent pulmonary blood flow include all of the following EXCEPT:

   A. Modified 3.5-mm Blalock–Taussig shunt
   B. 5-mm RV–PA shunt
   C. Superior cavopulmonary shunt
   D. Modified 4.0-mm Blalock–Taussig shunt
   E. Ductal stent

2. For a 2.8-kg infant with multiple Swiss-cheese VSDs, the optimum circumference of a main PAB would be:

   A. 5 mm
   B. 12 mm
   C. 15 mm
   D. 20 mm
   E. 23 mm

3. The Waterston shunt involves an anastomosis between the:

   A. Right PA and the SVC
   B. Right PA and the innominate artery
   C. Left PA and the descending aorta
   D. Right PA and the ascending aorta
   E. Left PA and the left subclavian artery

4. A 4.0-kg neonate with tricuspid atresia, Type 1a is undergoing a modified Blalock–Taussig shunt using a 4.0-mm conduit and concomitant ligation of the ductus arteriosus through a sternotomy. Which of the following is the LEAST likely complication?

   A. Right recurrent laryngeal nerve injury
   B. Subsequent right PA stenosis
   C. Shunt thrombosis
   D. Pulmonary overcirculation
   E. Seroma formation

5. A 5.7-kg infant who is status post a right modified Blalock–Taussig shunt for pulmonary atresia with intact ventricular septum without right ventricular-dependent coronary circulation is undergoing conversion to a bidirectional Glenn shunt. The patient is cannulated for cardiopulmonary bypass, yet upon commencement of bypass, the perfusion pressure is persistently low and there is tremendous left heart return. The best next course of action to correct the situation would be:

   A. Do the repair off bypass to avoid further myocardial injury from ventricular unloading.
   B. Ligate the existing Blalock–Taussig shunt.
   C. Place a common atrial vent to avoid distension and augment drainage.
   D. Give additional phenylephrine in the circuit to augment systemic perfusion pressure.
   E. Perform the repair under deep hypothermic circulatory arrest.

## ANSWERS

1. **Answer C.** A neonate with ductal-dependent pulmonary blood flow requires establishment of a controlled source of pulmonary blood flow before closure of the native ductus arteriosus. Creation of a surgical systemic-to-PA shunt or stenting of the ductus arteriosus are suitable

options for this patient. Neonates are not candidates for a superior cavopulmonary anastomosis owing to their relatively high pulmonary vascular resistance, which would severely impede the passive drainage required from a systemic venous–pulmonary anastomosis.

2. **Answer E.** Although guided by intraoperative measurements of distal PA pressure, the gradient across the band, and the estimated right ventricular pressure, Trusler's rule provides a good estimate of the ideal band circumference. The Trusler's formula for VSD is the child's weight in kilograms + 20, which would be approximately 23 mm in this scenario. The distal pulmonary arterial pressure should be reduced to somewhere between one-third and one-half of systemic, and systemic arterial saturations should remain between 75 and 85 percent on 50 percent inspired oxygen. The systemic pressure will usually increase by 10 to 15 mm Hg after proper banding.
3. **Answer D.** The Waterston shunt is a central shunt, and involves creation of an anastomosis between the right PA and the posterior ascending aorta through a right thoracotomy.
4. **Answer D.** A 4.0-kg neonate with type 1a tricuspid atresia (concomitant pulmonary atresia) has ductal-dependent pulmonary blood flow. A 4.0-kg neonate would require at least a 4.0-mm shunt to avoid early development of cyanosis. If the ductus was ligated at the time of systemic-to-PA shunt creation, the shunt would become the sole source of pulmonary blood flow and would be unlikely to develop thrombosis. All of the other listed complications are possible sequelae of any modified right Blalock–Taussig shunt placed through a median sternotomy.
5. **Answer B.** Patients with systemic-to-PA shunts must have their shunt controlled at the institution of cardiopulmonary bypass to avoid "steal" into the pulmonary circulation. Patent shunts will lead to inadequate systemic perfusion pressures unless excessively high flows are maintained via the bypass circuit. In addition, though not a concern for a bidirectional Glenn, copious left heart return from a patent shunt will also impede visualization of intracardiac repairs.

# Patent Ductus Arteriosus

*Tain-Yen Hsia*
*Jeffrey J. Wu*
*Richard Ringel*

**KEY CONCEPTS**

- Epidemiology
  - The ductus arteriosus is a normal fetal structure, that arises from the left sixth aortic arch, and connects the proximal left main pulmonary artery to the upper descending thoracic aorta. Persistent patency beyond the neonatal period occurs in approximately 1 in 2500 term live births, with a male-to-female ratio of 2:1. Patent ductus arteriosus (PDA) accounts for 5 to 10 percent of all congenital heart defects, with up to 30 percent of cases observed in preterm infants.
- Pathophysiology
  - The presence of a large, nonrestrictive PDA leads to left-to-right shunting with pulmonary overcirculation, subsequent left atrial dilatation, left ventricular volume overload, and congestive heart failure; if left untreated, irreversible pulmonary hypertension and Eisenmenger physiology with right-to-left shunting and cyanosis ultimately ensue.
- Clinical features
  - Presentation may range from absence of symptoms to the presence of a "machinery-like" murmur with poor feeding, failure to thrive, tachypnea, and recurrent respiratory infections.
- Diagnosis
  - Chest x-ray typically discloses increased pulmonary vascular markings, pulmonary edema, and cardiomegaly. Transthoracic echocardiography demonstrates the ductal anatomy and any coexisting defects.
- Treatment
  - Treatment strategies include pharmacologic closure with indomethacin in premature infants, catheter-based closure with coil occlusion in older children and adults, video-assisted thoracoscopic (VATS) closure, and conventional thoracotomy and ligation. Whereas operative outcomes in premature newborns are heavily dependent on associated comorbidities, morbidity and mortality from surgical or percutaneous closure in infants and children are almost negligible.

## INTRODUCTION

The ductus arteriosus is a normal vascular connection between the pulmonary arterial trunk and the proximal descending thoracic aorta, and is an essential component of the fetal circulation. During fetal life, it allows right-to-left shunting of maternally-derived oxygenated placental blood to the systemic circulation, bypassing the high-resistance pulmonary bed. Following birth, increases in oxygen tension and a drop in pulmonary vascular resistance trigger spontaneous closure (contraction and subsequent fibrosis) of the ductus. Patent ductus arteriosus (PDA) is the persistence of the ductus as a vascular structure (rather than a ligamentous connection) beyond the early neonatal period, leading to unabated left-to-right shunting between the aorta and pulmonary artery with subsequent pulmonary overcirculation.

With an incidence of 1 in 2500 to 5000 births, PDA is the second most common congenital cardiac malformation.[1] Although recognition of the presence of the ductus arteriosus during fetal circulation dates to Galen, it was not until 1907 that John Monro first suggested surgical ligation of PDA in an address to the Philadelphia Academy of Surgery.[2] Thirty-one years later, in 1938, the first operation was attempted by Graybiel and Stieder in a 22-year-old woman with bacterial endocarditis involving the arterial duct.[3] Although the PDA was successfully ligated, the patient succumbed to infection and gastrointestinal complications a week later. Although primacy is still disputed, Robert Gross is credited, later in that same year, with the first ligation of a PDA in a 7-year-old

child with severe heart failure.[4] Although a PDA can today be interrupted through interventional or minimally invasive techniques, operative ligation remains a model of finest surgical practice: predictable anatomy, minimal morbidity, and excellent outcomes.

## ANATOMY AND EMBRYOLOGY

Early in fetal development, the aortic sac is connected to paired dorsal aortae through six arterial arches (see Chapter 84).[5,6] The normal ductus arteriosus develops from the dorsal portion of the left sixth arch. However, because of the bilateral symmetry of the arterial system, arterial ducts can be bilateral or absent, right- or left-sided (the latter being by far the most common variant). The sixth arches develop from the plexus of capillaries that supply the developing buds. These capillaries initially arise from the aortic sac but later join the dorsal aorta. When the arterial segments separate to form the aorta and pulmonary trunk, the sixth arches remain connected to the pulmonary trunk. On the right, the dorsal sixth arch regresses, and the ventral portion becomes the proximal right pulmonary artery. On the left, the ventral sixth arch is incorporated into the main pulmonary trunk, while the dorsal portion remains to become the ductus arteriosus.

The fetal ductus arteriosus normally originates from the pulmonary trunk as a continuation of the lesser curve of the aortic arch, a few millimeters distal and opposite to the origin of the left subclavian artery. It is typically a short and wide vessel of variable length, lying posteriorly to the left main bronchus with the vagus nerve coursing anterior to it. When there is a right-sided aortic arch, the ductus usually arises from the proximal descending aorta in conjunction with the left subclavian artery. The pulmonary end of the ductus is narrower than the aortic end and is invested by the pericardial reflection, while the aortic end is invested by the parietal pleura. The length of the ductus in infancy varies between 2 and 8 mm, with the diameter ranging from 4 to 12 mm. The left recurrent laryngeal nerve branches off the vagus and encircles the inferomedial wall of the duct before ascending behind the aortic arch into the tracheoesophageal groove (Fig. 63-1).

The wall of the ductus arteriosus differs histologically from that of the adjoining aorta and pulmonary artery. Instead of the circumferential layers of elastic fibers, the media of the ductus is made up of smooth muscle cells arranged into a poorly organized spiral outer layer and a longitudinal inner layer that protrudes centrally to join the intima at "cushion" points. Large gaps between intimal cushions are filled with mucinous substance and called "mucoid lakes." The internal elastic intima is thicker than that of other vascular structures, forming wavy layers adjacent to the intimal cushions. The medial smooth muscle is particularly sensitive to $PGE_1$ and $PGI_2$, which cause, respectively, relaxation/dilatation and increased oxygen tension. The latter promotes ductal constriction.[7,8]

The first stage of ductal closure occurs within 15 to 20 hours after birth. This is triggered by a rapid decrease in plasma concentration of prostaglandins (due to loss of maternal supply) and accelerated metabolism (by increased pulmonary blood flow). In addition, increased $PaO_2$ inhibits prostaglandin synthetase, further blunting the level of circulating prostaglandins. The physiologic consequence of these changes is contraction of the smooth muscle in the ductal wall media, with subsequent thrombosis. The second stage of ductal closure is completed within 2 to 3 weeks of birth. This occurs by fibrous proliferation in the intima with necrosis of the inner layer of the media and hemorrhage into the wall. Development of neointimal mounds is stimulated by

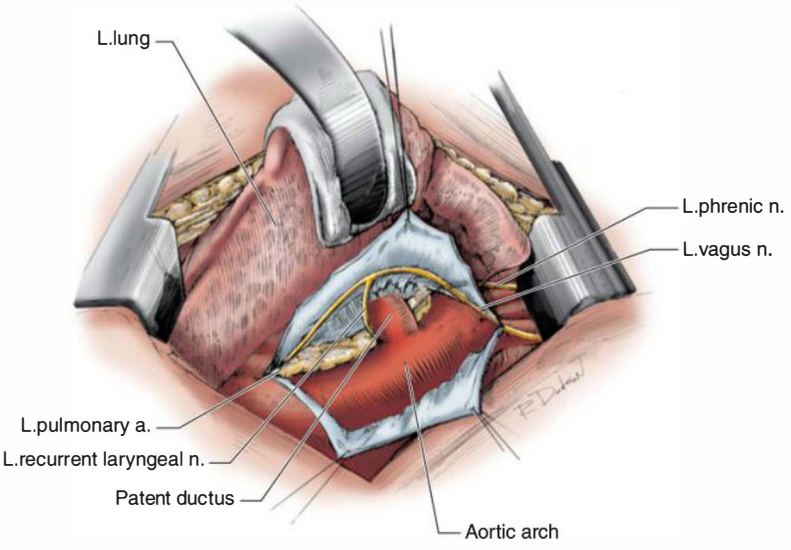

**FIGURE 63-1** Patent ductus arteriosus and contiguous structures through a left thoracotomy (surgeon's perspective). (From Castaneda AR, Jonas RA, Mayer JE, Hanley FL (eds). *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Saunders, 1994:208. With permission.)

vascular endothelial growth factor. The result is the permanent sealing of the lumen and the development of a fibrous ligamentum arteriosum. The ductus is closed by 8 weeks of age in 88 percent of infants with a normal cardiovascular system. Failure of this process results in persistent patency of the ductus arteriosus. Because of the immaturity of the ductal tissue, preterm infants respond poorly to increases in oxygen tension and therefore become the patient population at highest risk of developing PDA persistence. Inability of the immature lungs to clear circulating vasodilators may also contribute to ductal persistence. The incidence of PDA increases from 7 percent in very low-birth-weight infants to as high as 42 percent in extremely low-birth-weight neonates.

## CLINICAL PRESENTATION

As pulmonary vascular resistance falls shortly after birth, increased left-to-right shunting across the PDA results in decreased systemic perfusion and a high left ventricular volume load, with decreased pulmonary compliance. The magnitude of the shunt ($Q_p$:$Q_s$) depends on the size of the ductus, as well as on the balance between systemic and pulmonary vascular resistance. In the absence of fixed pulmonary hypertension, when $Q_p$:$Q_s$ is low, the hemodynamic effect of the PDA is insignificant and physiologic derangements are minimal. With a hemodynamically significant PDA, $Q_p$:$Q_s$ is high, and increased pulmonary runoff in systole and diastole becomes detrimental to systemic pressure, leading to end-organ hypoperfusion. Furthermore, high pulmonary blood flow increases pulmonary artery pressure and, if left uncorrected, can lead to permanent pulmonary vascular disease. The clinical features of a hemodynamically significant PDA are similar to those of left-sided heart failure, with tachypnea, frequent respiratory infections, pulmonary edema, and failure to thrive. Premature infants with a PDA may present with substantial metabolic acidosis, oliguria, respiratory decompensation, and necrotizing enterocolitis.

A hemodynamically insignificant PDA may present subtly later in life. In this setting, left ventricular failure does not develop and symptoms are absent in infancy and childhood. A murmur is usually detected on routine physical examination, leading to the echocardiographic diagnosis of PDA.

A rare late mode of presentation of a PDA is infective endocarditis. The presence of a PDA may alter the local vascular immune response mechanisms or cause endothelial damage, providing a nidus for bacterial colonization. In the preantibiotics era, the average age of death in patients with a PDA surviving beyond infancy was 36 years, and infective endocarditis accounted for 45 percent of such deaths.[9]

## DIAGNOSIS

Physical examination and echocardiography represent the cornerstones for the diagnosis of PDA. The patient will present with a widened pulse pressure, a hyperactive precordium, and an occasional systolic thrill. A continuous "machinery-like" murmur radiating from the pulmonic area to the midclavicle is characteristic. Electrocardiography may demonstrate left ventricular hypertrophy and left atrial enlargement. Chest radiography may show cardiomegaly with increased pulmonary markings and enlarged pulmonary trunk. Transthoracic Doppler echocardiography is diagnostic, showing the accelerated, narrow jet flow originating from the proximal descending aorta into the left pulmonary artery (Fig. 63-2). Cardiac catheterization is currently reserved for interventional device closure after echocardiographic diagnosis. Catheterization is also indicated in the older child with a large ductus and cyanosis due to right-to-left shunting at the ductal level in order to define the reversibility of pulmonary hypertension. If pulmonary resistance is over 75 percent of systemic and is unresponsive to nitric oxide and oxygen administration, PDA closure is contraindicated.

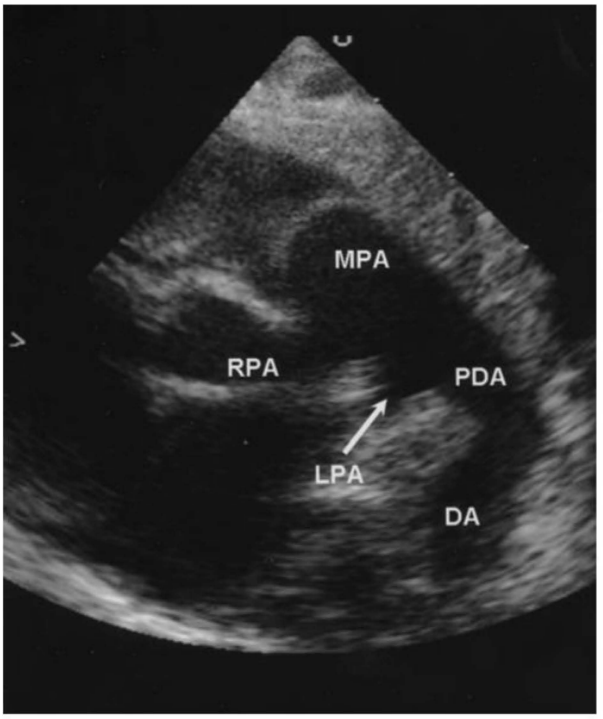

**FIGURE 63-2** Echocardiographic image of a patent ductus arteriosus from a high parasternal view. DAO, descending aorta; AI, aortic isthmus; PDA, patent ductus arteriosus. (Courtesy of William Ravekes, MD, Division of Pediatric Cardiology, The Johns Hopkins Hospital.)

## SURGICAL TREATMENT

Traditionally, the presence of a PDA is an indication for closure. With the improved sensitivity of diagnostic modalities, the very small and hemodynamically insignificant

ductus can be detected. Although likely not warranting early intervention, small PDAs can still be a potential site for bacterial endarteritis and will require monitoring.

Treatment strategies include pharmacologic closure, percutaneous closure in the catheterization laboratory, video-assisted thoracoscopic (VATS) hemoclip occlusion and conventional posterolateral thoracotomy with ligation. Percutaneous closure is effective in the treatment of children and adults with PDA. Primary surgical closure is reserved for premature newborns, small infants, and patients who have failed device closure. A randomized trial has demonstrated that early surgical ligation of PDA in neonates reduces the need for mechanical ventilation and oxygen supplementation, shortens hospital stay, and decreases the incidence of retrolental fibroplasia and necrotizing enterocolitis when compared to pharmacologic closure.[10] However, initial attempt at pharmacologic PDA closure remains the initial therapeutic modality at most institutions.

Pharmacologic treatment is successful in achieving PDA closure in up to 60 percent of premature infants.[5] A combined strategy of fluid restriction, diuretics, and indomethacin is used. Indomethacin has been utilized clinically since 1976 to facilitate ductal closure in premature infants[11] but is rarely successful in full-term neonates. Contraindications to indomethacin use in preterm infants include hyperbilirubinemia, sepsis, coagulopathy, gastrointestinal bleeding, and renal insufficiency. If indomethacin use is contraindicated or fails, surgical closure is undertaken. Preterm infants typically undergo two to three courses of indomethacin (12–24 h apart) before being considered for surgical closure.

Early operative PDA closure carries low operative morbidity and mortality. Ductal ligation is now frequently performed at the bedside in the neonatal intensive care unit in order to minimize the risks of hypothermia and transport of the critically ill neonate. Several series have in fact reported results of bedside PDA closure to be comparable to those of procedures performed in the operating room.[12] Surgical intervention in the premature infant requires close attention to maintenance of body temperature, precise ventilatory management, and fluid administration. The size and shape of the ductus can be variable. A wide, short ductus can be difficult to ligate, whereas a long, tortuous ductus is easier to interrupt. The ductal tissue in neonates tends to be extremely fragile and therefore must be handled with great caution. Care should be taken to avoid scissoring through the ductus with overaggressive ligation. A short, wide ductus may be better divided between clamps if tissue integrity is a concern. In selected cases, we prefer to gradually snare the PDA with a Goretex band, then tightened with several titanium clips. As described previously, the left recurrent laryngeal nerve makes its loop around the ductus. Care must be taken to identify and protect this nerve during surgical closure.

In the setting of a left-sided aortic arch, the patient should be positioned in the right lateral decubitus position with the left arm supported over the head to elevate the scapula. The chest is entered through a left posterolateral thoracotomy, with division of the muscular layers and entrance into the third or fourth intercostal space. The left lung is retracted anteriorly with a narrow malleable retractor, and the mediastinal pleura is incised over the descending aorta. The left recurrent laryngeal nerve should be identified and preserved. Especially in premature newborns, extensive dissection of the ductus itself should be avoided owing to the friable nature of the tissue. The left pulmonary artery, arch of the aorta, and subclavian artery should all be carefully identified (Fig. 63-2). The ductus is frequently larger than the aortic arch and isthmus. The most common technical error is the inadvertent ligation of the left pulmonary artery, which is mistaken for the ductus. The pleura is incised just above and below the ductus using fine scissors. We prefer to apply a hemoclip to close the PDA (Fig. 63-3); however, if the duct is unusually large or the patient is an older infant or child, it may be encircled with silk ties, doubly ligated, and divided. Although division is the ultimate form of interruption, it should be utilized with caution in the presence of a short, broad-based hypertensive duct or in the fragile premature newborn. Prior to ductal ligation, test-occlusion of the ductus with forceps should be performed. A rise in diastolic pressure should be noted, as well as maintained pulsatility in the descending aorta and unaltered oximetric signal in the lower extremities. A medium-sized hemoclip is applied, with the tip of the clip visible posteriorly beyond the inferior margin of the ductus. The mediastinal pleura is typically left open. A chest tube may be placed if there is concern for pulmonary parenchymal injury.

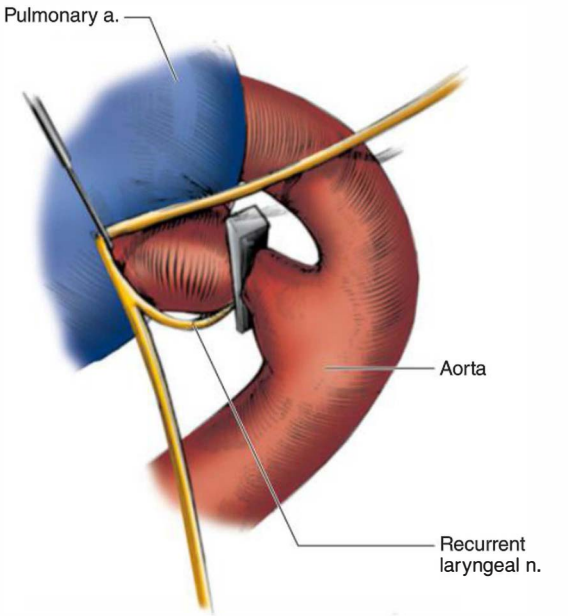

**FIGURE 63-3** A hemoclip is utilized to interrupt the patent ductus arteriosus in premature infants. (From Castaneda AR, Jonas RA, Mayer JE, Hanley FL (eds). *Cardiac Surgery of the Neonate and Infant.* Philadelphia: Saunders, 1994:209. With permission.)

Several specific considerations should be made for adults presenting with a PDA. Historical series from the 1960s suggest that 40 percent of patients with untreated PDA would die by age 45 because of chronic pulmonary vascular disease or Eisenmenger syndrome. When patients present in adulthood, diagnostic catheterization should be performed to determine operability by assessing the degree of pulmonary hypertension and responsiveness to nitric oxide and oxygen. Since adult patients may have significant calcification of the ductus, the PDA should be approached through a median sternotomy with cardiopulmonary bypass. A median sternotomy may also be useful in patients with a wide, short PDA. The transpulmonary artery approach described by Goncalves-Estella[13] with support of cardiopulmonary bypass can be used in these cases, with temporary occlusion of the branch pulmonary arteries. The aorta and the main pulmonary arterial trunk are dissected apart. Cardiopulmonary bypass is established with a single venous cannula and aortic return line, cooling is begun, and the patient is placed in the Trendelenburg position. The opening of the ductus is controlled by digital compression on the pulmonary arterial confluence, avoiding excessive pulmonary arterial runoff upon institution of corporeal circulation. When adequate systemic cooling is achieved, low-flow cardiopulmonary bypass is instituted. The pulmonary artery is opened and the incision extended onto the left pulmonary artery opposite the orifice of the PDA. The ductal opening is next closed with pledgeted mattress sutures if no calcification is present. If significant calcification of the pulmonary arterial end of the ductus is noted, the orifice should be closed using a bovine pericardial or Dacron patch. Alternatively, the duct can be controlled with a balloon-tipped catheter inserted though the pulmonary artery into the descending aorta at low-flow perfusion. In a variation of this technique, a patch can be slid over the catheter and secured in place.[14]

Aneurysmal dilatation of the arterial duct has been described, with potential risks of rupture, erosion, infection, and thromboembolism. Neonatal ductal aneurysms usually resolve spontaneously by thrombosis. Any patients above 2 months of age with a ductal aneurysm should undergo prompt surgical repair. These patients may present with hoarseness from recurrent laryngeal nerve traction, vocal cord paralysis, or obstruction of the left mainstem bronchus. Surgical treatment is performed on cardiopulmonary bypass, with aneurysmal excision and patch aortoplasty under circulatory arrest.

The first VATS PDA closure was performed in 1991 by Laborde.[15] Video-assisted closure can be performed with three to four small incisions for instrumentation. Port incisions are placed in a line to facilitate posterolateral thoracotomy extension should conversion to a conventional approach be required. This innovative approach minimizes chest wall trauma, division of muscular planes, and rib retraction.[16] The ductus is dissected free of surrounding tissues, the recurrent laryngeal nerve is identified, and the duct is interrupted with clips. Good results from VATS closure have been obtained in low-birth-weight infants. Postulated advantages are reduced patient discomfort and hospital length of stay. This technique has been used in neonates, children, and adults. In Laborde's series of 332 consecutive pediatric patients, mortality was zero, with minimal morbidity.

Closure with robotic assistance has also been performed. The limitations, however, are due to the physically large size of the instruments, requiring 7-mm ports. Current robotic systems use widely spaced operating arms, thus limiting their use to adults. No tactile feedback is available to indicate to the surgeon the degree of force applied.

Results of surgery with a traditional posterolateral thoracotomy approach have a long-standing record of providing a durable repair with minimal morbidity and mortality. In 1994, Mavroudis and coworkers reported the results of the traditional surgical approach at their institution between 1947 and 1993.[17] This series included 1108 patients who underwent ligation and division of a PDA. There were no mortalities and no recurrences. The authors concluded that these results represent the standard of care to which video-assisted and catheter-based closure should be compared. Recent series describing results with the VATS approach have shown comparable results with minimal residual shunts and no important complications.[18] Only 3 patients in a series of 300 endoscopic cases required conversion to a standard posterolateral thoracotomy, and only two experienced transient functional impairment of the recurrent laryngeal nerve.

## TRANSCATHETER OCCLUSION OF A PATENT DUCTUS ARTERIOSUS

The first nonsurgical PDA closure was reported by Porstmann in 1967.[19] Closure was accomplished by implantation of an expandable plug within the arterial duct. Although the required delivery system was much too large to be of practical use in small children, this report pointed to the possibility that repair of congenital heart defects could be accomplished by transcatheter techniques. Twelve years later, Rashkind developed a double-umbrella device to close the ductus arteriosus of a 3.5-kg infant.[20] Clinical trials met with some success, but rates of residual leakage and technical difficulties precluded wide acceptance or FDA approval of the device. In 1992, Gianturco embolization coils (Cook Inc., Bloomington, IN) were first used to produce embolization of the ductus arteriosus by modification of the technique used in the preceding decade to embolize fistulae, arteriovenous malformations, and other vascular abnormalities. Cambier and colleagues reported the first case of successful transcatheter PDA coil embolization in 1992.[21] This technique immediately gained wide popularity for its low cost, excellent safety, efficacy, and for its adaptability to a wide spectrum of patients ranging from infancy to adulthood. Coil embolization is still used to close small PDAs, but the technique can be cumbersome and the residual leak rate is higher when larger PDAs are encountered, particularly in small infants. Thus a number

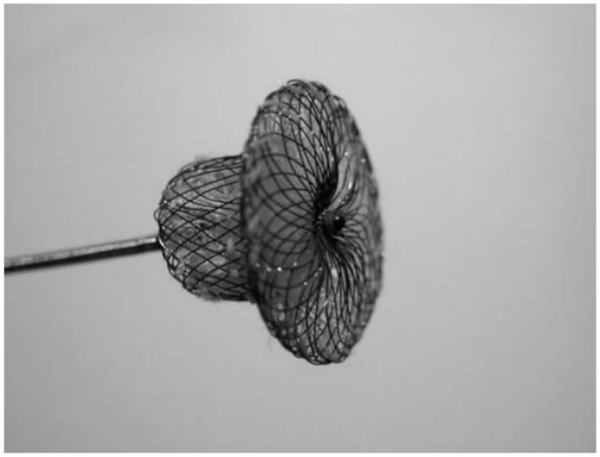

**FIGURE 63-4** Amplatzer ductal occluder (ADO) device. (Courtesy of Richard Ringel, MD, Division of Pediatric Cardiology, The Johns Hopkins University Hospital.)

of investigators have continued to work on the challenge of developing a device specifically designed to close the ductus arteriosus. In 2002 the first such device to obtain FDA approval was the Amplatzer ductal occluder (ADO); it remains to date the only device specifically approved for nonsurgical closure of the ductus arteriosus in the United States.[22] The device consists of 72 strands of nitinol wire woven into a mushroom-shaped plug with a core of polyester fiber (Fig. 63-4). It is particularly helpful for closure of moderate-to-large PDAs in patients above 6 months of age. For infants younger than 6 months, the right-angle orientation of the flat aortic retention disk to the plug portion of the device that fits within the ductus itself does not truly conform to aortic anatomy, and may protrude excessively into the aortic lumen of a smaller infant. However, a new, doubly articulated Amplatzer ductal occlude is currently in trials. It is softer, better able to mold into ductal variations and should be safer to use in smaller infants.[23] Device closure of the PDA offers the obvious advantage of avoiding a surgical incision. The procedure at most centers is performed on an outpatient basis under moderate sedation, with use of percutaneous femoral venous and arterial access (Fig. 63-5). Current contraindications to the use of nonsurgical techniques currently include a large (≥4 mm diameter) PDA in infants weighing 6 kg or less, active endocarditis, or pulmonary hypertension with right-to-left shunting through the ductus arteriosus.

Several treatment algorithms have emerged, wherein smaller PDAs (minimum diameter ≤2.5 mm) are closed by coil embolization[21,22] and larger PDAs are closed with an ADO; with this strategy, successful implantation with complete closure will approach 98 percent or greater.[23]

Complications of coil embolization are uncommon. Femoral artery thrombosis is rare and essentially seen only in smaller infants. Almost all of these problems are transient, responding to anticoagulant or thrombolytic therapy. Embolization of the coil into the pulmonary arteries is the most frequently described complication, occurring in up to 16 percent of procedures;[24] however, virtually all of these embolized coils can be removed immediately during catheterization without sequelae. Embolization into a systemic artery is very unusual, occurring in up to 3 percent of cases. Hemolysis

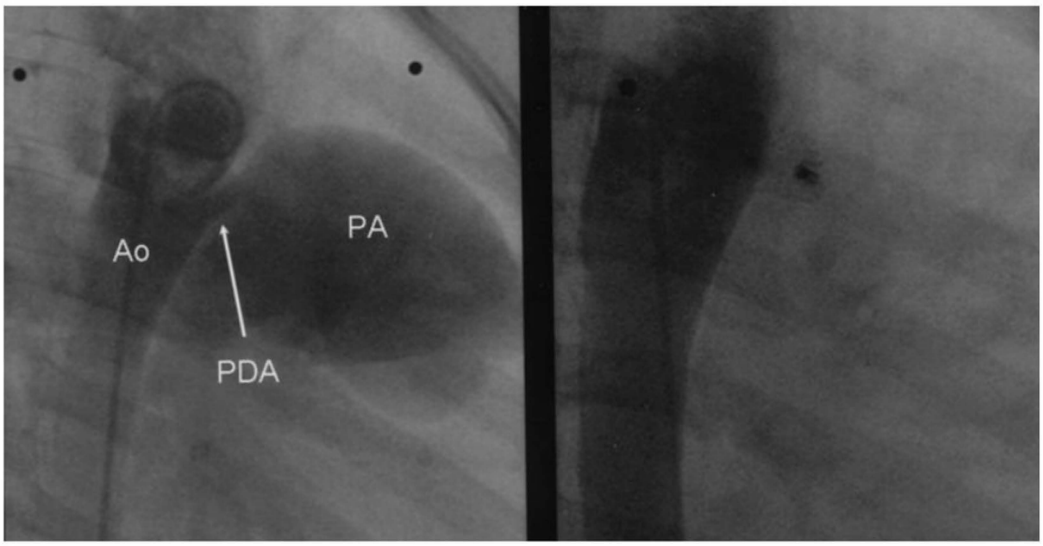

**FIGURE 63-5** Interruption of patent ductus arteriosus with Amplatzer ductal occluder (ADO) device. Left: Contrast is seen within t he ductus arteriosus with injection in the thoracic aorta. Right: Successful closure of the arterial duct. PDA, patent ductus arteriosus. (Courtesy of Richard Ringel, MD, Division of Pediatric Cardiology, The Johns Hopkins University Hospital.)

following coil embolization is very rare and can be avoided by implanting additional coils[25,26] to eliminate any residual shunting identified on the postimplant aortic contrast study. Creation of left pulmonary artery stenosis or aortic obstruction has been described infrequently, but is almost exclusively seen in the small infant with a PDA that requires three or more coils to achieve adequate closure. Complications associated with the Amplatzer device are likewise uncommon, and usually minor when use of the device is restricted to patients over 6 months of age. Major adverse events (i.e., device embolization, partial pulmonary artery obstruction, loss of femoral pulse, bleeding requiring transfusion) occurred in 10 of 439 (2.3 percent) patients during phase III FDA trials, with most of these occurring in smaller infants.[22]

## SUMMARY

Treatment of PDA can be performed with low mortality and morbidity. Multiple options are now available, ranging from medical to surgical to interventional catheter-based treatment. Nonsurgical device closure of the ductus arteriosus can be performed with a success rate of about 98 percent and a complication rate below 3 percent with the use of an interventional strategy that employs embolization coils for small PDAs and ADOs for moderate-to-large PDAs. Operative closure is recommended for infants with congestive heart failure who weigh 6 kg or less; such patients should not wait until they are of more appropriate size for a nonsurgical approach.

## PATENT DUCTUS ARTERIOSUS BOARD REVIEW QUESTIONS (CHAPTER 63)

1. Which is true regarding embryology of the ductus arteriosus?
   A. The normal ductus arises from the right sixth arch.
   B. The arches remain connected to the pulmonary trunk when the aorta and pulmonary artery divide.
   C. The ventral portion of the right arch becomes the distal right pulmonary artery.
   D. The dorsal portion of the left arch is incorporated into the main pulmonary trunk.
   E. The ventral portion of the left arch becomes the distal left pulmonary artery.

2. Which is correct regarding closure of the ductus arteriosus?
   A. The first stage is complete within 4 to 6 h of birth.
   B. The first stage is triggered by an increase in plasma prostaglandins.

C. Increased $Paco_2$ increases prostaglandin synthetase.
D. Second-stage closure is complete by 2 to 3 weeks after birth.
E. The ductus is closed by 4 weeks in 90 percent of infants.

3. Which is true regarding treatment of a PDA?
   A. Forty percent of patients will die by age 45.
   B. The PDA should be approached through a left thoracotomy in an adult.
   C. Control of the PDA is not required prior to cardiopulmonary bypass.
   D. Neonatal ductal aneurysms require urgent surgical repair.
   E. VATS closure is not applicable to neonates.

4. Which of the following is incorrect regarding early surgical ligation of PDA?
   A. Reduced need for mechanical ventilation
   B. Reduced requirement for oxygen supplementation
   C. Extended hospital stay due to surgical recovery
   D. Decreased incidence of retrolental fibroplasia
   E. Reduced incidence of necrotizing enterocolitis

5. Which is true regarding non-surgical approaches for a PDA?
   A. Residual leak rate is higher in large PDAs treated with coil embolization.
   B. The Amplatzer device is useful only in small PDAs for children older than 6 months of age.
   C. A PDA less than 8 mm in diameter in an infant weighing less than 6 kg can be safely closed percutaneously.
   D. Pulmonary hypertension with a left-to-right shunt is a contraindication to nonsurgical closure.
   E. Embolization into the pulmonary arteries occurs in less than 5 percent.

## ANSWERS

1. **Answer: B.** The arches remain connected to the pulmonary trunk when the aorta and pulmonary artery divide. The normal ductus arises from the left sixth arch. The dorsal portion of the right arch becomes the distal right pulmonary artery and the dorsal portion of the left arch becomes the distal left pulmonary artery. The ventral portion of the left arch is incorporated into the main pulmonary trunk.
2. **Answer: D.** Second-stage closure is complete by 2 to 3 weeks after birth. The first stage is complete by 15 to 20 h after birth and is triggered by a rapid decrease in plasma prostaglandins. Increased $Paco_2$ inhibits prostaglandin synthetase. The ductus is closed in 90 percent of infants by 8 weeks.
3. **Answer: A.** Forty percent of patients will die by age 45 from irreversible pulmonary hypertension if left untreated. The PDA should be approached via sternotomy in an adult due to calcification of the ductus, and the PDA should be controlled prior to instituting cardiopulmonary bypass to prevent excessive r unoff. Neonatal ductal aneurysms almost always resolve spontaneously by thromobosis. VATS closure can be used in neonates as well as infants and adults.
4. **Answer: C.** Early surgical ligation of a PDA decreases overall hospital stay. Early ligation is also associated with a reduced incidence of all of the remaining complications.
5. **Answer: A.** Residual leak rate is higher in large PDAs treated with coil embolization. The Amplatzer device should only be used in moderate-to-large PDAs. Contraindications to nonsurgical closure include a PDA greater than 4 mm in small infants and pulmonary hypertension with a right-to-left shunt. Embolization of devices into the pulmonary arteries occurs in up to 15 percent of procedures.

# Atrial Septal Defects and Partial Anomalous Pulmonary Venous Connection

*Dario Troise*
*Richard Ringel*
*Francesco Paolo Annecchino*

## KEY CONCEPTS

- Epidemiology
  - Atrial septal defects (ASDs) are among the most common cardiac malformations, with prevalence [including persistence of patent foramen ovale (PFO)] greater than 15 percent for the general population and, when other cardiac anomalies are present, as high as 35 to 50 percent, with slight female predominance.
- Morphology
  - Atrial septal defects can be categorized according to the area of deficient interatrial septum: Secundum-type/PFO (most common), superior/inferior sinus venosus (SV), primum defects, coronary sinus (CoS) ASDs. Partial anomalous pulmonary venous connection (PAPVC) and scimitar syndrome often occur in the setting of an ASD. Defects are variable in size: from restrictive, to unrestrictive, to virtual absence of any septal rim.
- Pathophysiology
  - Magnitude of left-to-right shunt depends on the respective compliance of right and left ventricles and on the diameter of the defect. Because of streaming of systemic venous return toward the LA, superior and inferior SV defects can present with mild cyanosis. A minority of patients with very large defects will develop pulmonary venous obstructive disease over several decades and, eventually, fixed pulmonary hypertension (PHTn) and right-to-left shunting.
- Clinical features
  - In the absence of other malformations, ASDs are rarely symptomatic in early infancy. Features of pulmonary overcirculation (dyspnea, failure to thrive, recurrent respiratory infections) are rare in early childhood. Arrhythmias or paradoxical emboli can be initial modes of presentation.
- Diagnosis
  - Physical exam (split and fixed second heart sound) and chest x-ray (CXR) (cardiomegaly, anomalous vascular markings in PAPVC) suggest the diagnosis, confirmed by transthoracic echocardiography (TTE). In equivocal cases and for PAPVC/scimitar syndrome (SS), transesophageal echocardiography (TEE), magnetic resonance imaging (MRI), and computed tomography (CT) might be utilized. Cardiac catheterization has almost no role in the diagnostic workup, except for patients with evidence of PHTn considered for surgical closure.
- Treatment
  - Surgical closure is rarely indicated in infancy, but should be performed for unrestrictive defects in preschool age and for symptomatic adults and cases of paradoxical embolization. When the anatomy is permissive, percutaneous device closure can be considered. Conventional primary or patch closure of the defect can be accomplished via a right thoracotomy or limited/full sternotomy and, in the current era, should be associated with virtually no mortality or significant morbidity.

## DEFINITION

We define an atrial septal defect (ASD) as a deficiency of any size in the atrial septum (Fig. 64-1). Although briefly mentioned in this chapter, we will not include among ASDs the patent foramen ovale (PFO); this flap-valve is bordered superiorly by the upper limbic tissue and inferiorly by the valve of the fossa ovalis, which opens only in specific circumstances, as during coughing or the Valsalva maneuver. The ostium primum (OP) defect is part of the spectrum of atrioventricular septal defects (AVSDs) and is discussed in detail in Chapter 66.

A partial anomalous pulmonary venous connection (PAPVC) is a condition presenting with variable anatomic patterns in which some but not all pulmonary venous flow lacks drainage into the left atrium (LA). This condition, characterized therefore by one or more pulmonary veins functionally draining into the right atrium (RA), may or may not be associated with an ASD. Similar considerations apply to scimitar syndrome (SS).

In this chapter, we will discuss clinical and surgical aspects that pertain to these malformations (ASD, PAPVC, and SS) and, eventually, briefly focus on current nonsurgical alternatives for ASD closure.

## HISTORICAL HIGHLIGHTS

Following the successes of surgical closed heart procedures in the 1940s, surgeons focused their attention, mainly because of its relative simplicity, on the correction of ASDs.

This pathologic condition was described as a "perforating channel in the atrial septum" by Leonardo da Vinci in 1513,[1] but it was only in the mid-1930s that the first antemortem diagnosis was made by Roesler, in his report on 62 cases of ASD found at autopsy.[2] It was only between the late 1940s and early 1950s that, with the introduction of cardiac catheterization, a definite diagnosis became possible.

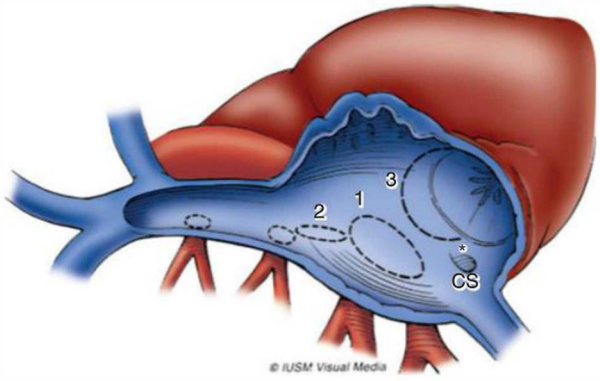

**FIGURE 64-1** Different locations of atrial septal defects as schematically seen through a right atriotomy. (Copyright IUSM Visual Media.)

On account of the brief temporal mismatch between the possibility of safely diagnosing the condition during life and the feasibility of treating it surgically, three eras in the surgical treatment of the ASD can be identified: the closed-heart era, the semi-open era, and the open-heart era.

Murray was the first surgeon to report, in 1948, the closure of an ASD in a 12-year-old boy, using the external suturing technique.[3] The patient survived, but success was subtotal owing to a residual shunt, later discovered on cardiac catheterization. In the early 1950s, various closed methods were investigated, including the intussusception technique of Santy,[4] the invagination technique of Swan,[5] the digital palpation closed technique proposed by Bailey,[6] and the Sondergaard circumclusion technique.[7] All these attempts led to unacceptable mortality and a high incidence of morbidity such as atrial distortion, coronary sinus (CoS) stenosis, and the persistence of significant residual defects.

In 1953, Robert Gross utilized a semi-open technique that entailed the introduction of a cone within the atrium, allowing for closure of the defect without direct vision in the depth of a blood-filled well.[8] The cone was sutured to the atrial wall, and an atriotomy could be performed under hydrostatic pressure averting the possibility of air embolization. John Kirklin reported a series of 29 patients corrected with this technique at Mayo Clinic without operative mortality.[9]

The experiments of a short period of inflow occlusion under surface hypothermia gave way to the era of open-heart correction. Inspired by the laboratory work of Wilfred Bigelow, John Lewis at the University of Minnesota first reported successful closure of an ASD under direct vision in a 5-year-old girl.[10] Shortly thereafter, closure was accomplished with cross-circulation by C. Walton Lillehei.

With the construction of the first heart-lung machine, John Gibbon ushered the current era of open-heart surgery in the treatment of ASDs.[11]

In 1858, Peacock described for the first time the anatomic findings of a sinus venosus defect (SVD) in a 6-year-old girl who died of scarlet fever.[12] After initial approaches to PAPVC with palliative and closed techniques, Kirklin and colleagues first reported successful outcomes with open correction of various types of PAPVC.[13]

## EMBRYOLOGY

The cardiac tube is formed by an inner layer of endocardium, separated from the external myocardium by an extracellular matrix, known as cardiac jelly.[14] At the fifth week of embryonic life, the primary septum (septum primum) appears as a partition, of mesenchymal origin, in the dome of the common atrium. With further development, it occupies more space and, at the same time, incorporates two segments of mesenchymal origin that are also concomitantly forming: the endocardial cushions of the atrioventricular

canal and the vestibular spine (spina vestibuli), which originate from the dorsal mesocardium and are situated between the endocardial cushions and the anteriorly and inferiorly located septum primum. In this early phase, the space between the septum primum and the endocardial cushions is called ostium primum. It has not yet been established whether the development of the septum primum consists in growth from the roof of the common atrium toward the inferiorly displaced endocardial cushions[15] or if, as stated by Van Praagh and apparently in contrast to mainstream embryology, in an upward growth, starting from the inferior vena cava (IVC, the left wall of which is in direct continuity with the septum primum) toward the roof of the common atrium.

Before complete fusion of all mesenchymal segments of the interatrial septum, the superior part of the primary septum is reabsorbed, forming multiple fenestrations that converge into a single defect known as the ostium secundum (OS).

From the dorsal aspect of the common atrium emerges to follow an infolding of the atrial wall (septum secundum) which will be directed toward (but on the right side of) the septum primum. The plane of growth of the two septa is not identical and may thus overlap for a variable extent (Fig. 64-2). The conformation of the septum resembles that of a flap valve, in which a superoinferior plane as well as a lateral plane of growth may be identified. The development of this structure allows for half of the oxygenated placental blood to cross the interatrial communication. The septum primum becomes involved in this process, leaving vestigial remnants in the segments located in proximity of the endocardial cushions. This vestigial part, which is not overlapped by the more superior septum secundum, is the floor of the fossa ovalis. The upper edge of the flap valve does not fuse with it, but simply overlaps. With postnatal changes in heart chamber pressures, the superior edge of the fossa ovalis fuses completely (in approximately 60 percent of cases) with the lower edge of the septum secundum. Fusion is otherwise incomplete and a communication between the atria persists as a PFO.

Development of the muscular septum primum and the ventral proliferation of extracardiac mesenchyme from the dorsal mesocardium aligns the common pulmonary vein (CPV) which, once incorporated into the posterior aspect of the left-sided atrium, eventually differentiates into left and right pulmonary veins. The sinus venosus (SV) segment is that part of the atrium which, in postnatal life, will be responsible for draining systemic and coronary return as well as for the development of the smooth venous tissue between the venous ostia. The connection of the sinus with the atrial segment after the primary tube is formed is represented by the sinoatrial orifice, which, forced by the predominant development of the right-sided sinus, migrates from its midline position toward the right. The sinoatrial orifice is surrounded by venous valves on the right and left sides. Once incorporated into the dorsal aspect of the right-sided atrium, the development of the sinus segment pushes the right side of the venous valve toward a ventral line and crosses two bands that are developing perpendicular to it: the superior and the inferior limbic bands. These bands develop underneath the endocardium at the periphery of the fossa ovalis. The superior band, from the upper edge of the fossa ovalis (superior limbus of the fossa ovalis) crosses the venous valve between superior and inferior caval orifices; the inferior band (inferior limbus of the fossa ovalis), crosses the venous valve between the IVC and the CoS orifices and, eventually, forms the base of the sinus septum.

The incomplete development of the septum primum results in a defect within the fossa ovalis (Fig. 64-3). This process may be related to different mechanisms, such as incomplete overlapping of the superior limbus of the fossa ovalis (patent foramen ovale); redundancy of the foraminal valve (aneurysm of the atrial septum); partial or total breakdown of the septum primum, resulting in a single perforation of the septum primum (OS defect); or in multiple fenestrations.

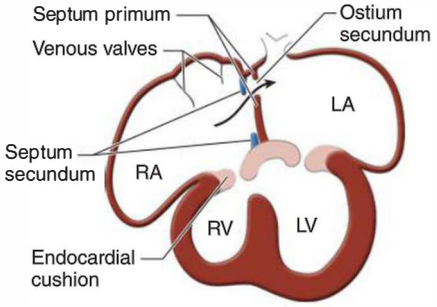

**FIGURE 64-2** Development of the interatrial septum. The atria are partitioned by the developing septum. On the left of the midline, the septum primum has obliterated the ostium primum, and is in the process of partial reabsorption in its cephalad portion (ostium secundum). The septum secundum originates from the right of the septum primum and covers the ostium secundum for a variable length. RA, right atrium, LA, left atrium, RV, right ventricle, LV, left ventricle. **FIGURE 64-3** Secundum-type atrial septal defect (fossa ovalis ASD). Schematic view as seen through a right atriotomy. AV, atrioventricular; IVC, inferior vena cava; SA, sinoatrial; SVC, superior vena cava. (From Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). Atrial septal defect and partial anomalous pulmonary venous connection. *Kirklin/Barratt-Boyes Cardiac Surgery*, 3rd ed. Philadelphia: Churchill-Livingstone, 2003:730. With permission.)

As previously mentioned, after maturation of the septum primum, the infolding of the dorsal common atrial cavity positions the CPV in its definitive location behind the LA. Hence, various theories have been advanced to explain the development of PAPVC. Hartley[16] suggested that the incomplete migration of the sinoatrial orifice from the midline, was the main cause of the development of a superior vena cava (SVC) medially, with displacement of the septum primum toward the septum secundum and subsequent underdevelopment of the latter. This theory would indeed account for the overriding of the SVC typically observed in the superior caval ASD but not for the high prevalence of PAPVC associated with it. An elegant echocardiographic study on SVDs from Children's Hospital Boston has shown that the deficiency in the wall that normally separates the right pulmonary veins or SVC and the RA is the leading cause of this particular defect.[17] Depending on the structures involved in this anomalous process, different subsets of ASDs (with one or more right pulmonary veins overriding the septum secundum) will occur.

Finally, a CoS defect may be due to a deficiency in the remnant of the left horn of the SV, which extends along the entire length of the CoS to reach its orifice. This defect is generally found in association with persistence of a left SVC.

Advances in genetic analysis and molecular biology have striven to investigate the embryonic mechanisms of cardiac looping, chamber development, myocardial cell growth, and cardiac valve formation. At present, the origin of most of the complex genetic traits of congenital heart disease remains to be completely defined. Studies focused on chromosomal abnormalities, autosomal dominant syndromes, and genetic linkage analysis of relatives of patients presenting with minor degrees of congenital heart disease have led to the detection of only a handful of the genes responsible for the development of congenital heart malformations.

Specifically (with regard to atrial septation defects), it is known that the Holt-Oram syndrome (association of ventricular septal defect and ASD with limb abnormalities) is the product of mutation of gene TBX5 in locus 12q24. Several investigations have revealed a heterozygous mutation in gene NKX2.5 in locus 5q34 in families with ASDs and conduction abnormalities.[14]

## ANATOMIC CONSIDERATIONS

The five more commonly occurring variants[18] of defects of the interatrial septum are (1) OS defect and PFO, (2) OP defect, (3) CoS defect, (4) SV ASD and its association in the superior position with PAPVC, and (5) SS.

The OS defect is the most common of all types of interatrial communications (80 percent). This defect is confined within the borders of the fossa ovalis (Fig. 64-3) and its name is in fact almost a misnomer, since the OS defect is actually the final result of deficiency in the development of the septum primum. OS defects may differ in size and morphology, depending on the degree of reabsorption of the septum primum and on the deficiency of the flap valve of the fossa ovalis. The degree of its absence varies from partial deficiency to complete absence, when the inferior border of the septum primum becomes continuous with the posterior wall of the IVC. Surgeons must bear this anatomic peculiarity in mind in order to distinguish the inferior edge of the defect from the eustachian valve: misperception of this may result in inadvertent baffling of the IVC to the LA. A PFO is found in approximately 30 percent of normal hearts. In the absence of left-to-right shunt (and with LA pressure > RA pressure), the lack of closure of the natural flap valve may be considered not a true interatrial communication. Intermittent shunting across the PFO may occur spontaneously or during provoking maneuvers that increase RA pressure, such as coughing or the Valsalva maneuver.

Because of the direct continuity between the leftward aspect of the IVC wall and the septum primum, when the floor of the fossa ovalis is absent and an ASD extends toward the IVC, the inferior caval ostium overrides the defect onto the LA. This anatomic pattern (or inferior SV ASD) may occasionally promote right-to-left shunt with cyanosis. Moreover, the proximity of right pulmonary veins to the deficient posteroinferior rim of the ASD favors a functional hemianomalous pulmonary venous connection.

At the extreme of septal maldevelopment is the common atrium, which may be described as an association of several defects involving structures of different embryonic origin. The association of a complete lack of the septum primum and of the superior and inferior limbi has been classified by some authors as the common atrium. This lesion is generally found in atrial isomerism in association with a persistent left SVC draining into an unroofed CoS.

Defects located beneath the inferior limb of the primary septum (10 percent of all ASDs) are associated with morphologic abnormalities of the atrioventricular valves and are described in Chapter 66. Even if these are to be invariably classified as AVSD or endocardial cushion defects, the OP defect has been reported in hearts with no evidence of AVSD morphology.[19]

The CoS defect (Fig. 64-4) results from variable fenestrations along the common wall between the CoS and the posterior aspect of the LA. It represents an infrequent type of ASD, accounting for only 1 to 2 percent of all defects of the interatrial septum. The ostium of the CoS is invariably present in its expected position along the posteroinferior margin of the triangle of Koch (see Chapter 59). This defect is generally found in association with a number of lesions, most frequently with persistence of the left SVC: these associated lesions (with the extreme form being the total absence of the CoS wall) determine the spectrum of the "unroofed coronary sinus syndrome." A surgical classification has been proposed that categorizes CoS defects into proximal, medial, and distal according to the site of the deficiency of the CoS wall along its length.[20–22]

The superior SVD (SV ASD) is associated with PAPVC in 5 to 10 percent of cases. This malformation (also known as superior caval ASD) is located in the posterosuperior

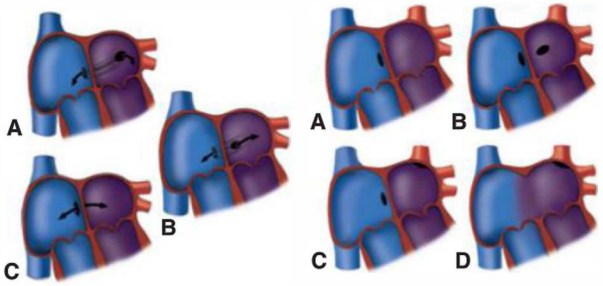

**FIGURE 64-4** Coronary sinus (CoS) defect with and without left superior vena cava (LSVC). Left panel: Proximal (**A**) and midportion unroofing (**B**) of the coronary sinus, resulting in interatrial communication. (**C**) Complete absence of the roof. Right panel: (**A**) Persistent LSVC with intact CoS roof. The roof of CoS draining the LSVC can be fenestrated (**B**) or absent (**C**) and can be associated with absence of the interatrial septum (**D**). (From deLeval M. Anomalies of the systemic venous return. In: Stark J, deLeval M (eds). *Surgery for Congenital Heart Defects*, 2nd ed. Philadelphia: Saunders, 1994:320,323. With permission.)

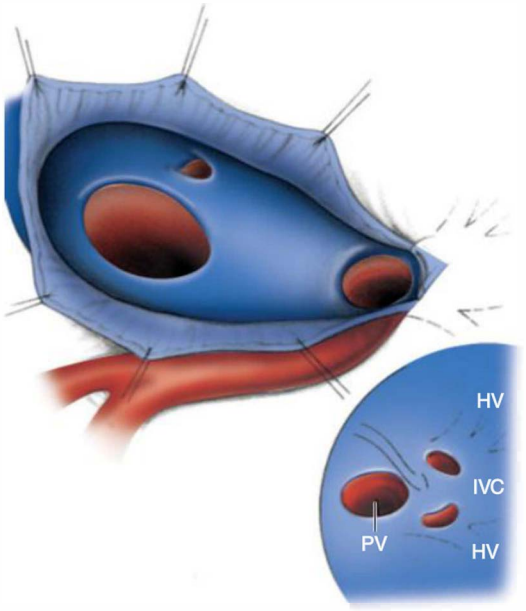

**FIGURE 64-6** Schematic representation of scimitar syndrome as seen through the right atrium. In the figure, a large fossa ovalis ASD is also represented. The anomalous draining vein enters the IVC right above the hepatic veins (inset). IVC, inferior vena cava; HV, hepatic vein; PV, pulmonary vein. (From Stark J. Secundum atrial septal defect and partial anomalous pulmonary venous return. In: deLeval M, Stark J (eds). *Surgery for Congenital Heart Defects*, 2nd ed. Philadelphia: Saunders, 1994:350. With permission.)

atrial septum, cranial to the superior limbic band. The most common position for the site of drainage of the anomalous pulmonary veins is at the superior atriocaval junction (Fig. 64-5). In 95 percent of cases with PAPVC, two right pulmonary veins (upper and middle lobes) are involved, but there may be three or even four pulmonary veins connected to the proximal SVC or SVC–right atrial junction. The SVC typically overrides the atrial septum and may result in right-to-left shunting across the ASD. When this defect is associated with the lack of the posterior limbus (posterior ASD), pulmonary venous drainage is somewhat anatomically unclear, although it flows functionally into the RA. When anomalous drainage of the right pulmonary veins is found with an intact posterior limbus or OS ASD, the anatomy is clear and a true PAPVC is present.

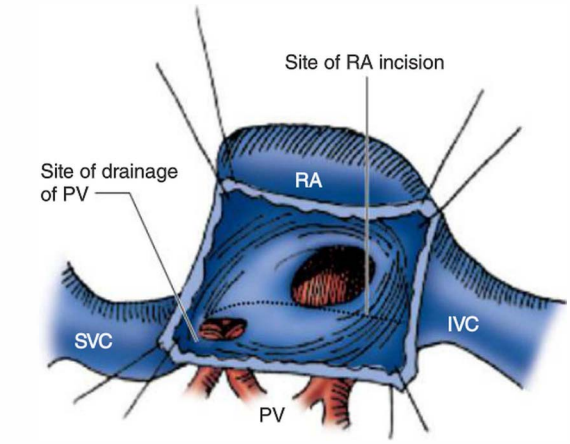

**FIGURE 64-5** Superior sinus venosus ASD, as seen through a right atriotomy. SVC, superior vena cava; IVC, inferior vena cava; RA, right atrium; PV, pulmonary vein. (From Jonas RA. *Comprehensive Surgical Management of Congenital Heart Disease.* London: Arnold, 2004:228. With permission.)

In SS (Fig. 64-6), an anomalous right pulmonary venous trunk (generally draining the entirety of the right lung) descends in a craniocaudal direction to connect to the IVC, generally above the IVC–RA junction.[23] This anomalous trunk usually descends along the right border of the pericardium. It has a crescent-like morphology (scimitar shape) and, at the level of the right hemidiaphragm, passes transversely and anteriorly to the hilum of the right lung to connect to the IVC. The radiologic appearance of this pathology is characteristic (Fig. 64-7). The interatrial septum may be intact or an OS/PFO defect may be associated to SS. SS generally occurs in association with several extracardiac malformations, such as right lung hypoplasia (invariably associated with a marked right mediastinal shift with dextrocardia), right pulmonary artery (PA) stenosis and/or hypoplasia and right lower lobe (RLL), or bronchopulmonary sequestration. Diaphragmatic anomalies occur in approximately 20 percent of cases, and consist of right lung herniation through the foramen of Bochdalek or of abnormal attachment of the hemidiaphragm. Very occasionally, a CPV trunk drains the entire right lung and descends in a craniocaudal direction to

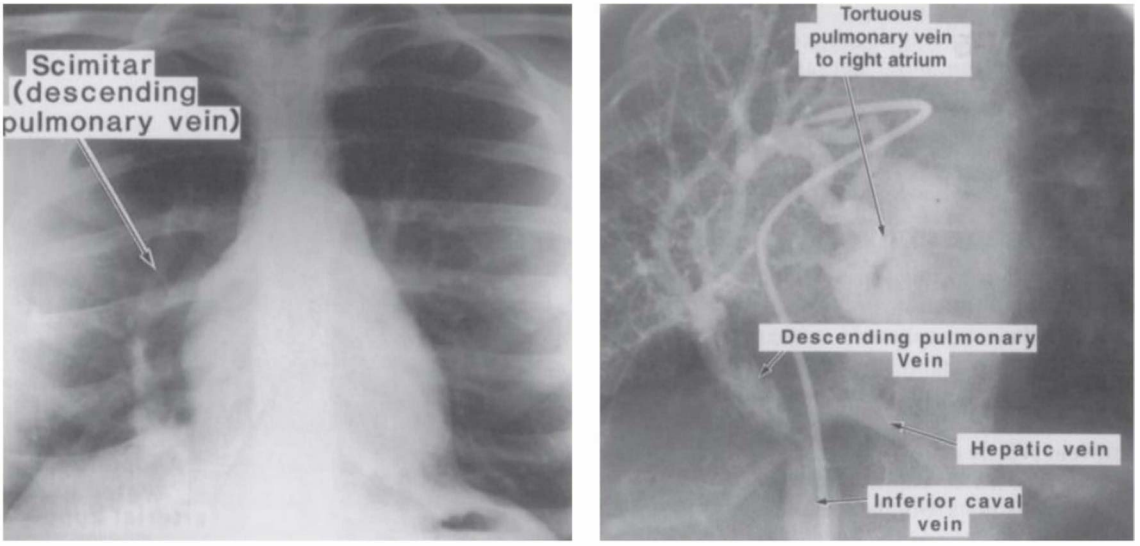

**FIGURE 64-7** Characteristic radiologic appearance of scimitar syndrome. On Chest x-ray, a right-lower-lung-field crescentic vascular marking is visible (left). Cardiac catheterization discloses the anomalous right inferior pulmonary vein draining into the inferior vena cava (right). Tortuous anomalous venous return from the upper and middle lobes to the right atrium is also seen. (From Anderson RH, Baker EJ, Mccartney FJ, Rigby ML (eds). *Paediatric Cardiology,* 2nd ed. Philadelphia: Churchill Livingstone, 2000. With permission.)

connect with the posterior LA. This peculiar arrangement shares similar radiologic findings with SS but has no clinical significance.

## PATHOPHYSIOLOGY

The magnitude of left-to-right shunting is determined by the size of the communication and relative compliance of the ventricles. As for ventricular septal defects (VSDs), the location of the ASD has very limited influence on the magnitude of the pulmonary-to-systemic flow ratio ($Q_p$:$Q_s$).

If even a relatively small subtricuspidal shunt (because of the high-pressure gradient between the ventricles) can give rise to a large left-to-right shunt, only a large ASD leads on the contrary to a large shunt. In the presence of a large ASD with an area similar to that of the mitral valve (MV), pulmonary venous return will be equally distributed between the ASD and the MV. If the ASD is restrictive, blood flow will be diverted preferentially toward the MV, and the $Q_p$:$Q_s$ will rarely exceed 2:1.[18]

Only in cases of associated acquired and/or congenital heart defects that increase LA pressure (as in systemic hypertension, MV stenosis, coarctation of the aorta, patent ductus arteriosus and VSD) will flow across the atrial septum be increased independently of ASD area. If a large defect is present atrial pressures will equalize. In this circumstance, the respective flows across mitral and tricuspid valves will vary according to the relative compliance of the ventricles. In the early months of life, the thickness of the right ventricle (RV) exceeds the thickness of the left (LV), resulting in right-to-left shunting. After the neonatal period, the LV exceeds in thickness the RV, yielding a net left-to-right shunt. The effect of atrial-level shunting results in enlargement of the RA, RV, and PAs. The overload is usually well tolerated by the RV, and heart failure seldom develops in childhood. Occasionally, heart failure occurs in infancy, but it is very rare and is generally related to various extracardiac conditions. In cases of ASD with pulmonary hypertension (PHT—as in rare pediatric cases and in some adult patients) RV thickness will increase and compliance of the RV may be similar and/or higher than that of the LV. In these cases, a right-to-left shunt will appear with a marked degree of cyanosis and hypoxia, with clinically evident heart failure.

The increase in pulmonary blood flow, over several years, may promote the development of PHT in adulthood. The onset of PHT is variable and, at present, it is not possible to reliably predict which patient will develop PHT and at what age. This variability may depend on the multiple factors involved in the pathogenesis of PHT: recurrent pulmonary infections with microatelectasis, progressive increase in left-to-right shunt with enlargement of the ASD, individual endothelial vascular hyperreactivity, thrombotic and thromboembolic lesions of pulmonary arteries, failure of the pulmonary vascular resistance to drop, and association with acquired heart diseases that would promote LV dysfunction (such as MV prolapse, coronary artery disease, and systemic hypertension among others).[24]

In the presence of an interatrial communication, a potential reverse shunt at atrial level may account for paradoxical embolization in the cerebral circulation. This condition may depend on instantaneous trans-ASD gradient modifications,

as well as the size, morphology, and position of the defect along the atrial septum. A large meta-analysis has indicated the presence of interatrial septal abnormalities as significantly associated to paradoxical embolism.[25] Furthermore, the incidence of PFO among adults suffering from cerebrovascular accidents was found to be higher than in the unaffected population. Coagulation disorders or thrombocytosis may also play a role in the pathogenesis of paradoxical embolization.

## CLINICAL FEATURES

The reported incidence of isolated ASD ranges from 7 to 14 percent, with a slight female predominance. This fairly broad range is due to the inclusion criteria used in the reports over the past few decades that considered ASDs and PFOs referred to surgery as identical pathologic entities. In the setting of other congenital heart defects, their incidence ranges from 33 to 50 percent.[26] The wide use of echocardiography has led to the detection of ASDs of any size and at any age. Several investigators have reported the results from populations of children bearing an ASD at long-term follow-up.[27,28]

The conclusions emerging from these studies may be summarized as follows:

- ASDs less than 6 mm in diameter, detected in infancy, almost always restrict spontaneously.
- ASDs between 6 and 8 mm in diameter, classified as hemodynamically insignificant, may restrict even after 5 years of age and not necessarily below 18 months of age, as once thought.
- ASDs greater than 8 mm in diameter may increase in size during childhood, although a restrictive physiology is still a more common possibility.

Among all diagnosed ASDs, the reported incidence of SVDs varies between 2 and 10 percent.[29] This relatively high incidence may be due to diagnostic bias, the incidence of SVD being higher in studies focusing on cohorts with more "complex" ASDs.

The signs and symptoms of ASD and PAPVC are strictly related to the direction and magnitude of the shunt and with the age of the patient at detection. $Q_p:Q_s$ is greater than 1 in predominant left-to-right shunt. When $Q_p:Q_s$ is below 1.8:1,[30] clinical signs and symptoms are typically mild or absent in both pediatric and adult patients. When $Q_p:Q_s$ exceeds 2:1, signs and symptoms often become clinically evident. In this subset of patients the classic "fixed split second heart sound" and systolic pulmonary flow murmur are typically audible. Reduced exercise capacity and a history of recurrent respiratory infections may be present in childhood as well as in adolescence. Several other conditions must be taken into consideration in the differential diagnosis, such as innocent murmur associated with a normal cardiovascular state and pulmonary valve stenosis; this is usually audible in the higher upper left sternal border, presents with an early systolic ejection sound, and, in cases of stenosis of the PA branches, is transmitted toward the back. In these conditions, however, splitting of the second heart sound is absent.

In cases of PAPVC, the amount of shunt through the abnormally connected veins will often result in heart failure, pulmonary infections, growth retardation, and poor effort tolerance even in infancy.

In adult patients, an episode of paroxysmal atrial fibrillation may represent the first clinical event.

The development of PHT and poor exercise capacity with cyanosis, dyspnea, and migraine often represents the pathophysiologic evolution of an ASD toward irreversible changes within the pulmonary vasculature (Eisenmenger syndrome).

Lastly, PFO with or without associated aneurysm of the atrial septum may promote paradoxical embolism and should be clinically ruled out in the context of an acute cerebrovascular event.[30,31]

SS is a rare cardiac malformation diagnosed in approximately 2 of 100,000 live-births and that is often associated with other congenital heart lesions, variable hypoplasia of the right lung, and PHT.[32] As mentioned in the morphologic considerations, the constant feature is a single trunk draining venous return from the entire right lung into the IVC. There are often accessory systemic-to-pulmonary collaterals from the abdominal aorta to the RLL. When symptoms emerge during infancy, other anomalies (such as septation defects or left ventricular outflow tract obstruction) are often associated. The presence of aortopulmonary collaterals does not generally have a critical impact on the development of heart failure, since the hypoplastic lung is typically underperfused. Furthermore, pulmonary sequestration of the right lung (in the absence of hypoplasia) usually involves a maximum of two pulmonary segments. When SS is discovered in late childhood or in adulthood, the patient may be asymptomatic or, more often, be a history of recurrent respiratory tract infections, cough, and dyspnea. Heart failure, if present, is of mild degree. Intracardiac lesions are generally absent, and extralobar sequestration of a RLL is observed in approximately 50 percent of cases. $Q_p:Q_s$ usually ranges from 1.5 to 3.1.[32]

As mentioned above, physical examination in early childhood is often less than revealing unless the shunt is substantial or there are associated lesions.[33] In large ASDs, a left parasternal lift can be detected, while a fixed, split second heart sound is typically audible, together with a soft "crescendo–decrescendo" systolic flow murmur over the pulmonary valve's auscultation focus. The second heart sound can be prominent in case of PHT. Clinical evidence of overcirculation is rare, as is cyanosis in cases without severe PHT. Cyanosis with streaming can be observed in superior or inferior defects where the SVC or IVC "straddles" the interatrial septum at the site of the defect, resulting in a functional right-to-left shunt of variable magnitude. This is, from a clinical standpoint, often underdetected. In a recent review of infants and children with ASDs without associated lesions treated at our institution, only 2 of 278 patients was cyanotic on presentation.

Even though symptoms might not present until the fifth decade of life, approximately 50 percent of adults will

manifest exertional dyspnea by the age of 20; among adults with sizable defects, almost all will be symptomatic by the sixth decade of life.[23] If untreated, adults with large ASDs show a 75 percent mortality rate within the fifth decade, rising to nearly 90 percent in the sixth decade of life.[34]

Symptomatic supraventricular arrhythmias often complicate the natural history of ASDs diagnosed in adulthood, the most common among them being atrial fibrillation followed by atrial flutter. In the elderly, sick sinus syndrome might be the initial rhythm abnormality upon presentation; given the risk of paradoxical embolization, insertion of a transvenous pacing system without percutaneous or surgical ASD closure is contraindicated.

Paradoxical embolization should be strongly suspected as the pathophysiologic entity underlying cryptogenic strokes, although the very low prevalence of venous thrombosis and procoagulant conditions make this a rare entity in infants and children. The presence of an atrial septal aneurysm (in the absence of interatrial communication) was considered a predisposing factor for paradoxical embolism; data from the SPARC study[35] and the Patent Foramen Ovale and Atrial Septal Aneurysm Study Group[36] did not find this morphologic variant of septal morphology to be an independent risk factor for embolism in the absence of a PFO or an ASD.

## DIAGNOSTIC STUDIES

In children, electrocardiographic examination almost always discloses normal sinus rhythm and incomplete right bundle branch block, with a right axis deviation on the frontal plane between 90 and 120 degrees. In adulthood, atrial flutter and fibrillation are more frequent after the fourth decade of life, and increase in incidence with advanced age. In this subset of patients, the counterclockwise loop on the frontal plane shows less rightward shift and complete right bundle branch block, with a prominent R' wave (>15 mm) on the right precordial leads in almost 50 percent of patients with PHT.

Radiologic findings are dependent on the magnitude of $Q_p$:$Q_s$, with plethoric lung fields typically seen in the presence of larger defects. Cardiomegaly also reflects the amount of blood flow across the ASD, with heart diameter increasing with a higher degree of left-to-right shunt, usually associated with a prominent radiologic projection of the PA trunk. Once obstructive pulmonary vascular changes and structural PHT worsen (leading to Eisenmenger syndrome and right-to-left shunting) cardiac size decreases, the central PAs become prominent and their branches appear truncated, with oligoemic peripheral lung fields (Fig. 64-8).

SV ASDs may be associated with additional pathognomonic findings, such as a significant prominence of the upper right vascular pedicle, in cases of superior caval ASD with right PAPVC or the right inferior crescentic shadow of the anomalous pulmonary vein on the frontal plane in SS.

Transthoracic echocardiography (TTE) is the diagnostic modality of choice for ASD. M-mode echocardiography provides indirect evidence of ASD, revealing right ventricular (RV) overload with increased RV diameter and, in most cases, flattened or paradoxical ventricular septal motion. Even though these ultrasonographic findings clearly support the evidence of increased right chamber preload, they are not specific; similar findings are in fact observed with several

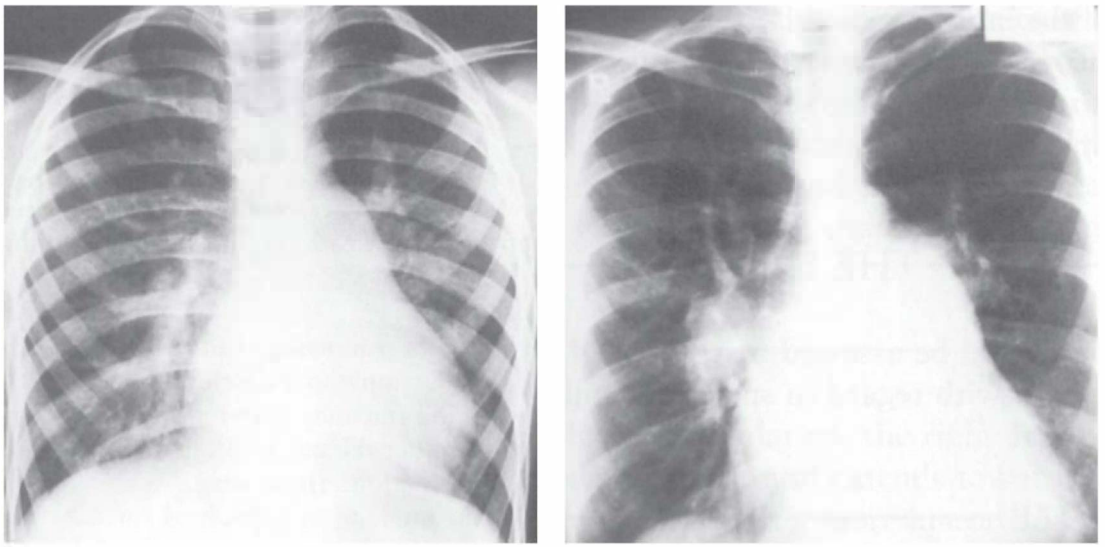

**FIGURE 64-8** Radiologic findings in atrial septal defect. Left: Pulmonary overcirculation with increased interstitial vascular markings and cardiomegaly. Right: Patient with advanced pulmonary vascular obstructive disease in the setting of an untreated atrial septal defect. Cardiomegaly, prominent central pulmonary arteries, and oligoemic peripheral lung fields. (From Anderson RH, Baker EJ, Mccartney FJ, Rigby ML (eds). *Paediatric Cardiology,* 2nd ed. Philadelphia: Churchill Livingstone, 2000. With permission.)

other cardiac diseases, such as, for example, tricuspid and pulmonary regurgitation and total or PAPVC, among others. Two-dimensional echocardiography is much more specific for the diagnosis of an ASD. The reported detection rate ranges from 89 to 99 percent for OS defects[37] with the use of subcostal and modified longitudinal scans (Fig. 64-9). Color Doppler-flow mapping techniques can be performed to confirm the presence of an ASD and to visualize the direction of the shunt, with good correlation with findings at cardiac catheterization.[38]

CoS ASDs may be suspected in patients with echocardiographic evidence of a dilated CoS. Besides the common findings of dilated RV, more posterior scanning views (subcostal and apical four chamber) can directly reveal the communication between the CoS and LA.

Contrast echocardiographic evaluation may better reveal the suspected ASD. In cases of unidirectional left-to-right shunt, the observation of a negative washout into the RA may confirm the suspicion of a shunt at the atrial level, whereas in cases of right-to-left shunting, the detection of contrast bubbles of agitated saline in the LA provides direct evidence of an inverted shunt.

TTE is much less reliable in patients with uncommon defects at the atrial level, such as SV ASDs and PAPVCs, with a sensitivity of approximately 70 percent.[39] Because of the shorter distance between probe and defect, transesophageal echocardiography (TEE) overcomes inadequate visualization, especially in older children and adults, in whom diagnostic sensitivity and specificity for SV ASDs and PAPVC approach 100 percent.[40] Longitudinal scans are particularly useful in the delineation of the upper atrial septum, while short-axis views may be fundamental for assessment of the pulmonary–systemic venous connection.

Three-dimensional TEE currently represents the most sophisticated tool for the morphologic evaluation of ASDs that are potential candidates for percutaneous closure (Fig. 64-10). Three-dimensional reconstruction allows for precise localization of the defect. Delineation of its proximity to valvular structures, visualization of the venous ostia and adequacy of margins, as well as provision of an immediate assessment of defect's obliteration following device deployment.[41] Similar advantages have been reported with the recent introduction of intravascular ultrasound (IVUS) techniques for diagnosis and treatment of ASDs.[42,43]

Although the vast majority of ASDs are diagnosed accurately with conventional ultrasonography, imaging techniques [magnetic resonance imaging (MRI) and computed tomography (CT)] have gained wide acceptance in defining anomalous venous connections in patients with complex ASDs.[44]

Cardiac catheterization is not indicated in the preoperative diagnostic workup of ASDs in children, adolescents, and young adults. Given the reliability of TTE and TEE, cardiac catheterization is currently only indicated in those cases with inadequate imaging or for complete assessment of complicated ASDs. Such conditions may include severe heart failure in infants, cases of suspected PAPVC not clearly defined by ultrasound, SS, and, in the adult population, associated

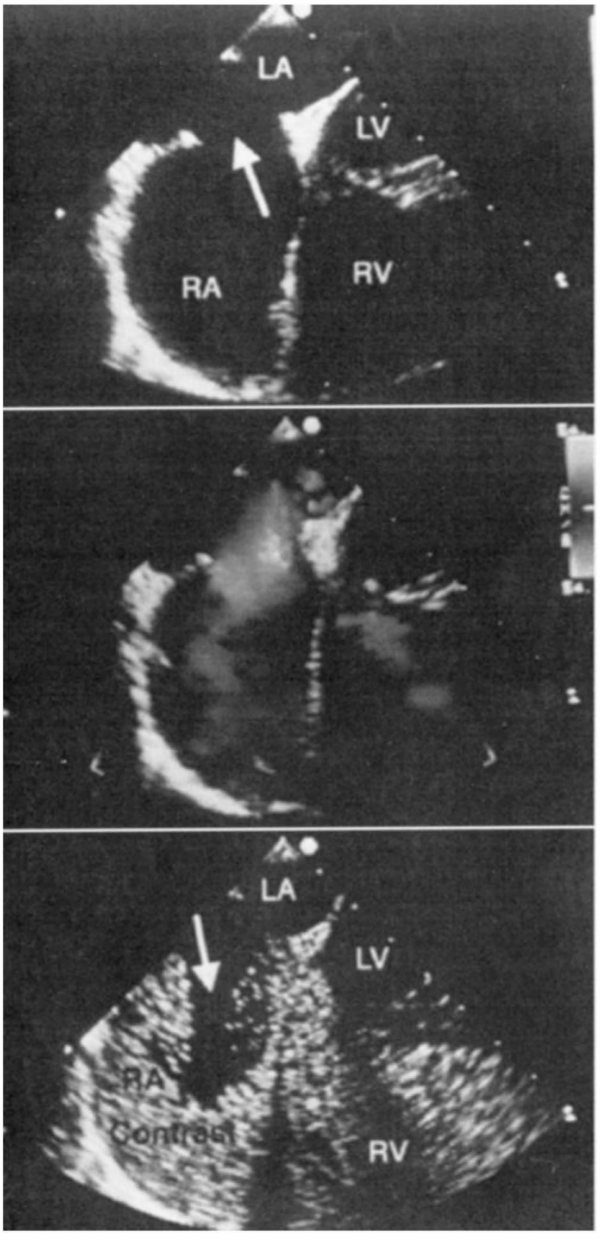

**FIGURE 64-9** Transesophageal echocardiography in a patient with a large secundum-type ASD. A large defect (arrow, top panel) is visible between the right and left atria. Color-flow Doppler interrogation reveals unrestricted left-to-right shunting (middle). Systemic venous injection of agitated saline reveals a "negative washout" of saline bubbles secondary to the left-to-right shunt, with paucity of contrast seen in the left atrium (lower panel). acquired heart lesions (such as valvular pathology and/or coronary obstructive disease).

A full invasive diagnostic study with hemodynamic evaluation is indicated in patients with secondary PHT and an ASD. Feasibility of surgery is judged upon calculation of pulmonary vascular resistance and its eventual decrease according to the administration of oxygen, inhaled nitric oxide (iNO), and infusion of prostacyclin analogues. With a significant decrease in pulmonary arterial pressure and resistance, the patient should be considered a surgical candidate. Lack of response to the abovementioned pulmonary vasodilators contraindicates surgical intervention. In intermediate cases, fenestrated ASD closure can be considered.

## NONOPERATIVE MANAGEMENT

As already mentioned, indications for surgical intervention are rarely met in children younger than 2 years of age. Failure to thrive and need for medical therapy or correction is, however, more frequent in infants and children with a common atrium or chromosomal abnormalities.[44,45] There are also other conditions in which early crossover from medical to surgical management might be indicated, such as otherwise unexplained PHT in infancy[46] and concomitant association of an enlarged CoS (atypical left cor triatriatum), functionally similar to totally anomalous pulmonary venous connection (Fig. 64-11).[47] If the child presents symptoms and/or evidence of RA/RV enlargement at echocardiography, continuing medical management until 5 years of age could be justified. Several investigators have in fact reported spontaneous restriction, even in those cases with heart failure in infancy.[28] In the interim (even though rarely needed), diuretics and angiotensin antagonists can be used to control symptoms and progression of heart failure, while cardiac status is monitored echocardiographically on a yearly basis. In cases not amenable to a conservative approach and not showing a tendency toward restriction, intervention can usually be postponed until 1 to 2 years of age, at a time when morbidity and mortality from ASD closure are usually negligible.[48]

The advantage of surgical intervention in ASD and/or PAPVC in adult and elderly patients has been debated.[49] The Canadian consensus conference on adult congenital heart disease[50] clearly underscored that any "significant ASD warrants intervention," implying that any ASD with RV volume overload, atrial arrhythmias, and/or late heart failure should be treated, given the low risk of surgical and percutaneous intervention.

Closure of the defect is not recommended in patients presenting with advanced pulmonary vascular obstructive disease. Medical treatment is indicated and should be individually tailored according to symptoms, comorbidities, and cardiovascular complications.

## SURGICAL TREATMENT

Closure of ASDs is conventionally performed through a median sternotomy, although a variety of alternative approaches are also utilized.

We will outline the surgical approach to closure of ASDs, along with a brief description of specific considerations that apply to more complex variants of ASD, namely CoS, SV ASD/PAPVC, and SS. A description of the techniques utilized for more complex subtypes of anomalous systemic venous connections and atrial septation is beyond the scope of this chapter.[51,52]

A median sternotomy is performed and bypass instituted with bicaval drainage and moderate hypothermia (30°C–32°C); the repair accomplished with either fibrillatory or cardioplegic arrest. Following cardiac arrest, caval snares are tightened and an oblique atriotomy is performed. Depending on preoperative localization of the defect, cephalad or caudad extension of the atriotomy is carried out. The LA is usually vented directly across the defect and the anatomy carefully evaluated, including the morphology of the mitral and tricuspid valves. The RV outflow tract is also assessed, and all pulmonary and systemic venous ostia are accounted for.

The technique chosen (primary or patch closure) to repair the defect is determined by the size, location, and shape of the ASD. In our opinion, the majority of ASDs (within the

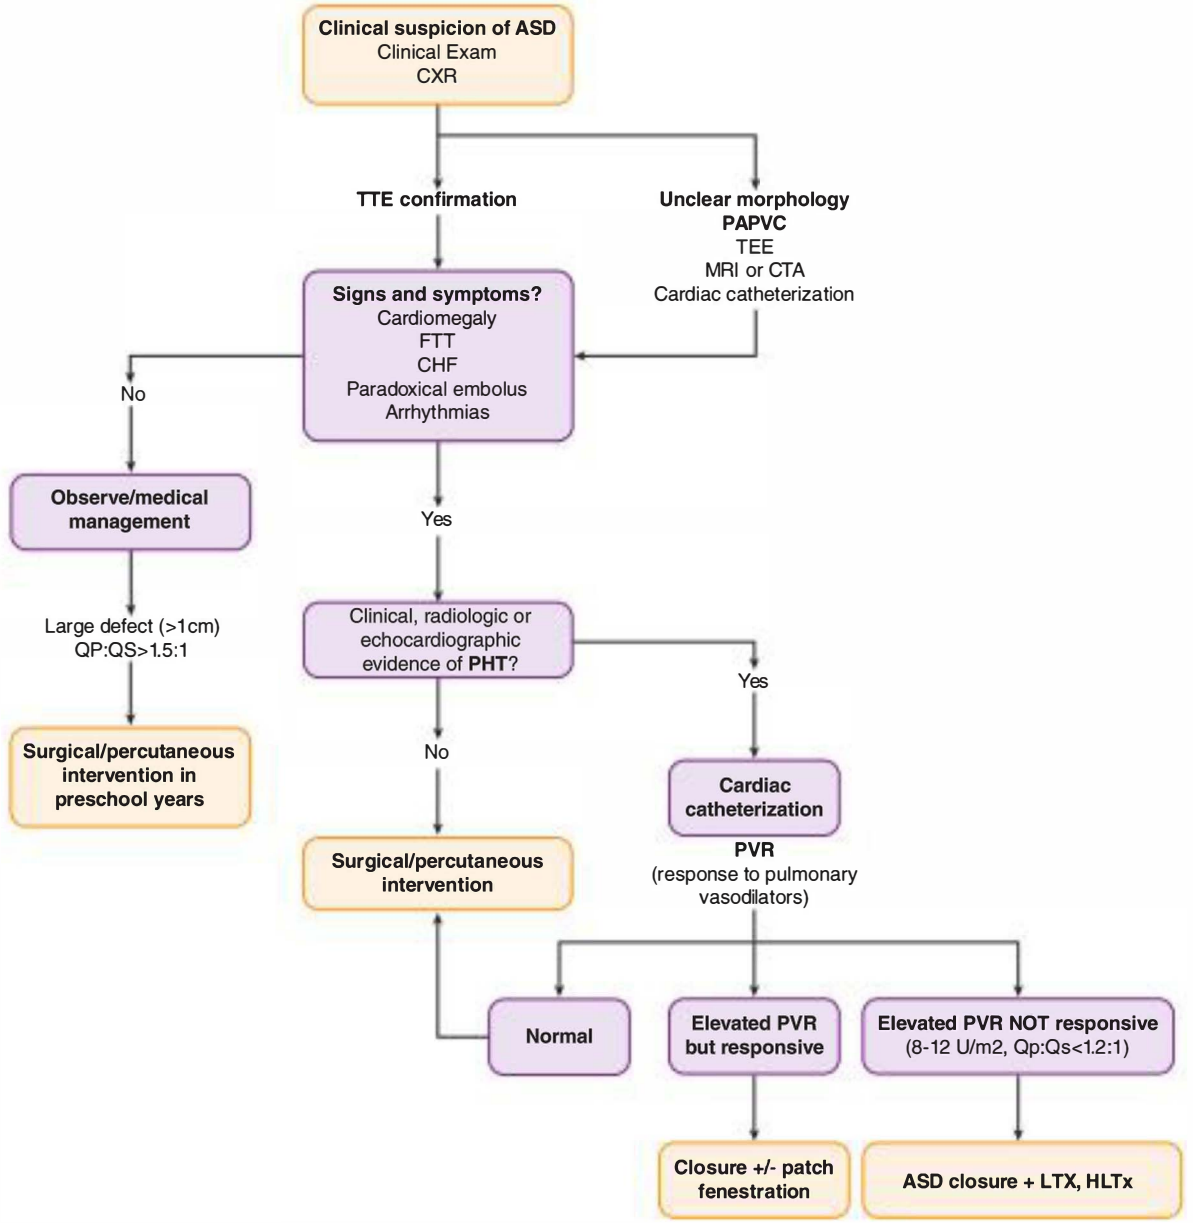

**FIGURE 64-11** Clinical decision-making algorithm for management of isolated atrial septal defects and partial anomalous venous connection. ASD, atrial septal defect; CHF, congestive heart failure; CTA, CT a ngiography; CXR, chest x-ray; FTT, failure to thrive; HLTx, heart–lung transplantation; LTX, lung transplantation; MRI, magnetic resonance imaging; PAPVC, partial anomalous pulmonary venous connection; PHT, pulmonary hypertension; PVR, pulmonary vascular resistance; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

fossa ovalis, with the exception of the single atrium) can be closed with a continuous double-layer nonabsorbable suture (see Fig. 64-12), catching strong bits of the posterior and anterior limbic tissue of the atrial septum and starting from the caudal edge of the defect. It is obviously recommended that the right pulmonary veins not be restricted, the MV not distorted, and the nodes not injured. Patch closure can be easily performed with a portion of autologous pericardium, harvested at the beginning of the procedure and tanned in 0.6 percent glutaraldehyde (Fig. 64-13). Alternatively, polytetrafluoroethylene, bovine pericardium or Dacron patches can be utilized. The latter should, however, be avoided in the presence of known mitral regurgitation, as persistent regurgitant jets on the Dacron fabric have been associated with hemolysis. Given the known thrombogenicity of the aneurysmal fossa ovalis ASD, we routinely resect

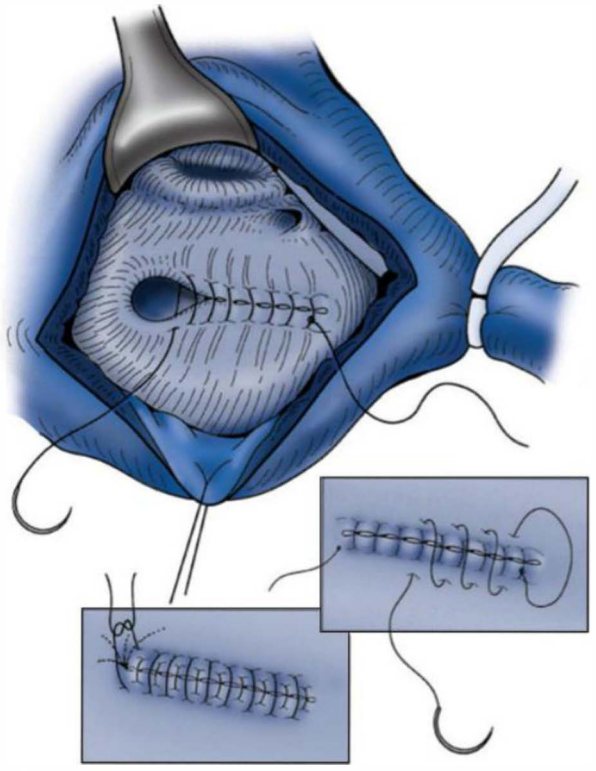

**FIGURE 64-12** Direct closure of ASD. A two-layer closure with nonreabsorbable suture is started at the inferior aspect of the oval-shaped defect and run in a cephalad direction (left side of the figure). (From Manning PB. Atrial septal defect. In: Gardner TJ, Spray TL (eds). *Operative Cardiac Surgery,* 5th ed. London: Arnold, 2004:595. With permission.)

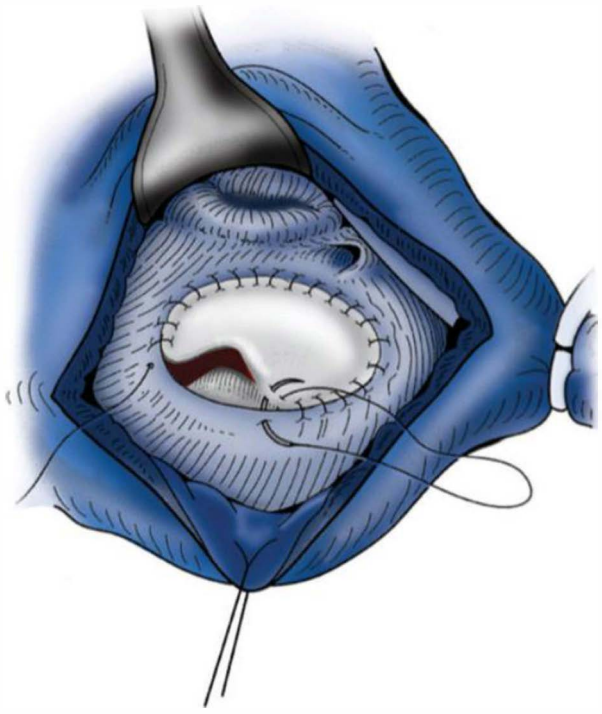

**FIGURE 64-13** Patch ASD closure. A patch of autologous pericardium is secured around the circumference of the defect with a running polypropylene suture. (From Manning PB. Atrial septal defect. In: Gardner TJ, Spray TL (eds). *Operative Cardiac Surgery,* 5th ed. London: Arnold 2004:596. With permission.)

the aneurysmal tissue and then perform patch closure rather than plicating or patching the redundant tissue.

In inferiorly located ASDs (Fig. 64-14), when there is deficiency of an inferoposterior rim, it is best to start patch closure in this area, proceeding from the IVC toward the more developed ASD rim. Modified ultrafiltration is carried out in our practice in all children with operative weight below 20 kg. Blood-conservation strategies (i.e., minimal priming of the circuit with autologous blood after cannulation and utilization of a "cell saver" system to scavenge and

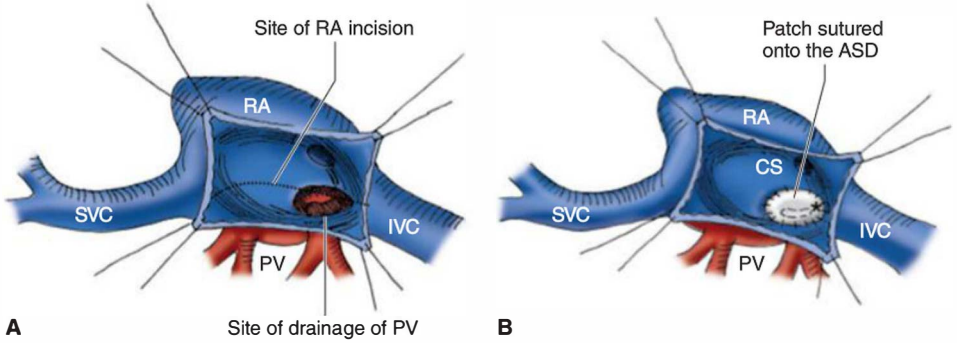

**FIGURE 64-14** **A.** Inferiorly located ASD, as seen through a RA (surgeon's perspective). **B.** Patch closure on inferiorly located ASD, as seen through a RA (surgeon's perspective). reinfuse shed blood) are considered for children with operative weight above 20 kg.

For closure of an isolated CoS defect, it is sufficient to simply close off the CoS bearing in mind that the cephalad margin is very close to the atrioventricular node. Since the tissue on that side is fairly soft, surgical closure with a patch secured with a continuous nonabsorbable suture is advisable. To avoid the atrioventricular node, the suture line should remain (anteriorly and superiorly) very deep within the CoS, taking small bites of tissue. Simple closure of the CoS will allow for a small obligatory right-to-left shunt from the unroofed CoS to the LA.

As mentioned in the morphology section, superior SV defects are located high in the septum secundum and are generally associated with anomalous connections of the right pulmonary veins in proximity of the superior cavoatrial junction. Direct cannulation of the SVC (as opposed to transatrial indirect cannulation) is optional and depends on SVC diameter and site of drainage of the anomalous pulmonary veins. A vertical incision (posterior to the sulcus terminalis and sinoatrial node and anterior to the pulmonary veins) is the standard approach. The right atriotomy is extended across the superior atriocaval junction, well above the superior margin of the anomalously connected pulmonary vein. The LA is usually vented via the ASD. The defect is closed with a patch of autologous pericardium, baffling the right-sided pulmonary veins toward the LA (Fig. 64-15). To prevent stenosis of the SVC, the atriotomy is closed with a generous patch of autologous pericardium or, when the SVC is large, by direct running closure.

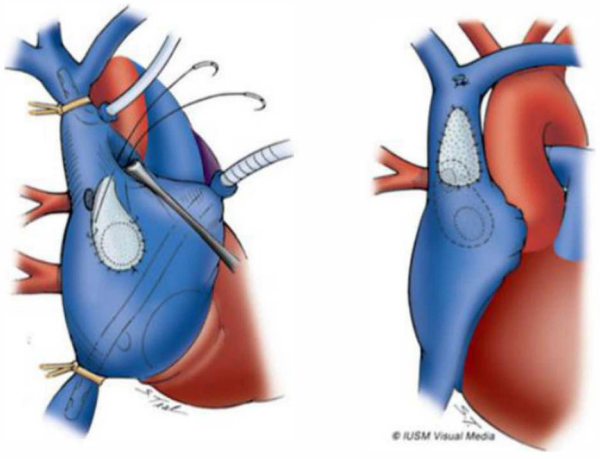

**FIGURE 64-15** Closure of superior sinus venosus atrial defect with partial anomalous pulmonary venous connection. Left: Through a superior right atriotomy, the defect is closed with a patch of autologous pericardium, rerouting the right superior pulmonary vein to the left atrium. Right: An additional pericardial patch is used to close the atriotomy extended across the superior atriocaval junction. (Copyright IUSM Visual Media.)

Since 2008, we have adopted a modified technique (Fig. 64-16A–E) for such type of defect. An "L-type" atriotomy (Fig. 64-16A) is the approach we have utilized with superior SV ASD undergoing correction at our institution. The upper edge of the right atriotomy is extended across the superior atriocaval junction, toward the superior margin of the anomalously connected pulmonary vein; the lower edge of the right atriotomy is extended toward the base of the right atrial appendage. The LA is usually vented via the ASD. The defect is closed with a flattened patch of autologous pericardium, baffling the right-sided pulmonary veins toward the LA. To prevent undue stenosis of the SVC, the atrium is closed with a "sliding plasty atrioraphy" that avoids the utilization of nonvascularized cavoatrial patch.

In those uncommon cases in which the SVC lumen appears to be extremely small or the anomalously connected veins drain very high above the RA-SVC junction, a more radical procedure should be considered (Warden procedure, Fig. 64-17). Through the right atriotomy, the anomalous return is rerouted to the LA. The atriocaval junction is transected and the distal aspect of the SVC is oversewn or closed with a patch so as to not compromise drainage from the anomalous pulmonary veins into the SVC. The proximal SVC is then anastomosed directly to the right atrial appendage. In older children, a polytetrafluoroethylene interposition graft can be used. In cases of PAPVC not associated with an ASD, the floor of the fossa ovalis can be excised, and the resulting unrestrictive communication utilized to baffle the anomalous return to the LA.

The surgical correction of SS is based on pre- and intraoperative localization of the anomalous pulmonary venous return. The anomaly is often amenable to rerouting toward the LA from within the IVC-RA junction (Fig. 64-18). If the anomalous pulmonary vein ostium is too low, the vein can be alternatively ligated at the diaphragm and either transected and anastomosed to the LA or RA or connected to the LA in a side-to-side fashion (Fig. 64-19). Variable depth of hypothermia is usually needed to aid in exposure.

## Alternative Surgical Approaches

After the introduction of alternatives to the relatively unattractive full sternotomy in the early 1980s, minimally invasive techniques for adult cardiac surgery gained great interest and popularity. The success of such alternatives led to enhanced public demand for a similar approach in the pediatric population, for whom constraints unique to the growing patient create a particular challenge. The simultaneous increasing popularity of percutaneous device closure further pushed heart surgeons to offer a reliable alternative to the standard, full sternotomy approach, while maintaining unaltered the almost negligible mortality and morbidity associated with a conventional sternotomy.

Among the minimally invasive approaches, mini-sternotomy, transxiphoid approach,[53] anterolateral thoracotomy,[54] posterolateral thoracotomy[55] and, most recently the

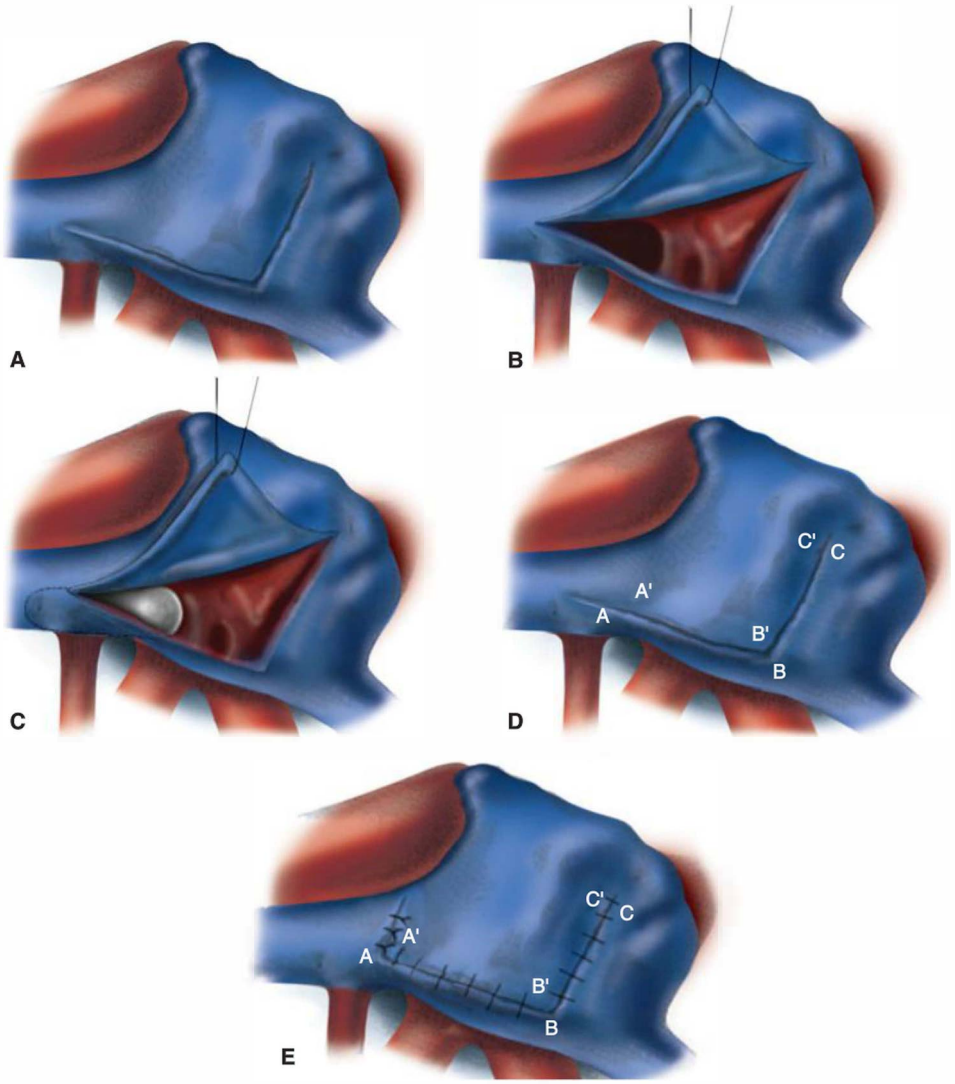

**FIGURE 64-16** Closure of modified superior sinus venosus atrial defect with partial anomalous pulmonary venous connection: after an " L-type" right atriotomy (**A**), a flap of atrium is lifted up (**B**) and the anatomy inspected; the defect is closed with a flattended patch of autologous pericardium, rerouting the right superior pulmonary vein to the left atrium (**C**). To close the atriotomy a "sliding plasty" is performed, in order to enlarge the pathway above the baffle with redundant atrial tissue (**D**, **E**).

midaxillary approach,[56] have gained in popularity. The analysis of all of these alternative options allows us to discover advantages and disadvantages for each of them.

Variations of the anterior approaches are represented by the longitudinal parasternal approach, introduced by Coosgrove and Sabik,[57,58], bilateral submammary incision, partial upper, partial lower sternotomy, and, finally the transxiphoidal incision.[59–63] The parasternal approach, consisting in the resection of one or more costochondral cartilages, allows a visualization of the cardiac and paracardiac structures comparable to the standard approach but with no need to violate chest wall integrity. Cannulation is performed directly through the operative field and the limited invasiveness has been demonstrated to lower postoperative pain and the length of hospitalization; unfortunately chest wall deformity in the growing patient and lung herniation have led several centers to abandon such approach. Because of the location of the defects, a lower sternotomy approach, has been adopted by most centers with success.[64] This form of access allows for optimal visualization of the structures and is preferable even when additional cardiac anomalies like patent ductus arteriosus, pulmonary valve stenosis and left SVC are associated with an ASD. The pliable infant thoracic cage also permits an exclusively subxiphoid incision, leaving the sternum intact.

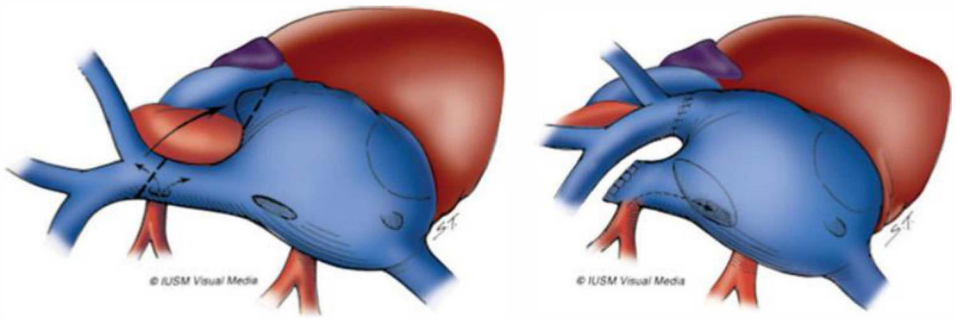

**FIGURE 64-17** Warden procedure. When the partial anomalous return to the superior vena cava is remote from the superior atriocaval junction, the superior vena cava (SVC) is transected (left). Pulmonary venous return is rerouted to the left atrium via an existing or surgically performed atrial septal defect, and the SVC is anastomosed to the right atrial appendage (right). (Copyright IUSM Visual Media.)

With lower sternotomy or hemi-sternotomy approaches, bicaval venous, aortic and cardioplegic cannulation are directly performed through the limited sternotomy incision, whereas this is not always achievable with an anterolateral or posterior thoracotomy approach. Furthermore, size and collapsibility of the great vessels in children are not condusive of peripheral cannulation.[65] The heart is either arrested with cardioplegia or induced ventricular fibrillation is utilized when aortic cross-clamping is difficult (thoracotomy). De-airing of the heart might also be more problematic with a thoracotomy approach. Several studies have demonstrated that recovery from a full-length sternotomy does not differ from the mini-sternotomy[66] in terms of pain tolerance, length of hospital stay and respiratory complications, an improved cosmetic result being the only advantage of the minimally invasive anterior approach. Likewise, the benefit derived from an anterolateral thoracotomy might be purely cosmetic.[67]

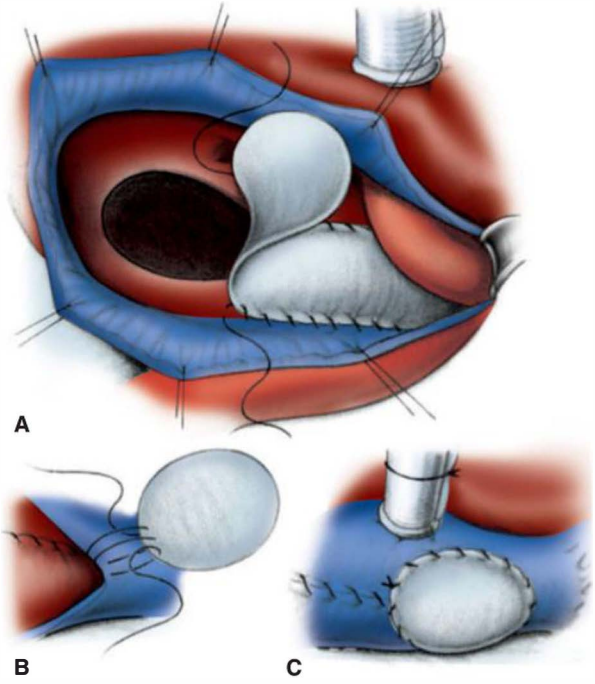

**FIGURE 64-18** Surgical correction of scimitar syndrome. An intracardiac baffle of autologous pericardium (**A**) is used to reroute pulmonary venous return to the left atrium via an ASD. The lower portion of the atriotomy is enlarged with a second patch to avoid stenosis of the inferior vena cava (**B**, **C**). (From Stark J. Secundum atrial septal defect and partial anomalous pulmonary venous return. In: deLeval M, Stark J (eds). *Surgery for Congenital Heart Defects*, 2nd ed. Philadelphia: Saunders, 1994:351. With permission.)

Given these considerations, it might be prudent to offer ASD closure via a limited inferior hemisternotomy incision in infants and small children, as well as possibly a trans- or subxiphoid approach in small children who typically have a relatively pliable thorax. Procedural safety, the likely need for peripheral cannulation and the potential to harm the growing breast tissue in small girls might further make an anterior approach preferable to a lateral thoracotomy in this age group. For cosmetic reasons, an inframammary approach should be offered to older girls and young women requiring ASD closure, whereas a limited anterior access should be considered as the procedure of choice for adolescent males and young men. Although considered in some centers, robotically assisted ASD closure is an attractive option. Surgeon's expertise with this particular approach must be weighted against the safety of conventional surgical intervention accomplished via the above-mentioned limited sternotomy or thoracotomy approaches.

## SURGICAL OUTCOMES

The postoperative course that follows correction of ASD and PAPVC is generally uneventful, and the majority of patients can be separated from mechanical ventilation in the operating room and discharged home within 3 to 4 days.[68]

Aside from morbidity that can be observed in any cardiac operation, specific minor early complications are represented by postpericardiotomy syndrome (typically 7–14 days

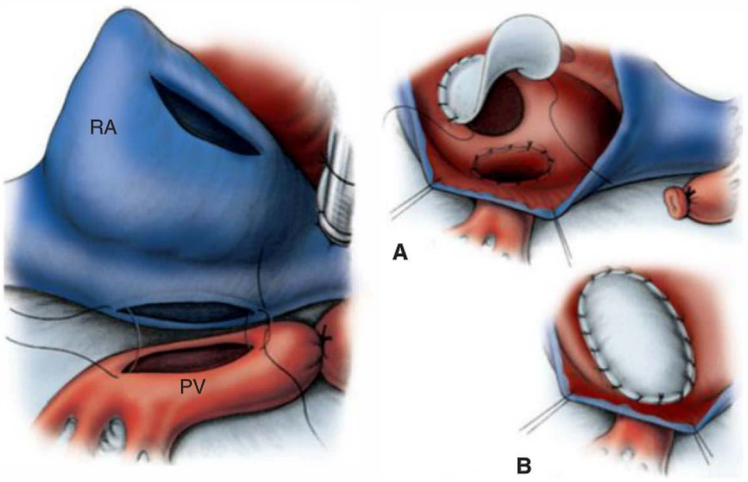

**FIGURE 64-19** Surgical correction of scimitar syndrome. When return of the anomalous pulmonary vein is very low, a side-to-side anastomosis can be constructed between the vein and the left atrium (left). Alternatively, the vein can be transected distally and anastomosed in an end-to-side fashion, with pericardial baffle rerouting to the left atrium (right). PV, pulmonary vein; RA, right atrium. (From Stark J. Secundum atrial septal defect and partial anomalous pulmonary venous return. In: deLeval M, Stark J (eds). *Surgery for Congenital Heart Defects*, 2nd ed. Philadelphia: Saunders, 1994:351. With permission.)

after the operation) and arrhythmias, particularly following SV ASD/PAPVC repair.[52,68]

Excellent long-term outcomes for patients of all ages have been reported[69–73] and, in the current era, morbidity and mortality for surgical closure of any type of ASD should approach zero.[30] Between 1993 and 2012, 277 children (age <18 years) underwent surgical ASD closure at our institution. Most patients had isolated secundum-type defects, 51 patients had SVD ± PAPVC, one infant had a CoS ASD, and three had SS; there was 1 operative death, due to PHT in a case of SS operated at 7 months of age, and no cerebrovascular accidents; the incidence of delayed pericardial effusions was 5 percent.

When surgery is indicated in smaller infants, mortality is similar (but not quite as low) as in older children, while reported morbidity ranges between 2.5 and 11 percent.[48,71,74]

## Percutaneous Closure of Atrial Septal Defects

Transcatheter ASD closure was first described in 1976 by King and coworkers.[75] In the subsequent 2 decades, multiple ingenious devices were developed to effectively close secundum ASDs. The goal has been to design a device that could be delivered through a small vascular sheath, produce complete closure in 98 percent or more of patients, be technically easy to insert, and remain removable until the point of final deployment. The Amplatzer Septal Occluder® (ASO) was introduced in 1995 and subsequently proven to be safe and effective in producing closure of OS ASDs, gaining FDA approval in November 2001 (Fig. 64-20). By the end of 2005, the manufacturer estimated that 80,000 implants had been performed worldwide. The ASO and the Gore Helix® device are the two devices currently approved for clinical use in the United States.

As part of the FDA approval process, a study of 596 patients was performed, with 442 undergoing ASO device closure of their ASDs and 154 having surgical repair of their defects.[76] Device implantation rate was 96 percent, with successful closure rate (<2-mm residual shunt) of 99 percent at 12 months. Patients undergoing catheterization remained in the hospital for 1 day on average (vs 3.4 days for surgical patients), and outcomes compared favorably with those of the surgical cohort.[77] Eligibility rates for device closure are much higher for older children and adults, with only 3.7 percent of all subjects enrolled in the initial FDA trial having ASDs that were judged inappropriate for device closure.

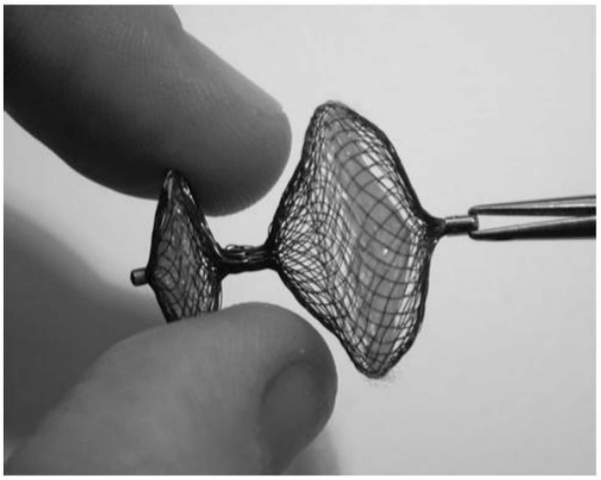

**FIGURE 64-20** Amplatzer atrial septal occluder device. (Courtesy of Dr. Richard Ringel, the Johns Hopkins University.)

Although closure of very large ASDs (greater than 30 mm) can be challenging, most defects are readily occluded using standard technique. Simultaneous use of fluoroscopy and TEE or intracardiac echocardiography is now standard practice and makes it possible to exclude from device implantation those defects with diminutive rims (<5 mm) or locations that would jeopardize valvular function or inflow and potential erosion. The procedure typically requires 60 to 90 minutes, with 10 to 20 minutes of fluoroscopy time. Overnight observation is strongly advised, with next-day discharge after echocardiographic confirmation of stable device position, minimal or no residual shunting, absence of pericardial effusion or interference with atrioventricular valve function or venous drainage. Postmarketing surveillance has identified 37 instances of device erosion (ASO) through the atrial wall into either the pericardial space or the ascending aorta, leading to hemopericardium and, in some cases, cardiac tamponade. Three deaths have been attributed to this phenomenon. A detailed review of all reported cases identified device oversizing and deficient retro-aortic (<5 mm) rim to be the greatest risk factors for device erosion.[78,79]

## ATRIAL SEPTAL DEFECTS AND PARTIAL ANOMALOUS PULMONARY VENOUS CONNECTION BOARD REVIEW QUESTIONS (CHAPTER 64)

1. Which is correct regarding anatomy of ASD and PAPVC?
   - A. An OS defect occurs because of inadequate reabsorption of the septum primum.
   - B. An inferior SVD may promote left-to-right shunting without cyanosis.
   - C. The ostium of a CoS defect is invariably present along the posteroinferior margin of the triangle of Koch.
   - D. A superior caval ASD is located in the anterosuperior atrial septum, caudal to the superior limbic band.
   - E. In SS, the anomalous drainage passes vertically behind the hilum of the right lung.
2. Which is true regarding pathophysiology of ASD and PAPVC?
   - A. The location of the ASD has significant influence on the magnitude of the shunt.
   - B. If the ASD is restrictive, the $Q_p$:$Q_s$ will rarely exceed 2:1.

C. Mitral stenosis has no effect on flow across an associated ASD.
D. Heart failure in an infant is usually due to a large ASD.
E. The onset of pulmonary hypertension is predictable.

3. Which of the following is incorrect?
   A. An ASD less than 6 mm will almost always restrict spontaneously.
   B. An ASD between 6 and 8 mm may restrict even after age 5.
   C. An ASD over 8 mm may increase in size during childhood.
   D. The signs and symptoms of an ASD are not related to direction or magnitude of the shunt.
   E. An episode of paroxysmal atrial fibrillation may be the first presentation of an ASD in an adult.

4. Which is the most appropriate test prior to percutaneous closure of an ASD?
   A. TTE
   B. Three-dimensional TEE
   C. MRI
   D. Contrast CT scan
   E. Cardiac catheterization

5. Which is true regarding percutaneous closure of ASD?
   A. The Amplatzer device is the only FDA approved device.
   B. Successful closure was achieved in 95 percent of patients with the Amplatzer device.
   C. Eligibility rates for device closure are much higher in younger children.
   D. Success is defined as a residual shunt less than 4 mm.
   E. A deficient retro-aortic rim is a significant risk factor for device erosion.

## ANSWERS

1. **Answer: C.** The ostium of a CoS defect is invariably present along the posteroinferior margin of the triangle of Koch. An OS defect occurs when there is deficient development of the OP. An inferior SVD may promote right-to-left shunting with cyanosis. A superior caval ASD is located in the posterosuperior atrial septum, cranial to the superior limbic band. In SS, the anomalous drainage passed transversely and anterior to the hilum of the right lung.
2. **Answer: B.** If the ASD is restrictive, the $Q_p$:$Q_s$ will rarely exceed 2:1. The location of the ASD has little effect on the magnitude of the shunt. Mitral stenosis and other lesions that increase left atrial pressure can independently influence flow across the ASD. Heart failure in an infant is usually due to some other major condition rather than the ASD. The onset of pulmonary hypertension is variable and unpredictable.
3. **Answer: D.** The signs and symptoms of an ASD are strictly related to direction or magnitude of the shunt. An ASD less than 6 mm will almost always restrict spontaneously. ASDs between 6 and 8 mm may restrict even after age 5. An ASD over 8 mm may increase in size during childhood. An episode of paroxysmal atrial fibrillation may be the first presentation of an ASD in an adult.
4. **Answer: B.** Three-dimensional TEE is the most sophisticated test prior to percutaneous closure of an ASD.
5. **Answer: E.** A deficient retro-aortic rim is a significant risk factor for device erosion. The Amplatzer and Gore Helix devices are both FDA approved. Successful closure was achieved in 99 percent of patients with the Amplatzer device, defined as a shunt less than 2 mm. Eligibility rates are much higher in older children and adults.

# Ventricular Septal Defects

*David L.S. Morales*
*Brandi B. Scully*
*Charles D. Fraser Jr.*

**KEY CONCEPTS**

- Epidemiology
  - Ventricular septal defect (VSD) is the most common noncyanotic cardiac anomaly (20 percent of all malformations); it is present in over 50 percent of children with complex congenital heart disease. VSDs occur in 0.5 of 1000 live births, and 5 percent are related to chromosomal syndromes.
- Morphology
  - VSDs vary in size, number, and location along septum. They are classified as (1) perimembranous (PM, most common), (2) inlet type, (3) nonmuscular outlet, and (4) muscular. The conduction system and aortic valve leaflets are in anatomic proximity and are at risk during repair.
- Pathophysiology
  - Degree and direction of shunting between the right and left ventricles depend on size (restrictive or nonrestrictive) and balance between the systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR). Aortic regurgitation can ensue as a consequence of leaflet prolapse through the defect.
- Clinical features
  - Small, restrictive defects are often asymptomatic. Symptoms of overcirculation are present in unrestrictive VSDs; with the development of irreversible pulmonary vascular changes in untreated large shunts, fixed pulmonary hypertension and cyanosis develop (Eisenmenger syndrome).
- Diagnosis
  - Echocardiography accurately defines the anatomy of VSD and associated lesions. Cardiac catheterization is rarely required.
- Treatment
  - Timing of closure is indicated by the degree of shunting and aortic valve involvement, and is most typically performed in infancy. Transatrial or transventricular approaches are most commonly utilized, with minimal morbidity and mortality. Percutaneous or periventricular device closure is still experimental, while a staged approach (with pulmonary arterial banding and delayed complete repair) is now considered only in selected cases.

## DEFINITION AND EPIDEMIOLOGY

A ventricular septal defect (VSD) is a deficiency in the ventricular septum that can vary in size, number, or location on the septum. All three determine its physiology, while the location alone determines its nomenclature. This is the most commonly recognized congenital heart defect excluding bicuspid aortic valve. Approximately 20 percent of patients with cardiac malformations have isolated VSDs and, if one includes VSDs in combination with other defects, VSDs are diagnosed in 50 percent of all patients with congenital heart disease.[1] VSDs occur at a rate of 0.5 per 1000 live births and in 4.5 to 7 of 1000 premature infants,[1,2] with a slightly higher prevalence in females (56 percent).[3] About 5 percent of VSDs are related to chromosomal syndromes (such as 22q11 deletion and trisomy 21), in which VSD is the most common cardiac defect identified.[4]

## HISTORICAL NOTE

In 1891, Dupren coined the term *Maladie de Roger* in honor of Henry-Louis Roger, who first described the clinical and pathologic findings of a VSD in 1879.[5] Eisenmenger then chronicled the natural history of an unrestrictive VSD by his account of the postmortem findings in a cyanotic patient

who died at age 32 with a large VSD, a severely hypertrophied right ventricle (RV), pulmonary valve (PV) and tricuspid valve (TV) insufficiency, and thickened pulmonary arteries (PAs).[6] However, the term *Eisenmenger syndrome* was not introduced until Abbott delineated the pathophysiology of a VSD in the 1930s.[7]

Muller was the first to surgically address a VSD in 1952 by placement of a pulmonary artery band (PAB).[8] Lillehei, using controlled cross-circulation (see Chapter 58), was the first to perform a VSD repair in 1954.[9] DuShane reported transventricular repair in 1956, while a transatrial approach was introduced the following year by Stirling.[10,11] Truex's description in 1958 of the atrioventricular node (AVN) and the conduction pathway in patients with VSDs is an integral part of all modern surgical techniques of VSD closure.[12] Kirklin and associates established in 1961 the ability to repair VSDs in small infants, therefore avoiding the two-staged approach of banding of the PA followed by VSD closure.[13]

## ANATOMY

In order to comprehend the different nomenclatures that are used for VSDs and the approaches and techniques for repairing this anomaly, one must understand the anatomy of the RV, the conduction system, and the TV.

The TV has three leaflets: septal, anterior, and posterior (Fig. 65-1). The posterior papillary muscles, which are located on the inferior wall of the RV near the septum, give rise to the chordae of the septal and posterior leaflets. The anterior papillary muscle gives rise to the chordae of the anterior and posterior leaflets. It is anchored at the acute margin of the RV and fuses with the RV muscle to become the moderator band, which travels inferiorly and becomes the septal band (alternatively termed trabecula septomarginalis or septomarginal trabeculation), which travels toward the RV outflow tract. The septal band then divides into its posterior and anterior arms. Between these two arms is the infundibular septum, also known as the conal, outlet, or supracristal septum. The medial papillary muscle (the muscle of Lancisi), which gives chordae to the anterior and septal leaflets of the TV, is most prominent and identifiable during infancy and attaches to the septal band or its posterior arm. The parietal band is the continuation of the septal band's posterior arm anteriorly onto the RV free wall. The parietal band and both arms of the septal band join to form the supraventricular crest (crista supraventricularis), the C-shaped nonobstructive entrance into the outlet region (subpulmonary conus) of the RV. This muscle shelf between the TV and PV creates PV–TV discontinuity.

It is essential to know the location of the AVN and the bundle of His in order to perform safe closure of a VSD. The AVN is located in the triangle of Koch (formed by the tendon of Todaro, the ostium of the coronary sinus, and the septal leaflet of the TV). More precisely, it is in the muscular region right below the triangle's apex and directly on the right atrial side of the central fibrous body. From another perspective, the AVN is under the nadir of the noncoronary (posterior) cusp of the aortic valve (Fig. 65-2). The AV bundle (bundle of His) arises from the AVN and exits at the apex of the triangle of Koch, passing to the ventricular side through the right aspect of the central fibrous body. At this point, the bundle is on the posteroinferior margin of the membranous septum, which lies just posterior to the commissure of the septal and anterior leaflets of the TV (Fig. 65-3). The bundle penetrates the ventricular septum and continues on the left ventricular (LV) side in 75 percent of patients. Whether on the right or left, it courses along the inferior border of the

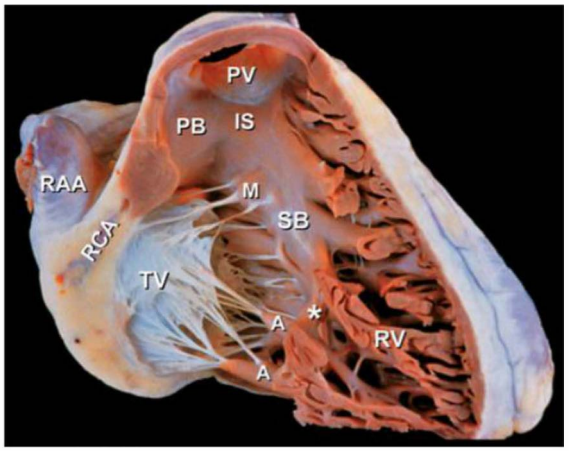

**FIGURE 65-1** Anterior view of the right ventricle in the anatomic position, as seen after removal of the anterior wall. *, moderator band; A, anterior leaflet of the tricuspid valve; IS, infundibular septum; M, medial papillary muscle of Lancisi; PB, parietal band; PV, pulmonary valve; RAA, right atrial appendage; RCA, right coronary artery; RV, trabecular portion of the right ventricle; SB, septal band; TV, tricuspid valve. (Reproduced with permission from Fuster V, Walsh RA, Harrington RA. *Hurst's the Heart*, 13th ed. www.accessmedicine.com. Copyright The McGraw-Hill Companies, Inc., all rights reserved.)

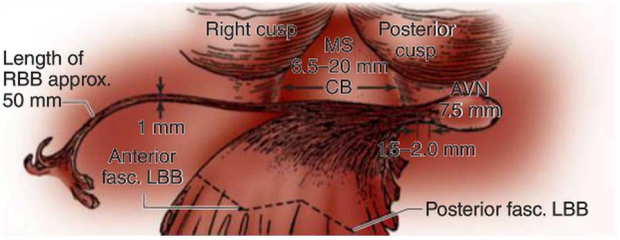

**FIGURE 65-2** A view of the atrioventricular conduction system from the left ventricle and its relationship to the membranous septum and the aortic valve. AVN, atrioventricular node; MS, membranous septum; fasc, fasciculus; RBB, right bundle branch; LBB, left bundle branch. (From Titus JL. Normal anatomy of the human cardiac conduction system. *Mayo Clin Proc* 1973;48:24–30. With permission.)

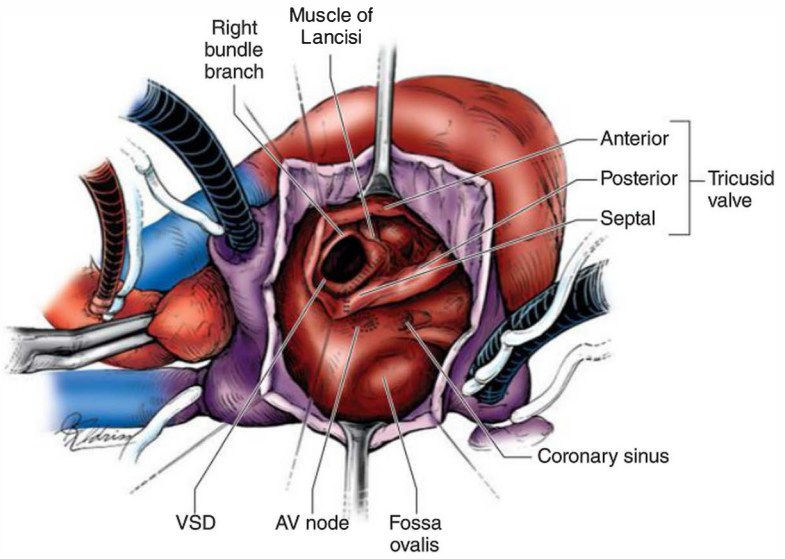

**FIGURE 65-3** Depiction of the atrioventricular node and its course on the inferior border of a perimembranous VSD; viewed from a right atrial surgical approach. (Drawing by Rachid Idriss. Used with the artist's permission, who reserves all rights. The drawing has not been modified; however, the labeling is that of the authors.)

membranous septum and begins to give off fibers to the left bundle branch over a distance of 1 to 2 cm. When the membranous septum is intact, this area is just below and to the left of the commissure between noncoronary and right coronary cusps of the aortic valve. In considering the bundle from the aortic valve perspective, one should imagine its path as coursing a few millimeters below the area between the right-noncoronary (posterior in Fig. 65-2) commissure and the nadir of the right coronary sinus. The remaining fibers of the bundle, which now surface to the anteroinferior border of the membranous septum, become the right bundle branch. The left bundle branch fans out over the septum while the right bundle branch courses as a single radiation (Fig. 65-3). From the anteroinferior border of the membranous septum, the right bundle passes below the muscle of Lancisi and then to the inferior borders of the septal and moderator bands until it reaches the anterior papillary muscle, where it disperses to innervate the RV. Therefore, the bundle of His is most often in harm's way during operations on a perimembranous (PM) VSD. The bundle of His runs along a PM VSD's inferior border from where it penetrates the TV annulus to the most inferior papillary muscle on the VSD's muscular rim (the muscle of Lancisi) (Fig. 65-4). The fact that the AVN and bundle of His are specialized myocytes and thus exist only in muscular tissue and not in fibrous tissue is an important fact to consider when placing sutures for VSD repair. The conduction system can also be at risk at the superior edge of a muscular inlet VSD, where the conduction system runs in the muscle between the VSD and the membranous septum.

## NOMENCLATURE AND PATHOLOGIC ANATOMY

There are many classifications of VSDs that have been proposed and used; our preference is a modification of the classic Anderson classification. However, to make our classification useful to the reader, we will compare other terms and classification to this terminology.

The ventricular septum can be sectioned into four regions: (1) the *inlet septum*, which is the area of the septum bounded by the attachments of the TV; (2) the *muscular septum*, which is the area from apex to the crista supraventricularis outside these attachments; (3) the *outlet septum*, which is the area from the crista supraventricularis to the PV, and (4) the *PM septum*, which is quite small and lies under the commissure of the anterior and septal leaflets of the TV. The muscular region is further subdivided into anterior, posterior, apical, and midmuscular regions. The Anderson classification names VSDs according to the region in which they are located. However, from a surgical perspective, one wants to know not only the location of the defect but also its relation to the conduction system. The latter can be transmitted to the surgeon by first defining whether the defect is PM (an absence of the membranous septum) or not (all other types of defects). This automatically tells the surgeon whether or not the conduction system is remote, and if not remote, where it is (inferior to a PM defect for a d-looped heart and superior to a PM defect for an l-looped heart, see Chapter 75). The exception to this rule is an inlet VSD, which is discussed below. One can also describe the type of PM VSDs by the areas defined

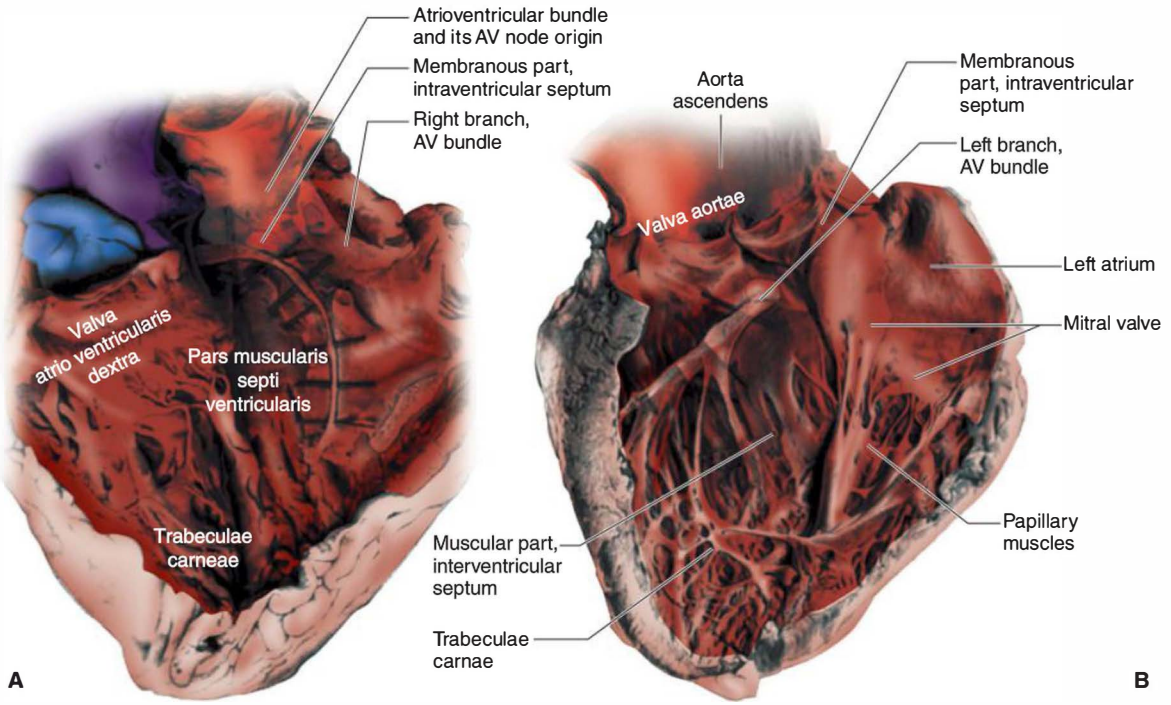

**FIGURE 65-4** Anatomy of the atrioventricular conduction system. **A.** The atrioventricular bundle and its right branch dissected in the right ventricle. **B.** The atrioventricular bundle and its left branch dissected in the left ventricle. (From Sobotta. *Atlas der Anatomie des Menschen*, 16th ed. Munich: Urban & Schwarzenberg, 1963. With permission.)

by Anderson. Therefore, a PM VSD can be one with muscular extension, outlet extension, inlet extension, or any combination. Non-PM VSDs can be muscular in type (outlet, inlet, anterior, posterior, apical, midmuscular) or outlet or inlet types bound by valve tissue (Fig. 65-5). The synonyms in other classifications for all the terms used above can be found in Table 65-1. The table lists all the different names by which a VSD within a certain region can be designated. The different names listed under a certain region are sometimes used imprecisely to denote any VSD in the area, but most of the terms are not interchangeable and refer to a very specific type of VSD. For example, some might use the terms *subaortic* and *supracristal* to refer to the same VSD; however, the former is a general term that refers to any VSD abutting the aortic valve, whereas the latter specifically refers to an outlet VSD abutting a semilunar valve.

The PM VSD represents approximately 80 percent of all VSDs; the remaining 20 percent are evenly distributed among inlet, outlet, and muscular VSDs. A notable exception to this distribution is the almost 30 percent overall prevalence of outlet-type VSDs in the Asian population with VSDs.[14] Small asymptomatic muscular VSDs, which are probably the most common heart defect (present in about 5 percent of all neonates), are grossly underestimated in these statistics, since the vast majority close in the first months of life without recognition.[15]

PM VSDs are intimately related to the TV and aortic valve. In fact, the absence of the PM septum often creates TV–aortic valve fibrous continuity. "Spontaneous closure" of PM VSDs usually occurs from partial or complete occlusion of the VSD by aneurysmal TV tissue. This aneurysmal tissue is formed from the sheer force of the left-to-right (L–R) shunt resulting in creation of fibrotic tissue, "accessory valve tissue," and/or, perhaps, remnants of endocardial cushion tissue. Some have described a defect of just the atrioventricular septum causing a shunt from the left ventricle to the right atrium, known as a "Gerbode defect."[16] When seen on echocardiography, this almost always represents a PM VSD with a jet directed through a cleft in the TV or the septal–anterior commissure, giving the echocardiographic appearance of a Gerbode defect. A consequence of this physiologic shunting from the LV to the right atrium can be extensive right atrial enlargement and, if an atrial septal defect exists, streaming of the blood can possibly cause right-to-left atrial (LA) shunting with resulting cyanosis.

Malalignment of the infundibular septum is also associated with PM VSDs, usually with outlet extension. If one considers the infundibular septum as being in the coronal plane with the RV outflow tract above and the LV outflow tract below, then comprehension of the malaligned VSDs is more straightforward. In an anteriorly malaligned VSD, the infundibular septum is deviated anteriorly into the RV

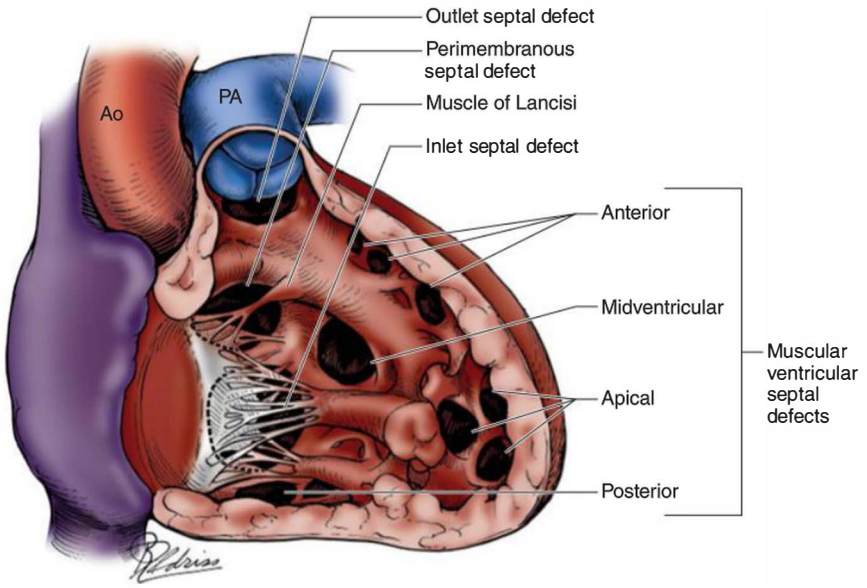

**FIGURE 65-5** The different types of VSDs as viewed via the right ventricle. (Drawing by Rachid Idriss. Used with the artist's permission, who reserves all rights. The drawing has not been modified; however, the labeling is that of the authors.)

outflow tract, causing obstruction. The aortic valve also moves anteriorly, so that it overrides the ventricular septum. In a posteriorly malaligned VSD, the infundibular septum deviates posteriorly into the LV outflow tract, causing obstruction.

**TABLE 65-1: Nomenclature Utilized for Ventricular Septal Defects**

| Preferred Terminology | Synonyms |
|---|---|
| **Perimembranous VSD** | |
| PM VSD with inlet extension | Membranous, infracristal, paramembranous |
| PM VSD with outlet extension | Membranous, conoventricular, subaortic |
| PM VSD with muscular extension | Membranous, infracristal, paramembranous |
| **Nonmuscular-outlet VSD** | Conal, supracristal, subarterial, subaortic, subpulmonary, infundibular, intracristal, doubly committed, conalseptal, juxta-arterial |
| **Inlet VSD** | Canal type, atrioventricular |
| **Muscular** | |
| Inlet | Canal type |
| Outlet | Conal, supracristal, subarterial, infundibular, conalseptal |
| Midmuscular VSD | Central |
| Apical muscular VSD | — |
| Anterior muscular VSD | Marginal |
| Posterior muscular VSD | Inferior |

Outlet defects are often differentiated between those that are completely bound by muscle and those that are bounded on one side by aortic valve tissue (subaortic, juxta-arterial VSDs), by PV tissue (subpulmonary VSDs), or both (doubly-committed, subarterial VSDs). This differentiation is useful in terms of the pathophysiology. The nonmuscular outlet defects along with PM VSDs with outlet extension can both be associated with aortic valve insufficiency, characterized by lengthening and eventual prolapsing of the right coronary leaflet (outlet defect) or noncoronary leaflet (PM VSD). This valve tissue can partially or completely close the defect. The conduction system is remote to outlet defects.

Inlet defects are beneath the septal leaflet of the TV, just inferior and posterior to the membranous septum. These defects can be an atrioventricular septal defect or a muscular inlet defect. The former is an endocardial cushion defect, characterized by absence of the PM septum, atrioventricular valve abnormalities, and a conduction system traveling along the inferior aspect of the defect. A muscular inlet defect is a VSD that can be remote to the conduction system or have the conduction system border the defect superiorly.

Muscular VSDs can be multiple or appear to be so because of the overlying trabeculae in the RV. This topography and multiplicity may cause difficulty in closure of these defects. When these impediments become prohibitive to conventional surgery, the term "Swiss cheese septum" is usually used to describe them. However, it should be noted that some believe that a Swiss cheese septum is actually an entity distinct from multiple VSDs. The morphology of the Swiss cheese septum is believed to originate from septal noncompaction during embryologic development; thus, unlike a group of muscular VSDs, Swiss cheese defects cannot close spontaneously.[17,18]

## PATHOPHYSIOLOGY

The pathophysiology of a VSD is determined by the size of the defect and its location. If the defect is smaller than the aortic annulus (a restrictive VSD), then the shunt's direction and volume is determined by the difference in systolic pressures of the ventricles. If the defect is larger than the aortic valve, then the defect is nonrestrictive and the pressure in the ventricles should equalize. The direction and volume of this shunt is determined by the difference in PVR and systemic vascular resistance (SVR).

Restrictive VSDs can be further categorized as small or moderate in size. A small VSD has a large resistance to flow, resulting in a small L–R shunt, and the pulmonary vasculature is well protected. The small shunt volume does not increase ventricular work or volume, and the LA and LV tend not to dilate. The large pressure gradient across the small VSD favors L–R flow throughout the cardiac cycle, which can produce a continuous murmur. Moderate-sized defects remain restrictive but allow a large enough L–R shunt to cause left-sided volume overload, characterized by LA and LV dilation. The pulmonary vasculature remains protected; however, some pulmonary hypertension can exist, which will cause RV pressure and work to increase. This results in mild RV hypertrophy.

Nonrestrictive VSDs allow for RV and LV to have equal pressures, with the determination of flow across the defect resulting from outflow resistance. In the LV, this is determined by SVR or by LV outflow tract anomalies (subaortic stenosis, aortic stenosis, coarctation, etc.). In the RV, this is determined by PVR or by RV outflow tract anomalies (PV stenosis, tetralogy of Fallot, etc.). PVR is high at birth and lessens the amount of L–R shunt; however, the PVR naturally decreases as the pulmonary vascular bed matures. The decline in PVR occurs mostly over the first few days, but the process is not completed until 2 to 6 weeks after birth.[19,20] The thinning of the vascular media, the enlargement and proliferation of the peripheral PAs, and the regression of the PA's perinatal muscularity mark the normal maturation of the pulmonary vessels. However, a large L–R shunt disturbs the growth and remodeling of the pulmonary vasculature, so that medial hypertrophy develops, muscularization of PA's persists, and the size and number of peripheral PAs is reduced. These structural changes are the basis of pulmonary vascular disease.[21,22] Any patient with a nonrestrictive VSD and no RV outflow tract obstruction has pulmonary hypertension, but this does not necessarily indicate that the patient has pulmonary vascular disease. The latter is a disease state of the pulmonary vasculature correlating to specific pathologic changes in the PAs, while pulmonary hypertension is simply a hemodynamic state of the PAs at any given time. A nonrestrictive VSD is characterized by a large L–R shunt, which will cause volume overload of the LA and LV, resulting in significant dilation of these chambers. This shunt will also result in pulmonary hypertension, which in time will cause RV hypertrophy and increasing PVR. As the PVR increases, the L–R shunt decreases. When end-stage pulmonary vascular disease ensues, the shunt can even reverse direction to a R–L shunt (i.e., Eisenmenger syndrome). Reversal of shunting and cyanosis rarely present in children below age 5 with isolated VSDs and is usually seen in adolescents and adults.

## CLINICAL FEATURES

The presentation of a patient with a VSD varies according to the size of the defect, the amount of L–R shunting, and PVR (Fig. 65-6). The majority of VSDs are small; these patients are asymptomatic and are diagnosed because of a loud systolic murmur, prompting an echocardiogram. The murmur is often not heard until the first postnatal visit, after PVR has dropped. Many of these defects will close spontaneously by muscle hypertrophy, fibrosis of the defect's margins, or leaflet adherence to the defect. In a study by Turner and colleagues, 290 children with isolated VSDs of all sizes were followed for a mean of 65 months.[23] The study revealed that 68 percent of VSDs with complete muscular borders closed spontaneously, while 29 percent of PM VSDs closed over the same time period. There were no cases of endocarditis in this nonoperative series. The aortic valve can also contribute to the narrowing of defects that have an outlet component, which can cause aortic insufficiency; this is a situation that demands prompt surgical treatment. Despite therapy, the natural history of the damaged aortic valve may no longer be normal. Thus waiting for spontaneous closure of PM VSDs or outlet VSDs, even with close follow-up, is not without risk.

Patients with large VSDs present with varying degrees of pulmonary overcirculation. The amount of overcirculation usually determines their age at presentation. Patients with larger defects and significant overcirculation can present in the first months of life, as PVR falls. These patients present with tachypnea, poor feeding, slow weight gain, and diaphoresis with activity. They are at risk for repeated upper respiratory tract infections, "cardiac asthma," and failure to thrive. Shunt size and the length of exposure to the resulting pulmonary hypertension will determine the time frame for the development of the varying degrees of pulmonary vascular disease. Patients with trisomy 21 have a shorter time course to reach significant pulmonary vascular disease than most children.[24] The end-stage of pulmonary vascular disease is termed Eisenmenger syndrome: PVR greater than SVR, reversal of shunt flow from L–R to R–L, cyanosis, and eventually RV failure.[25]

## DIAGNOSIS

### Physical Examination

Small defects usually have minimal physical findings and a normal chest x-ray (CXR) and electrocardiogram (ECG). Precordial activity is typically normal, but a thrill may be palpable on the lower left sternal border. The murmur is a

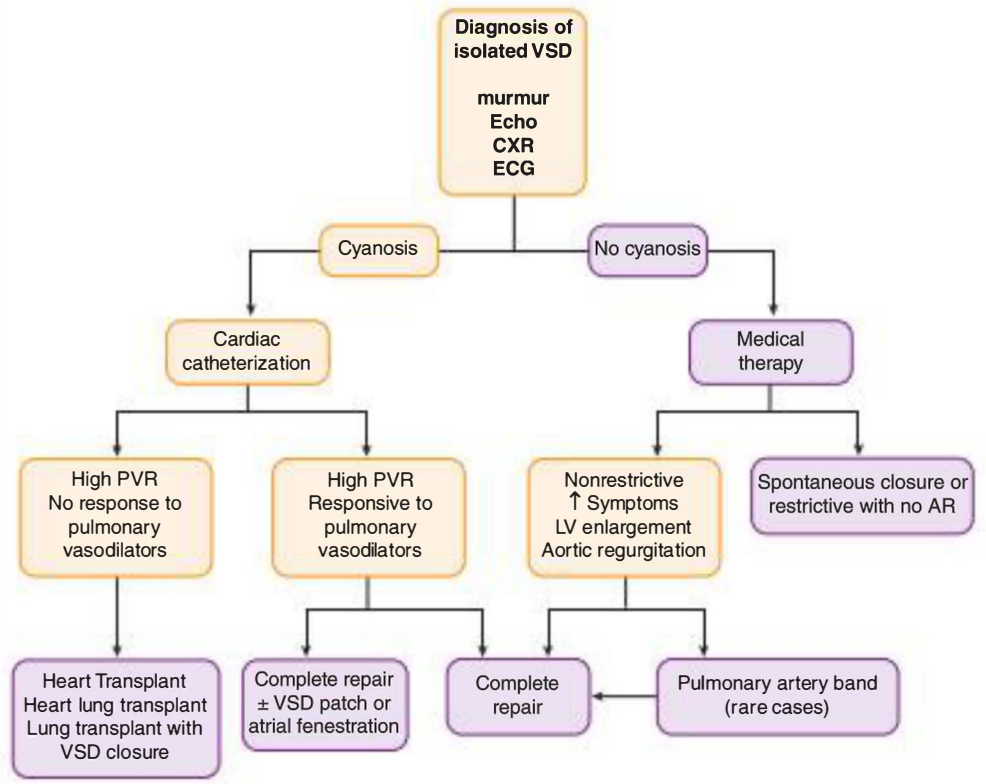

**FIGURE 65-6** Decision-making flowchart for isolated ventricular septal defect.

loud, high-frequency holosystolic murmur that includes and sometimes goes beyond the second heart sound and is heard best over the left lower sternal border. The murmur's continuous nature in systole provides evidence of a large pressure gradient between the RV and LV. Small muscular defects can sometimes have short murmurs that cut off at midsystole because of septal contraction.[26] Heart sounds are usually normal.

Moderate-to-large defects with minimal elevation of PVR present with similar exam findings that vary according to the amount of shunting. Precordial activity is accentuated and can span from the left apical area at first, indicating increased LV volume, to the right parasternal area eventually, indicating pulmonary hypertension and RV hypertrophy. As LV volume increases, the left thorax may begin to bulge, especially in younger infants. As the shunt increases, the third heart sound becomes more prominent, as does a middiastolic rumble, which indicates increased pulmonary blood flow at least double systemic blood flow. The holosystolic nature and the loudness of the murmur begin to dissipate as defects become larger and the pressure gradient between the RV and LV decreases. As pulmonary hypertension increases, the second heart sound has a narrower split and the pulmonary component becomes louder. There are no specific ECG patterns that are pathognomonic for VSDs and most patients' ECGs are normal. There can be ECG evidence of increased left heart volume (LA enlargement), but these findings are not specific to VSDs. On CXR, as the LV volume increases, there is a downward and leftward elongation of the cardiac silhouette on the anteroposterior (AP) film, whereas LA enlargement is seen on the lateral film or, when severe, by carinal widening on the AP film (Fig. 65-7). The increase in vascular markings denotes the amount of overcirculation.

Large VSDs coupled with high PVR allow for minimal shunting. Therefore, the LV work is close to normal, resulting in little precordial activity. There will, however, be a notable RV lift. A short or absent VSD murmur is usually heard. Murmurs that may be heard are a result of tricuspid regurgitation (TR) (harsh holosystolic murmur) or pulmonary insufficiency (PI) (early diastolic murmur). There is usually no third heart sound or diastolic rumble. The pulmonary component of the second heart sound is quite prominent; however, in over 50 percent of cases, the second heart sound is single. ECG may show RV hypertrophy. The CXR on these patients can demonstrate a normal-size heart or RV hypertrophy, both accompanied by marked prominence of the main PA and its immediate branches. There is a paucity of vascular markings on the outer third of the lung fields.

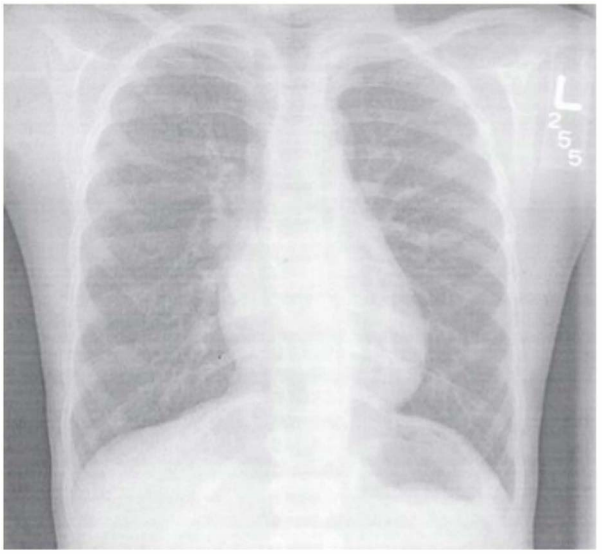

**FIGURE 65-7** Anteroposterior chest x-ray of a patient with a VSD. Note the leftward elongation of the cardiac silhouette, representing an increase in left ventricular volume, and the plethoric lung fields.

## Diagnostic Imaging

Two-dimensional echocardiography with color Doppler flow evaluation is the most widely used imaging to diagnose and characterize a VSD. To assess a VSD completely, one must not only localize it but also define its shape and dimensions, which is accomplished by viewing the defect from multiple imaging planes. Color Doppler allows for small VSDs not seen on two-dimensional echocardiography (usually <2 mm) to be identified and, more importantly, provides physiologic information about the VSD. One can measure the peak velocity across the VSD, which, if placed in the modified Bernoulli formula [4 × (peak velocity)$^2$], can yield the interventricular pressure gradient.[27] If this velocity is high, one has a restrictive VSD. If this velocity is low, one usually has a nonrestrictive VSD with near equalization of RV and LV pressures. However, at times a low velocity can be seen with a restrictive VSD if there is high RV pressure secondary to RV outflow obstruction or elevated perinatal PVR that has not yet fallen. Therefore, a low intraventricular pressure gradient does not necessarily correlate with pulmonary vascular disease, even in the presence of a nonrestrictive VSD. Right ventricular pressure may be estimated by measuring the velocity of the TR jet [4 (TR jet velocity)$^2$ + (central venous pressure) ≈ RV pressure]. If a PI jet exists, then an estimation of the diastolic PA pressure can be calculated by measuring its velocity [4(PI jet velocity)$^2$ + (RV diastolic pressure)]. One can also get a sense of where the patient is in the spectrum of VSD pathophysiology by assessing the amount of LV and LA dilation as well as RV hypertrophy. The echocardiogram should obviously seek other cardiac anomalies, in particular patent ductus arteriosus, aortic coarctation, and RV or LV outflow tract obstruction.

The principal indication for diagnostic cardiac catheterization of a patient with a VSD is when echocardiography and the clinical assessment indicate the possibility of advanced pulmonary vascular disease. Again, this would be rare for young children. One should keep in mind that the PVR of a child with an isolated VSD would have to be extremely elevated not to attempt a repair in this era of multiple pulmonary vascular bed dilators [inhaled nitric oxide (iNO), prostacyclin, sildenafil milrinone, etc.]. Therefore, one may question exposure to the risks of catheterization to quantify the echocardiographic findings more precisely when the results will not change the therapeutic decision. Catheterization of a VSD patient is also useful in attempting to define the anatomy of multiple apical VSDs, which magnetic resonance imaging (MRI) and echocardiography sometimes cannot identify. Catheterization of a patient with an isolated VSD should determine (1) a $Q_P$:$Q_S$ that can be estimated by (aortic $O_2$ sat—SVC $O_2$ sat)/(pulmonary venous $O_2$ sat—PA $O_2$ sat); (2) the calculated PVR = (mPAP—LA mean pressure) / pulmonary blood flow ($Q_P$) resulting in Wood units (mm Hg/L/min); (3) the PA pressures; (4) if PVR is high, the determination of the pulmonary vasculature reactivity to vasodilators such as 100 percent $FIO_2$ and iNO; and (5) the delineation of any unclear anatomy.

MRI has recently been used to provide accurate information about the morphology of VSDs. When surgical referral is being considered, MRI may be recommended in those patients in whom it is difficult to discern ventricular volume overload. The MRI can supply a noninvasive estimate of the $Q_P$:$Q_S$ as well as an accurate account of the heart's volumes and of associated anomalies that are sometimes difficult to diagnose by echocardiography (anomalous pulmonary venous return, for example). Also, three-dimensional intracardiac reconstruction MRI may soon be more widely available.

# THERAPEUTIC MANAGEMENT

## Medical Therapy

The medical treatment of VSD patients is aimed at decreasing L–R shunting and the symptoms of overcirculation. This is usually done with a combination of diuretics (i.e., furosemide), afterload-reducing agents (ACE inhibitors), and digoxin. Patients may also require nutritional support such as nasogastric tube feedings. Close surveillance for and aggressive treatment of upper respiratory infections is an important aspect of these children's care. Most children presenting with VSDs have some degree of pulmonary vascular disease; however, the presentation of an older cyanotic child with end-stage pulmonary vascular disease requires catheterization. The treatment and workup of such cases is outside the scope of this chapter. One should exercise caution when a patient requires intubation or inotropic support for a supposedly isolated VSD. Before embarking on surgical therapy, a careful investigation should be performed to make sure that no other cardiac anomaly (e.g., left-sided obstruction

or an additional source of L–R shunting) or primary pulmonary disease exists.

## Invasive Therapy

### SURGICAL THERAPY

Surgical techniques for VSD closure have progressed tremendously over the past 3 decades, and have allowed for neonatal surgical therapy to move from palliation to repair. At most institutions, all patients with isolated VSDs that require surgical correction undergo single-stage closure.

At the authors' institution, all repairs are generally performed with aortic and bicaval cannulation. Once the heart is arrested with cold cardioplegia, the right atrium is opened and the left heart is vented via the atrial septum. This should produce a bloodless and still intracardiac surgical field in which to work. There are several approaches to VSDs at this point, depending on the location.

The majority of VSDs (PM, inlet, and the majority of muscular defects) can be addressed via a right atrial approach (Fig. 65-8). The leaflets of the TV are retracted to visualize the defect. A particular variation in technique to visualize transatrially inlet defects or PM VSDs with outlet extension is the incision of the septal and/or anterior leaflet(s) of the TV via a radial incision or one parallel to the annulus. This will often provide excellent visualization for repair; once this has been completed, the TV is reattached to its annulus. The actual closure of the VSD can be done with a patch secured to the septum with interrupted pledgetted stitches, a running stitch, or a combination of the two. The patch can be made of various materials, including autologous pericardium tanned in glutaraldehyde, Dacron, or Gore-Tex. Primary (no patch) closure is usually reserved for a small muscular VSD or a windsock type defect in which the small effective orifice is surrounded by TV aneurysmal tissue. A key to successful VSD closure is the surgeon's awareness of the conduction system and the aortic valve. The TV annulus, which is the structure to which the VSD patch is often anchored posteriorly and superiorly, is just anterior to and sometimes in fibrous continuity with the aortic valve. Therefore, the aortic valve leaflets are at risk for injury when these superior sutures are being placed. The conduction system is at risk in stitching the inferior rim of a PM VSD between the muscle of Lancisi (the most inferior papillary muscle bundle on the VSD rim) and the TV annulus (Fig. 65-4). In this area, interrupted sutures can be taken far from the rim or a running suture can be placed very superficially along the rim. It is important to remember that the conduction system exists only in muscular tissue and not in fibrous tissue.

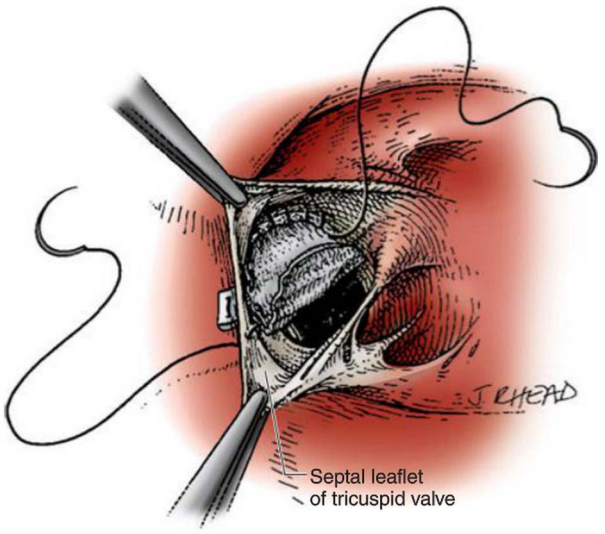

**FIGURE 65-8** Transatrial approach to VSD patch closure. In the illustration, a running suture technique is utilized. (Reproduced with permission from Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). *Kirklin/Barratt-Boyes Cardiac Surgery,* 3rd ed. Philadelphia: Churchill Livingstone, 2003:874. Copyright Elsevier.)

Approach through the PA is usually reserved for outlet defects. The pure outlet muscular defects can be closed with a simple primary or patch technique. However, the majority of outlet defects abut the PV annulus. These defects are also closed with a patch, but several unique factors must be considered. These particular VSDs have the highest incidence of significant aortic valve involvement. The aortic valve leaflets (usually the right coronary cusp) can prolapse and/or fill the defect. Therefore, it is essential to identify the aortic valve and not to include it in the repair. The patch will not only close the defect but also serve to support the aortic valve and eliminate the Venturi effect, which can be the cause of aortic valve prolapse. Some mild forms of aortic insufficiency will improve with repair of the defect alone, but this is unpredictable. If the aortic insufficiency is moderate or greater and/or the aortic leaflet clearly has a pathologic change, then the aortic valve should be addressed. PM defects can also be associated with aortic insufficiency and usually involve prolapse of the noncoronary cusp. A discussion of aortic valve repair techniques—which include triangular resection, subcommissural stitches, Trussler-type repair (horizontal plication of the redundant leaflet to the aortic wall), and Yacoub-type repair (primary closure of the VSD with vertical plication of the sinus and leaflet)—are beyond the scope of this chapter. There is no superior rim to outlet defects, so interrupted pledgetted sutures are usually placed through the fibrous base of the pulmonary valve leaflets and then through the patch. Interrupted or running sutures can anchor the remainder of the patch, with little concern for the conduction system, which is remote. However, if the posterior limb of the septal band (part of the crista supraventricularis) is not identified, the VSD may be a PM defect with outlet extension. Thus the conduction system would be on the inferior border of the defect.

A transaortic approach is usually applied in addressing a VSD that is associated with another left-sided lesion such as aortic valve insufficiency or valvular/subvalvular

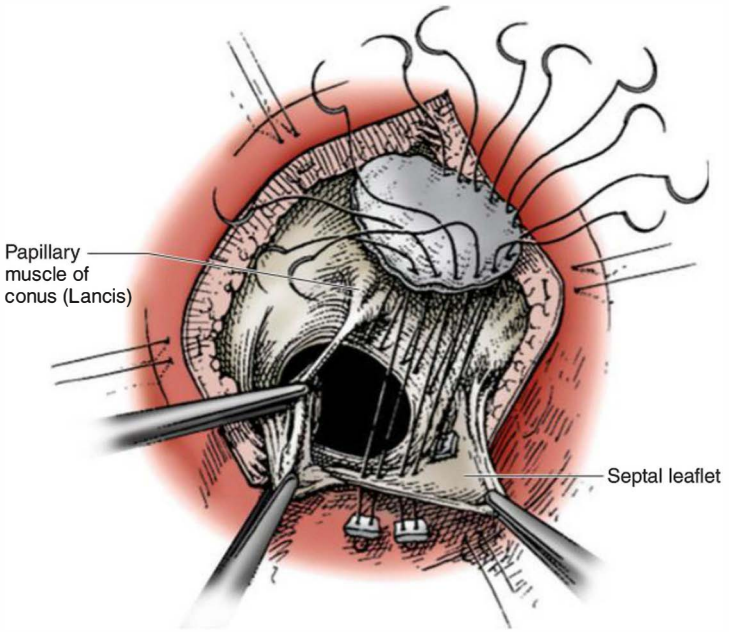

**FIGURE 65-9** Transatrial approach to VSD closure. In the illustration, an interrupted suture technique is utilized. (Reproduced with permission from Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). *Kirklin/Barratt-Boyes Cardiac Surgery*, 3rd ed. Philadelphia: Churchill Livingstone, 2003:876. With permission.)

stenosis. Our practice is still to close these defects from the RA approach to avoid left bundle branch block; however, many still use this approach, and discussion of it is helpful in contemplating the relationship of VSDs and the conduction system.

An RV approach (Fig. 65-9) for an isolated VSD is unnecessary except in very rare situations in which the VSD is inaccessible from the different approaches; for example: (1) When the posterior limb of the septal band is absent in a large outlet VSD, it is difficult to approach its inferior border from the PA or its superior border from the right atrium; thus neither approach suffices. (2) Visualization of a PM VSD with outlet extension can be hindered by hypertrophied infundibular muscle bundles. Resection of such bundles may at times be difficult from the RA or PA approaches; thus exposure is optimized by a small right ventriculotomy. Mapping out the ventricular incision in relation to the coronary anatomy is essential in avoiding significant ischemic complications, such as disruption of an anomalous anterior descending artery coming from the right coronary artery or of a large conal branch responsible for the proximal septal perforators. Again, we emphasize that right ventriculotomy is rarely needed to close an isolated VSD.

The LV approach is used even more infrequently than the RV approach and is reserved only for addressing those patients with multiple apical defects. Swiss cheese defects are difficult to approach from the right side because the trabeculations make the identification of distinct VSD borders impossible. However, this sieve-like defect on the right is well delineated on the nontrabeculated smooth septum of the LV. After careful mapping of the coronary arteries, an incision parallel and to the left of the anterior descending artery is started at the apex and extended vertically. These incisions are obviously avoided whenever possible because of pseudoaneurysms, ventricular dysfunction, and ventricular arrhythmias arising from scar tissue. These complications are why many authors still attempt closure of these Swiss cheese defects from the right side of the heart or with multiple VSD devices with a per-ventricular hybrid approach.

## RESULTS

### Surgical Outcomes

Complications from surgical VSD closure are infrequent; they include the following:

1. TV insufficiency from chordal shortening, leaflet entrapment by the VSD patch, or leaflet distortion if incised for exposure.
2. Possible aortic valve insufficiency if the sutures in the superior aspect of the patch catch or damage the aortic valve leaflets.
3. Complete heart block if the bundle of His is damaged or transected by sutures: Temporary block can occur secondary to edema in the area or trauma caused by careless

suctioning or manipulation around the AVN area with instruments. The decision of when to place a pacemaker depends on the individual situation. Factors in one's decision include preoperative AVN function, the nature of the procedure and cardiac anatomy, and the postoperative course. The frequency of this complication should be approximately 1 percent, and several centers have reported zero incidence of complete heart block postoperatively.[28–30] Right bundle branch block (RBBB), on the other hand, is a frequently seen rhythm change postoperatively (about 35 percent).[31]

4. Residual VSD: Leaving the operating room with a clearly significant residual VSD has been greatly reduced with the use of intraoperative transesophageal echocardiography (TEE). The difficulty arises when one must decide whether a small residual defect is physiologically and clinically significant enough to warrant rearresting the heart and attempting complete closure. A $Q_p$:$Q_s$ of less than 1.5:1 is used as a general guideline for a residual VSD shunt that could be observed. However, in practice, the decision to leave a residual VSD is multifactorial and based on such aspects of the case as the difficulty of the VSD closure, one's perception of how the heart will tolerate another arrested period, and the residual shunt that is left.

Operative mortality for isolated VSD closure is quite low, ranging from 0 to 3 percent.[32,33] The most common mode of death is acute cardiac failure, which is usually the result of one of the following: poor intraoperative myocardial protection, pulmonary hypertensive crises, a preoperative viral pulmonary process, or any combination of these with a small malnourished infant in heart failure. The risk factors for hospital death have changed significantly over the past decade. Young age, multiple VSDs, location, aortic insufficiency, PAB, and patient size, which all have been predictive of hospital mortality at various times in the past, are no longer risk factors.[31] In the current era, only major associated cardiac anomalies, especially when associated with multiple VSDs, are risk factors for hospital mortality. Preoperative PA pressures or resistance do not affect hospital mortality but do affect long-term results, which manifest as late deaths secondary to progression of pulmonary vascular disease.[34] Late mortality after repair, when pulmonary pressures are low, is less than 2.5 percent; most of these deaths result from ventricular arrhythmias.[31] The surgical repair of an isolated VSD before complications begin to arise (usually before 2 years of age, depending on the VSD) can return a patient to a normal life expectancy with full functional activity and normal growth.[31]

Scully et al. recently analyzed a cohort of patients with isolated VSDs over a 5-year period to determine the current expectations for VSD repair, which are that: (1) The patient will survive, (2) The operation will take an average of 4 hours, (3) The patient will be in the hospital for an average of 5 days, (4) The patient will have a very low risk (<1 percent) of adverse events, including complete heart block, extended hospital stay, arrhythmias, valve injury, depressed ventricular function, and (5) The risk of reoperation for a residual VSD is extremely low (<1 percent).[28] These are the expectations that can now be communicated to patients and their families.

## Device Closure

Device closure of VSDs is an emerging field that should be offered as a therapeutic option in very selected cases. These devices are usually introduced via percutaneous catheterization techniques but can also be positioned via a periventricular approach. The periventricular technique, which is performed off bypass and uses TEE guidance, passes an occluding device through the right ventricular free wall and deploys it.[35] This technique can be repeated for multiple muscular VSDs. Experience with percutaneous device closure is greatest with muscular defects. The two devices presently offered in the United States for closure of muscular defects are the Cardio-SEAL (NMT, Boston, MA) device (a modified ASD clamshell occluder, FDA-approved for high-risk surgical VSD patients) and the Amplatzer Muscular VSD occluder (AGA Medical, Plymouth, MN), a specifically designed nitinol wire with polyester mesh device, recently approved by the FDA. Clinical experience with percutaneous closure of muscular VSDs can be considered in the management of VSDs that are challenging to address surgically.

On the other hand, closure of PM VSDs using percutaneous device closure is still very much experimental, with only one available device (the Amplatzer Membranous VSD occluder, currently under study for patients weighing more than 8 kg). One recent study reported the immediate and midterm results of 100 patients in 24 international centers who underwent percutaneous device closure with the Amplatzer Membranous VSD occluder.[36] This study reported a 29 percent incidence of complications, with 13 patients experiencing rhythm or conduction anomalies postoperatively, and a complication rate of 58 percent for patients under 10 kg.[36] Xunmin and colleagues report equivalent results between device and surgical closure of PM VSDs.[37] Patients in this study, however, were greater than 2 years of age with a median age at device closure of 7.5 years. The young age and low weight of children who require early VSD closure due to heart failure, failure to thrive, and pulmonary hypertension remains a significant limitation for device closure. The challenge for this therapeutic approach is that PM VSDs are almost always surgically approachable with negligible mortality and minimal morbidity. Also, the possible complications for devices in this position include device embolization, air embolism, perforation, residual shunt and hemolysis in addition to heart block and aortic insufficiency.

## Palliation

The list of clinical and anatomic features that discourage early primary repair of VSDs becomes shorter with every year, and the number of cases in which surgical palliation for

isolated VSDs using PA banding has continued to decline. Size of the patient, which in the past was one of the most frequent reasons for a PAB, is no longer a contraindication for complete repair in major centers, where the expansion of neonatal heart surgery has rendered this consideration almost null. Successful repair in a premature neonate of 700 g has been reported.[38] In patients with isolated VSDs, a "Swiss cheese septum" and multiple VSDs are the most frequent diagnoses to be palliated with a PAB. PA banding is performed off bypass, can be approached either via a median sternotomy or a left thoracotomy, and is described in detail in Chapter 62. Placement of a PAB may not be necessarily a simple or low-morbidity procedure. It is not always straightforward to balance the pulmonary and systemic circulations, especially with a reactive and/or high PVR; PA banding can carry a hospital mortality of up to 8 percent and even higher in neonates.[39–41] It may require early reoperation for PAB adjustment; furthermore, 29 percent of PABs can be inadequate (too loose or tight)[37] and, after PAB removal, PA reconstruction is often required at the time of complete intracardiac repair.

## VENTRICULAR SEPTAL DEFECTS BOARD REVIEW QUESTIONS (CHAPTER 65)

1. In which of the following patients could a diagnostic cardiac catheterization be an appropriate next step in management?
   A. A patient with clinical features and echocardiography compatible with advanced pulmonary hypertension
   B. A term infant with low birth weight and isolated VSD demonstrated on echocardiography
   C. A patient presenting in clinic with a holosystolic murmur
   D. Patient 3 days post repair of isolated VSD with RBBB
   E. Healthy child with echocardiographic, clinical, and radiographic evidence of VSD.

2. Which statement regarding surgical repair of isolated VSD is true?
   A. If complete heart block is present after repair, it is always permanent and placement of a pacemaker is indicated.
   B. Operative mortality for repair of isolated VSD remains at 3 percent in recent studies.
   C. There is no currently available transcatheter device closure of PM VSDs.
   D. RBBB is a relatively common result of VSD closure, occurring in approximately 35 percent of patients.
   E. Young age, multiple VSDs, and aortic insufficiency are all risk factors for death.

3. Which of the following is a possible consequence associated with waiting for spontaneous closure of an isolated PM VSD?
   A. Endocarditis
   B. Aortic insufficiency
   C. Pulmonary hypertension
   D. Failure to thrive
   E. All of the above

4. Which of the following is incorrect regarding outcomes after surgical repair of VSD?
   A. Operative mortality approaches zero.
   B. Risk of congenital heart block is less than 1 percent.
   C. Risk of valvular injury is less than 1 percent.
   D. Length of stay averages 3 days.
   E. The risk of reoperation for a residual VSD is less than 1 percent.

5. An infant with a loud, high-frequency holosystolic murmur heard best over the left lower sternal border presents with difficulty feeding. The patient is tachypneic and diaphoretic, and CXR reveals an enlarged heart. Which of the following would be an expected finding on echocardiography?
   A. LA dilation
   B. LV dilation
   C. An L–R shunt
   D. RV hypertrophy
   E. All of the above

## ANSWERS

1. **Answer: A.** As stated in the "Diagnostic Imaging" section of the chapter (page 1036), two-dimensional echocardiography with color Doppler flow evaluation is the most widely used imaging modality to diagnose and characterize a VSD, and is sufficient in most cases. A cardiac catheterization would only be indicated when echocardiography and the clinical assessment indicate the possibility of advanced pulmonary vascular disease.
2. **Answer: D.** As discussed in the "Results: Surgical Outcomes" section of the chapter (page 1039), RBBB is a frequently seen rhythm, occurring in approximately 35 percent of patients following VSD repair. Complete heart block is often temporary, secondary to edema in the area or trauma caused by instrument manipulation, and frequency of permanent heart block is approaching zero in most experienced centers. Operative mortality is also approaching 0 percent, and ranges from 0 to 3 percent. As discussed in the "Device Closure" section (page 1039), the Amplatzer Membranous VSD occluder is currently available for patients weighing more than 8 kg. Young age, multiple VSDs, and aortic insufficiency are no longer risk factors for death in this population.
3. **Answer: E.** As discussed in the "Clinical Feature" portion of the chapter (page 1034), patients with isolated VSDs can develop endocarditis, aortic insufficiency from the aortic valve prolapsing into the defect, pulmonary hypertension, the end stage of which is termed Eisenmenger's syndrome, where the PVR becomes greater than the SVR, and a reversal of shunt flow to R–L flow, cyanosis, and eventual RV failure, and patients with larger defects and significant overcirculation can present in the first months of life with slow weight gain, poor feeding, tachypnea, and diaphoresis with activity.
4. **Answer: D.** As discussed in the "Results" section of the chapter (page 1039), **A–C**, and **E** are all expected outcomes of surgical closure of isolated VSDs. Hospital length of stay remains longer than that for device closure, averaging 5 days.
5. **Answer: E.** As discussed in the "Diagnostic Imaging" and "Pathophysiology" portions of the chapter (page 1034), the size of an isolated PM VSD can be assessed by measuring the amount of LA and LV dilation as well as RV hypertrophy. A large L–R shunt would be expected in a patient with a nonrestrictive PM VSD.

# 66 Atrioventricular Septal Defects

*Mazyar Kanani*
*Martin J. Elliott*

**KEY CONCEPTS**

- Epidemiology
  - The prevalence of atrioventricular septal defect (AVSD) is 0.19 per 1000 live births, accounting for 2.9 percent of congenital cardiac malformations. In about 60 percent of these cases, shunting is confined to the atrial level. Tetralogy of Fallot (ToF) is associated in 2 to 10 percent of cases of AVSD, while Down syndrome is seen in 75 percent of infants with complete AVSD.
- Morphology
  - This is variable, according to extent and presence of atrial and ventricular components; however, a common atrioventricular valve (AV) and displacement of the AV node are common features. These defects typically fall into three categories: (A) partial (primum component only); (B) complete atrial septal defect (ASD) and ventricular septal defect (VSD); and (C) transitional (restrictive VSD). Complete AVSD is further subdivided according to the degree of bridging of the superior leaflet. Although Rastelli type A is most common (70 percent of all complete AVSDs), type C is the one most frequently associated with ToF.
- Pathophysiology
  - Pathophysiology varies with the degree of shunting, left ventricular AV valve regurgitation, and pulmonary vascular resistance, as well as with associated anomalies.
- Clinical features
  - Larger left-to-right shunts (complete AVSDs) will present early in infancy with congestive heart failure and pulmonary hypertension, while presentation of partial and transitional AVSDs (in the absence of significant left AV valve regurgitation) will present later and have a similar presentation and natural history as ASDs.
- Diagnosis
  - Chest x-ray (CXR) will disclose an enlarged cardiac silhouette and increased pulmonary markings in large shunts. Echocardiography is diagnostic and defines type of defect, valvar morphology and degree of regurgitation, relative ventricular balance, and associated anomalies. Cardiac catheterization is used in selected cases and shows the characteristic "gooseneck deformity" from subaortic elongation of the left ventricular outflow tract (LVOT).
- Treatment
  - A staged approach [pulmonary artery banding (PAB) followed by complete repair] is relegated to selected cases of complete AVSD. Most cases should be repaired before 6 months of age, whereas partial defects without valvar regurgitation and defects with a restrictive VSD component can be repaired between 2 and 4 years of age.
- Outcomes
  - Operative mortality for complete AVSDs is currently below 5 percent, and incomplete defects have similar morbidity and mortality as ASDs. Long-term prognosis is defined by long-term valvar completenvy and associated lesions.

## INTRODUCTION

Following the first successful repair of atrioventricular septal defects (AVSDs) at the dawn of modern cardiac surgery, significant advances have been made in many aspects of overall patient management. In line with improvements in cardiopulmonary bypass, postoperative care, and refinement of surgical technique together with morphologic understanding,[1] there has been a striking reduction in both postoperative mortality and early morbidity.

Reflecting this increased confidence in the operative management in the last quarter century,[2] there has been an

evolution in the timing of surgery from a staged approach to an era of complete repair in early infancy (Fig. 66-1).[1,3]

## EPIDEMIOLOGY

The prevalence of AVSD has been put at 0.19 per 1000 live births, accounting for 2.9 percent of congenital cardiac malformations. In about 60 percent of these defects, the shunting is confined to the atrial level.

## Anatomic Considerations

The principal malformation that defines the AVSD lies at the atrioventricular (AV) junction. The normal arrangement is considered first.

### THE NORMAL ATRIOVENTRICULAR JUNCTION

The AV junction is defined as the muscular area that surrounds the orifices of the AV valves and marks the point at

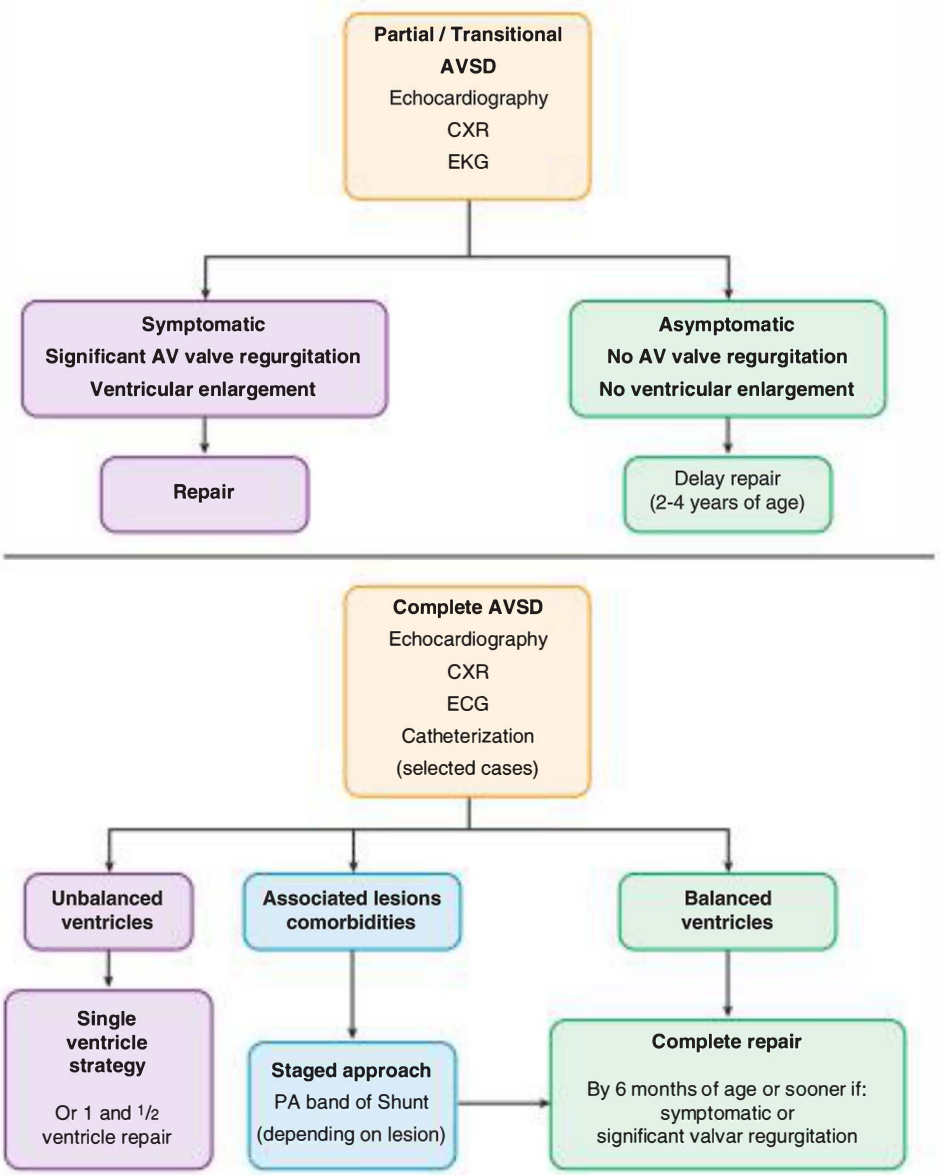

**FIGURE 66-1** Decision-making flowchart for atrioventricular septal defects (AVSDs). AV, atrioventricular; CXR, chest x-ray; ECG, electrocardiogram.

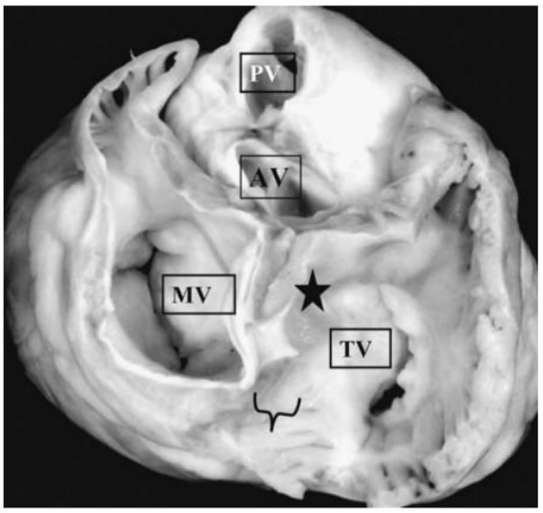

**FIGURE 66-2** The normal heart from above, with the atrial roof removed. There is normal atrioventricular septation, resulting in two separate atrioventricular junctions. The black star indicates the site of the atrioventricular septum that is bisected by the septal leaflet of the tricuspid valve. The black parenthesis is the position of the atrioventricular muscular sandwich. AV, aortic valve; MV, mitral valve; TV, tricuspid valve; PV, pulmonary valve.

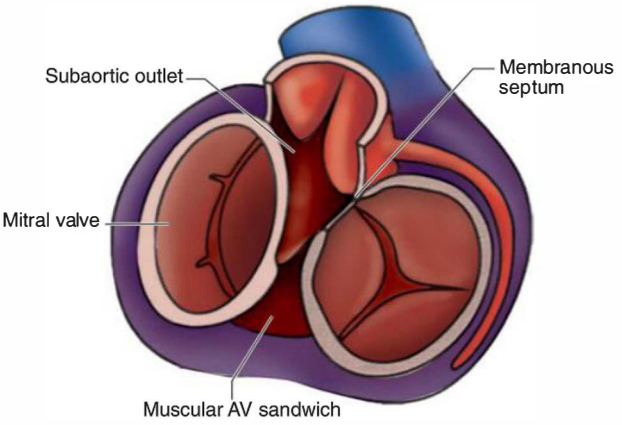

**FIGURE 66-3** A diagrammatic representation of the normally septated heart, showing the relationship between the subaortic outflow tract and the atrioventricular septum and sandwich. Note how the subaortic outflow tract is wedged between the two atrioventricular junctions. AV, atrioventricular.

which the distal margins of the atrial musculature meet the ventricular myocardium. Thus, there are two AV junctions in the normal heart, one supporting the tricuspid and the other the mitral orifices. Although the musculature of the two chambers abuts over the circumference of this junction, they are nevertheless separable apart from the area of the muscular axis of AV conduction—the bundle of His. Wedged in between the two junctions is the subaortic outflow tract, incorporating the indwelling aortic valve. Beyond this anteriorly is the subpulmonary outflow tract, mounted on its free-standing infundibulum (Fig. 66-2).

In considering junctional morphology, it is possible to distinguish the points of attachment of the AV valvar hinges from the points of muscular AV contiguity. At the right AV junction, where the hinges of the tricuspid valve are anchored by muscle throughout, these two areas are essentially the same apart from the short length where the septal leaflet of the valve crosses the membranous septum. In doing so, it divides the membranous septum into AV and interventricular components (Fig. 66-3).

This disparity between the muscular AV junction and the valvar annulus is most clearly seen at the mitral valve, where the fibrous tissue of the aortomitral fibrous continuity supports one-third of the annulus (Fig. 66-4).

## THE ATRIOVENTRICULAR SEPTUM AND "SANDWICH"

Observed in the four-chamber view, the tricuspid annulus is seen to lie at a more apical position than its mitral counterpart. Consequently, in the region immediately caudal and posterior to the area where the septal leaflet traverses the membranous septum, the muscular atrial septum overlaps the crest of the ventricular septum. This area between the offset hinges of the AV valves has previously been called the muscular AV septum,[4] but it is, in fact, none other than an extension of the fibro-adpose tissue of the posteroinferior AV groove (Fig. 66-5). The term *AV septum* should therefore be reserved for the AV component of the fibrous membranous septum. It is the absence of these two components—the fibrous membranous septum and the fibro-adipose muscular "sandwich"—that define hearts with AVSDs more than any other anatomic feature.

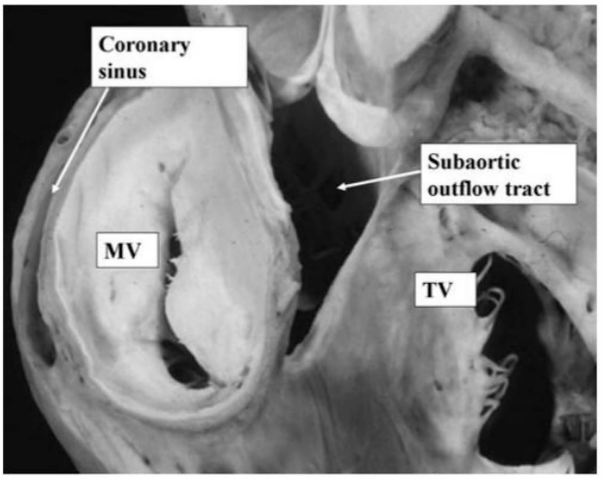

**FIGURE 66-4** A photographic equivalent of Fig. 66-3. The coronary sinus and circumflex branch of the left coronary artery skirt around the parietal left atrioventricular junction. MV, mitral valve; TV, tricuspid valve.

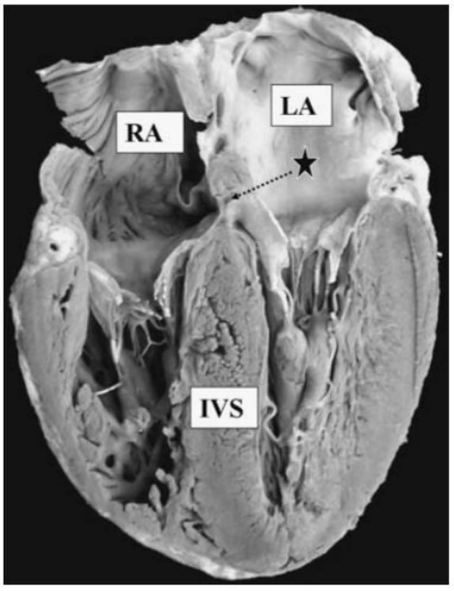

**FIGURE 66-5** A specimen of the normal heart taken in four-chamber section. The normal offsetting of the hinge points of the mitral and tricuspid valves gives rise to the atrioventricular septum (marked by the black star). IVS, interventricular septum; LA, left atrium; RA, right atrium.

## The Common Atrioventricular Junction in Atrioventricular Septal Defects

The common AV junction is the fundamental feature that sets the AVSD apart from the normal heart (Fig. 66-6).

It occurs irrespective of the number of valvar orifices and is seen even in the absence of septal deficiency. All other morphologic features seen in this defect arise as a direct consequence of this singular arrangement of the junctional structures. Other morphologic markers can be considered under the following subheadings:

- Leaflets arrangement
- Septal deficiency
- The ventricular mass
- The subaortic outflow tract
- The conduction axis

### LEAFLET ARRANGEMENT AND THE SUBVALVAR APPARATUS

The oval-shaped common AV junction in AVSDs surrounds an orifice guarded by a valve that usually possesses five leaflets. There is some variability in this arrangement, depending on the permutation of leaflet fusion. Variable fusion may result in separate right and left orifices or may produce any number of accessory orifices, depending on the location and extent of fusion.

Lying across the crest of the ventricular septum, to a variable extent, are the superior and inferior bridging leaflets (SBLs and IBLs). These were previously known as the anterior and posterior bridging leaflets, respectively, and have no counterparts in the normally septated heart (left in Fig. 66-6).

Adjacent to the SBL over the orifice of the right ventricle is the anterosuperior leaflet (ASL), which is analogous to its tricuspid counterpart. Supported by the parietal margins of the common junction on both sides are the right and left mural leaflets. The right mural leaflet lies against

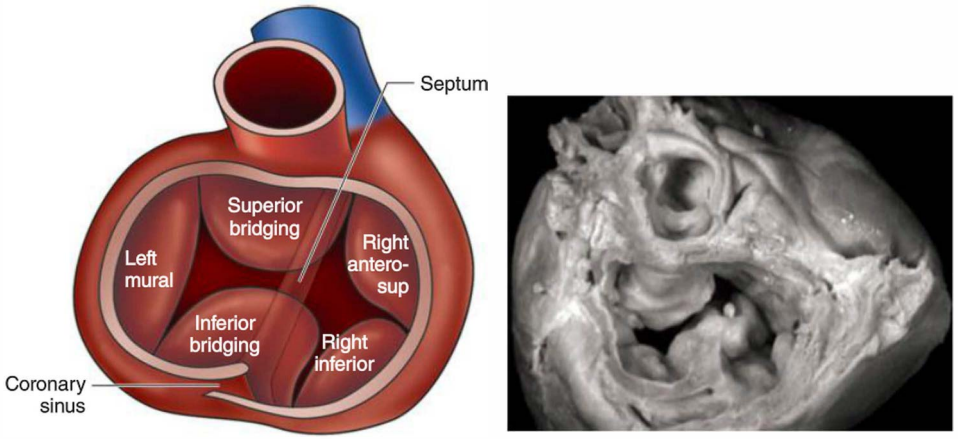

**FIGURE 66-6** Left: Schematic representation of a heart with atrioventricular septal defect and common atrioventricular junction, looking from the atrial aspect. The atrial roof has been removed. There is a common annulus that serves both ventricles, being surrounded by a common atrioventricular valve with five leaflets. The rightward black arrow indicates the position of the zone of apposition between the left sides of the superior and inferior bridging leaflets, which has previously been called a "cleft." Right: A photographic equivalent of the left panel. (Anderson RH, Becker AE. *Controversies in the description of malformed hearts*. London: Imperial College Press, 1997.)

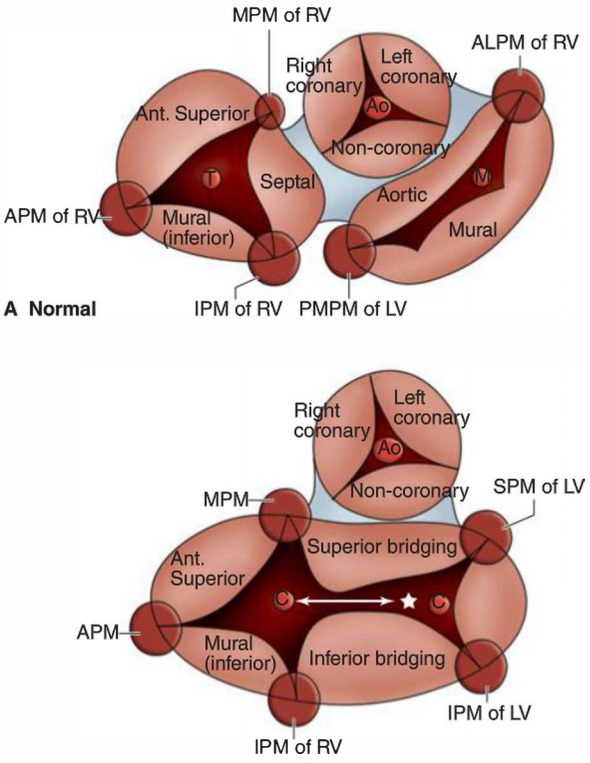

**FIGURE 66-7** Diagrams of the atrioventricular arrangement in the normal heart (**A**) and in the heart with deficient atrioventricular septation (**B**). View is from the ventricles (below). This shows not only the abnormal atrioventricular arrangement in atrioventricular septal defects but also the abnormal leaflet and papillary muscle positioning. ALPM, anterolateral papillary muscle; Ao, aortic orifice; APM, anterior papillary muscle; C, common orifice; IPM, inferior papillary muscle; LV, left ventricle; M, mitral orifice; MPM, medial papillary muscle; PMPM, posteromedial papillary muscle; RV, right ventricle; SPM, superior papillary muscle; T, tricuspid orifice. (From Anderson RH, Baker EJ, et al. *Pediatric Cardiology, vol 1*. Churchill Livingstone, 2001. With permission.)

the ASL and IBL, the left leaflet lies in apposition with the SBL and IBL.

The subvalvar apparatus is similarly abnormal, most importantly in the arrangement of the papillary muscles. The two left-sided papillary muscles normally lie obliquely, assuming anterolateral and posteromedial attitudes. In AVSD, these two muscles are located in the same vertical plane, being positioned superiorly and inferiorly; hence their names (Fig. 66-7).

The superior muscle supports the zone of apposition at the SBL–mural leaflet interface, and the inferior muscle supports the zone of apposition between the IBL and mural leaflets. Unlike the case on the right side, the position of these left-sided muscles is consistent. However, they may be found in clusters, as in the so-called parachute arrangement, where the chords from all leaflets converge onto only one papillary muscle (Fig. 66-8).

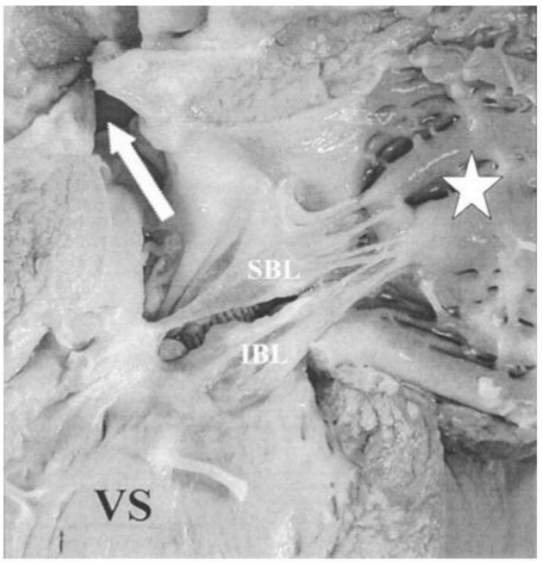

**FIGURE 66-8** A specimen of atrioventricular septal defect looking from the left ventricular aspect. There is a solitary papillary muscle arrangement in which the superior (SBL) and inferior (IBL) bridging leaflets converge to a single papillary muscle (white star). The white arrow indicates the position of the subaortic outflow tract. VS, ventricular septum.

## RASTELLI CLASSIFICATION AND RIGHT VENTRICULAR PAPILLARY MUSCLES

The papillary muscle arrangement of the right side depends on the degree of bridging of the SBL across the VSD. This forms the basis for the Rastelli classification.[2,5]

When there is minimal bridging of the SBL into the left ventricle, or Rastelli class A, the edge of the leaflet is tethered to the crest of the septum (Fig. 66-9A). Here, the ventricular septum is analogous to a papillary muscle, supporting the zone of apposition between the SBL and IBL. In this situation, the ASL of the right AV valve is well developed and morphologically similar to its tricuspid counterpart. At operation, this arrangement gives the appearance of the SBL being divided over the septum (Fig. 66-10A). Subsequent anatomic observation determined that this "division" of the SBL over the septum merely represents the zone of apposition between the SBL and well-formed ASL in the class A defect and that the SBL is undivided over the ventricular septum in all classes of the defect.[6–8]

In the class B defect, the SBL extends even more into the right ventricle, with further reduction in the size of the ASL (Fig. 66-10B). It is usually unattached to the ventricular septum but at its right margin is supported solely by an anomalous right ventricular papillary muscle that arises from the septomarginal trabeculation. In the so-called type C defect (Fig. 66-9B), the SBL extends even further into the right ventricle and floats freely above the ventricular septum, extending from the anterior papillary muscle of the right ventricle to the superior papillary muscle of the left ventricle (Fig. 66-10C). The ASL is necessarily smaller,

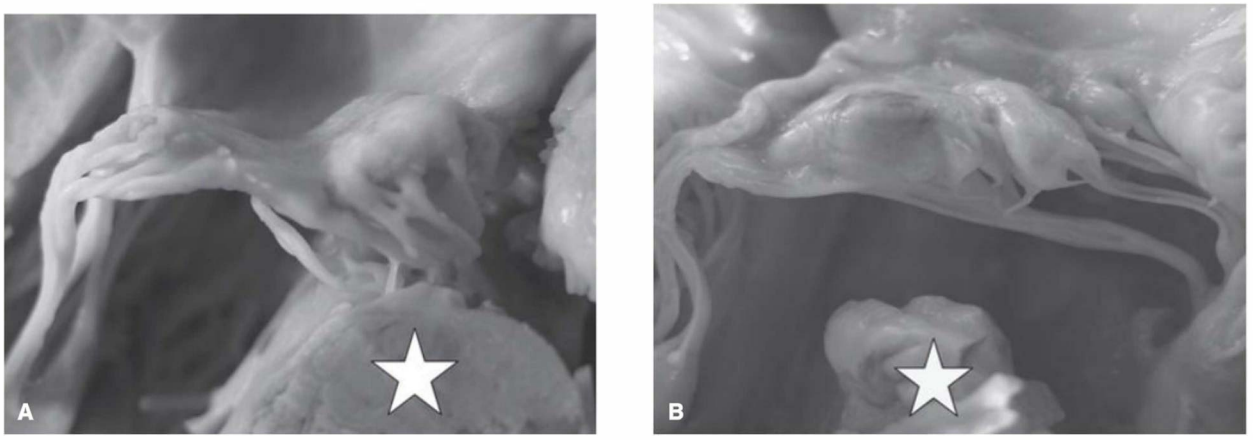

**FIGURE 66-9** Specimens showing variations in the degree of bridging of the superior bridging leaflets, forming the basis of the Rastelli classification. This is a four-chamber orientation; the white stars indicate the position of the ventricular septum. **A.** Rastelli type A arrangement where the SBL is minimally bridged and bound to the crest of the ventricular septum. **B.** The type C arrangement where the superior bridging leaflet bridges the septum to the greatest extent and floats freely. (Rastelli GC, Ongley PA, Kirklin JW, et al. Surgical repair of the complete form of persistent common atrioventricular canal. *J Thorac Cardiovasc Surg* 1968;55:299–308.)

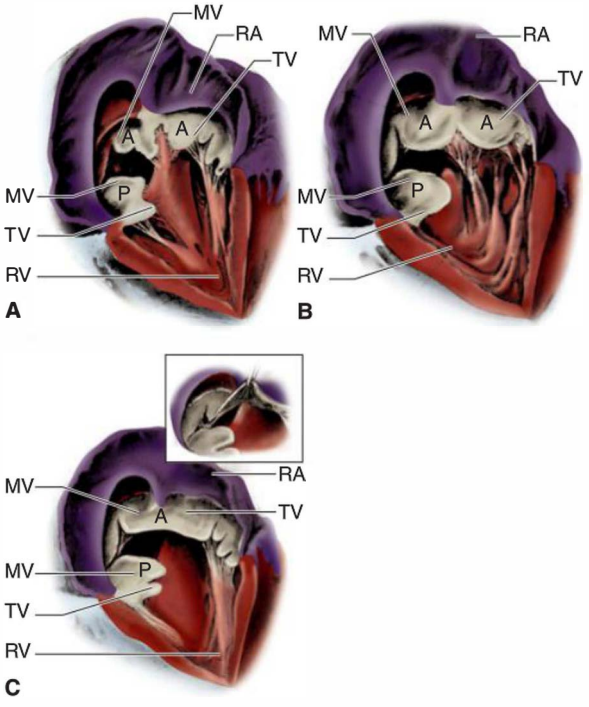

**FIGURE 66-10** Figures taken from Rastelli's original study on the arrangement of the superior bridging leaflet in atrioventricular septal defects (**A–C**). In (**A**), the superior bridging leaflet is minimally bridged, with most of the leaflet confined to the left ventricle and tethered to the septum. In (**B**), the degree of bridging is greater, with its right ventricular attachment being to an anomalous papillary muscle. In (**C**), the leaflet is maximally bridged, being free-floating and attached onto the medial papillary muscle of the right ventricle with the anterosuperior leaflet. (From Rastelli G, Kirklin JW, Titus JL. Anatomic observations on complete form of persistent common atrioventricular canal with special reference to atrioventricular valves. *Mayo Clin Proc* 1966;41:296. With permission.)

accommodating the greater encroachment of the SBL into the right side. Lack of chordal attachments to the septum ensures unhindered access to the aortic valve beneath.[9,10] In the type C defect, there is a high association with tetralogy of Fallot (ToF). The reasons for this are developmental, as rightward displacement of the outlet septum during the development may limit chordal attachment to the septum.[11,12]

Epidemiologically, the type A defect has the greatest prevalence, both in morphologic and clinical series, ranging from 50 to 75 percent of cases.[7,13–15] Variability in the degree of bridging of the SBL may also be seen in cases of AVSD with separate orifices, or the "partial defect," where minimal bridging of the SBL is the most common pattern.

## THE NATURE OF THE ZONE OF APPOSITION: "CLEFT" OR "COMMISSURE?"

The area between left sides of the bridging leaflets has been the subject of much controversy. The principal question is whether it represents a cleft, as in the so-called isolated cleft of the anterior leaflet of the mitral valve,[16] or whether it is the commissure between the leaflets of a left AV valve. A commissure is the functional division between the leaflets of a valve that is supported by a fan-shaped tendinous chord atop a papillary muscle. A cleft is defined as a space or opening made by splitting the anterior leaflet.[17] Given these definitions, this space between the bridging leaflets may be best thought of as septal commissure in a trifoliate leaflet AV valve.

## MORPHOLOGY OF THE ATRIAL AND VENTRICULAR SEPTAL DEFECTS

Although septal deficiency is almost uniformly seen in hearts with this defect, the pattern of blood flow between the chambers is largely determined by the chordal and leaflet anatomy.

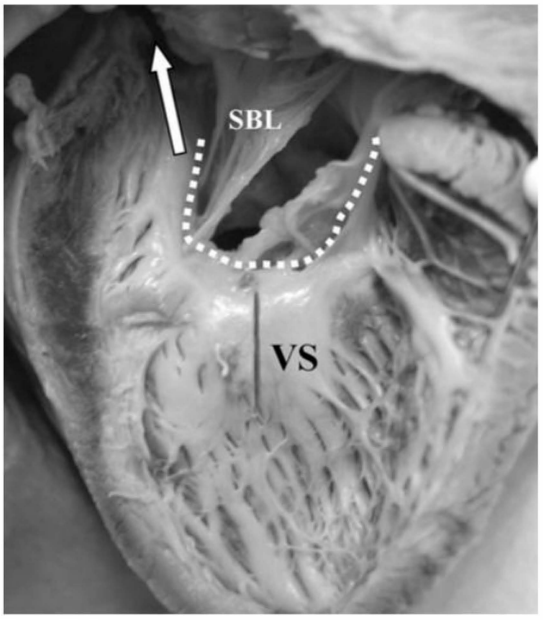

**FIGURE 66-11** A specimen of atrioventricular septal defect looking from the left ventricle in long-axis section. The "scooped out" appearance of the crest of the ventricular septum (VS) has been marked by the white line. The white arrow points to the narrowed subaortic outflow tract. SBL, superior bridging leaflet.

The ventricular septum in AVSD is "scooped," with a gentle curve extending from the crux of the heart to the left ventricular outflow tract (LVOT) (Fig. 66-11). The depth of the scoop and the resulting deficiency are very variable, being more extensive in hearts with common orifices.[7,18,19]

Above the plane of the annulus is the so-called ostium primum defect (Fig. 66-12), which, in some instances, may be obliterated through attachments of the leaflets to its edge, giving rise to obligatory ventricular shunting. If combined with a secundum atrial septal defect (ASD), it may produce a common atrium.

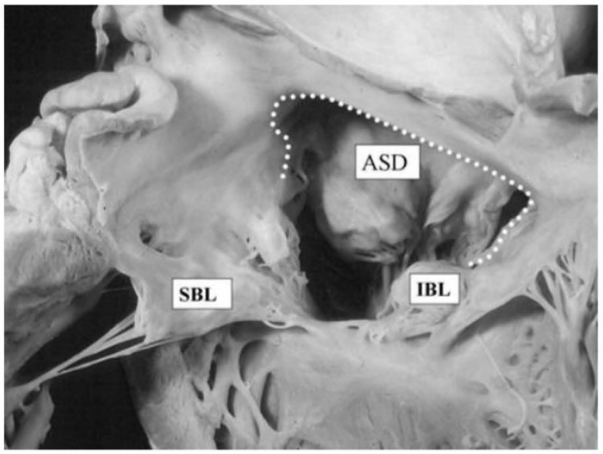

**FIGURE 66-12** Specimen of atrioventricular septal defect looking from the left ventricle, showing the relationships between the atrial septal defect (ASD), ventricular septal defect, and bridging leaflets (SBL and IBL). The white line shows the characteristically crescentic shape to the primum ASD component.

## COMMON VERSUS SEPARATE ORIFICES

There are two varieties of AVSD, depending on the level of intra-cardiac shunting caused by the pattern of leaflet fusion. However, when the leaflets are stripped from both variations, their junctional morphology is identical.[4]

In the defect with separate orifices, also known as the partial AVSD, there is a tongue of leaflet connecting the bridging leaflets over the ventricular septal crest. Therefore, the septal communication beneath the leaflets is obliterated, limiting shunting to the atrial level (Figs. 66-13 and 66-14).

Although this fusion results in separate AV orifices, the connecting tongue is not a continuation of the common annulus across the septum. The morphologic extent of this tongue again shows variability. In some instances, the bridging leaflets are fused with each other, but multiple interchordal spaces beneath the leaflets leave the potential for interventricular shunting (Fig. 66-15).

Hearts exhibiting this latter phenomenon have been termed the "intermediate" or "transitional" AVSD, emphasizing separate orifices in the context of persisting ventricular shunting, as if it were embryologically a transitional form between two extremes. We believe that this term is misleading and loses sight of the fact that the defining feature of hearts with this defect is deficiency of AV septation and not leaflet morphology. As such, septation may be deficient

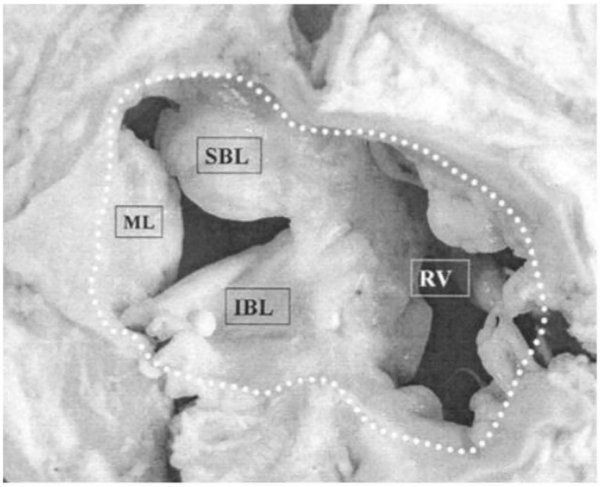

**FIGURE 66-13** A specimen of atrioventricular septal defect with common atrioventricular junction (encircled by the white line) but with separate orifices. The orifices are divided by a connecting tongue of tissue between superior and inferior (SBL and IBL) bridging leaflets, which is also bound to the crest of the ventricular septal defect. This closes off the ventricular communication. ML, mural leaflet of the left atrioventricular valve; RV, right ventricle.

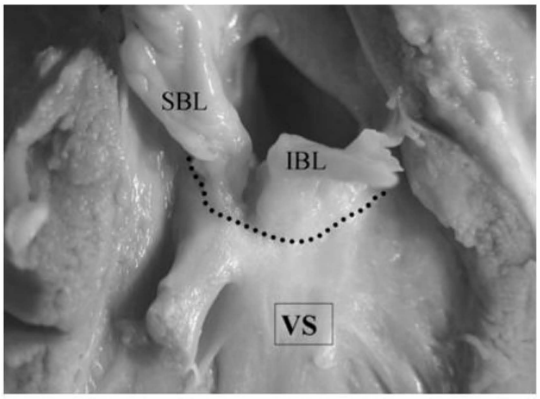

FIGURE 66-14 Specimen of atrioventricular septal defect with separate orifices, looking from the left ventricle. The dotted line shows the position of the crest of the ventricular septum (VS), which is bound to the bridging leaflets (SBL and IBL), thus closing off any ventricular communication. Note how the zone of apposition has a three-dimensional configuration in that it rises up from the septum before continuing forward.

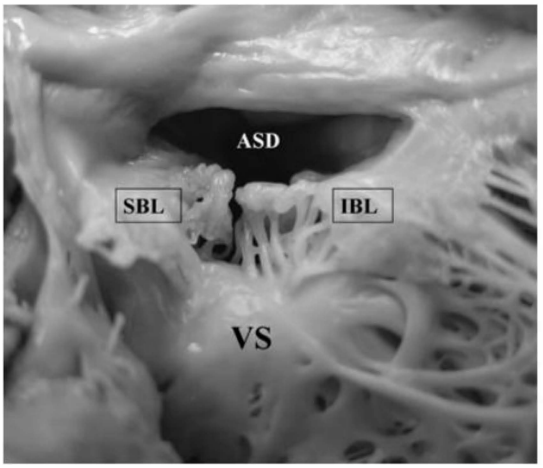

FIGURE 66-15 Specimen of atrioventricular septal defect, looking from the left ventricle. This is a defect with a common orifice, but there are multiple small inter-chordal communications between the ventricles. This has previously been called the "intermediate" or "transitional" defect.

or otherwise, with no intermediate arrangement.[20] Despite the clinically more benign course of the defect with separate orifices, there is a greater prevalence of subaortic obstruction, papillary muscle anomalies, and leaflet dysplasia. Nevertheless, the association with other complex malformations is more common in hearts with a common orifice.

## VENTRICULAR MORPHOLOGY AND BALANCE

In the normal heart, the inlet/outlet ratio is the same (Fig. 66-16, left panel). This is also seen in hearts with perimembranous VSDs and those with an isolated "cleft" in the anterior leaflet of the mitral valve, which have all been previously described as the "forme fruste" of AVSD.[21] In the latter, the outlet length is significantly longer than the inlet and can be appreciated from the "gooseneck" deformity of the subaortic outflow tract (Fig. 66-16, right panel). This has been explained in terms of a shorter inlet[22] or a longer outlet.[23] These ratios are the same in AVSDs with common and separate orifices.

The diameters of the inlets of both ventricles as well as the volumes of the ventricles are the same, or balanced, with the atrial and ventricular septa being in line. In the era of two-staged repair, a reduction in the volume of the right

FIGURE 66-16 Left-hand panel: The comparable inlet and outlet dimensions of the normal heart. Right-hand panel: The inlet dimension of the heart with the atrioventricular septal defect, which is much smaller than the elongated outlet. This accounts for the scooping of the ventricular septum.

ventricle was occasionally observed after pulmonary trunk banding, owing to hypertrophy of the trabecular layer of the myocardium. Aside from this specific situation, left dominance may occur with hypoplasia of the right ventricular and pulmonary arterial components, typically in association with malalignment of the atrial and ventricular septa. This leads to the most extreme case of double-inlet left ventricle with common AV valve.[24] In the case of right dominance, there is usually hypoplasia of the left ventricular and aortic structures, with normal alignment of the atrial and ventricular structures.[25]

## THE SUBAORTIC OUTFLOW TRACT AND SUBAORTIC STENOSIS

Although the subaortic outflow tract is narrower[26] and longer[10] than normal (as seen on angiography), obstruction is surprisingly uncommon (Fig. 66-16, right panel).[27]

The principal source of obstruction derives from the anterior and unwedged position of the subaortic outflow tract, which is a direct product of failure of AV septation. This exaggeration of the subaortic outflow tract is also more pronounced in hearts with the Rastelli type A leaflet morphology, where the SBL is tethered to the crest of the ventricular septum, narrowing the outflow tract even further. This also explains why obstruction is more frequent in the setting of separate orifices.

In addition, the superior papillary muscle or an anomalous portion of it may extend into the subaortic outflow tract, or there may be a prominent anterolateral trabecular muscle bundle. Similarly, there may be accessory tissue tags or chordal attachments from the SBL, further obstructing the path. Such hearts may also become obstructed through mechanisms that affect normally septated hearts, such as fibrous subaortic shelves.

There may also be a further, dynamic component to the potential for obstruction in these hearts. The elongated outflow tract is a muscular tube that constricts during systole, heard as a persisting systolic murmur in the absence of clinically significant left AV valve regurgitation. Obstruction is also well recognized in the postoperative setting, as after left AV valvar replacement, where it accounts in part for the high mortality.

## THE MORPHOLOGY OF THE ATRIOVENTRICULAR CONDUCTION AXIS

The displacement of the conduction axis is the direct result of deficient septation, with absence of the central fibrous body that normally marks the point at which the AV node continues as the AV bundle. There is some variability among hearts with the AVSD, depending on the alignment of the atrial and ventricular septa. Thus, the nodal triangle is displaced posteriorly and inferiorly and lies in the posterior right atrial wall, between the orifice of the coronary sinus and the crux of the heart.

From this position, the bundle of His passes to the crest of the ventricular septum through the crux, which is the first point of contact of the atrial and ventricular musculature. It runs along the crest of the septum under the cover of the IBL, giving off left bundle branches. At about the midpoint of the ventricular septum, it becomes the right bundle branch, which descends to the medial papillary muscle of the right ventricle (Fig. 66-17). Thus, at operation, the greatest danger is at the time of securing the atrial septal patch, when the node is approached at the crux.

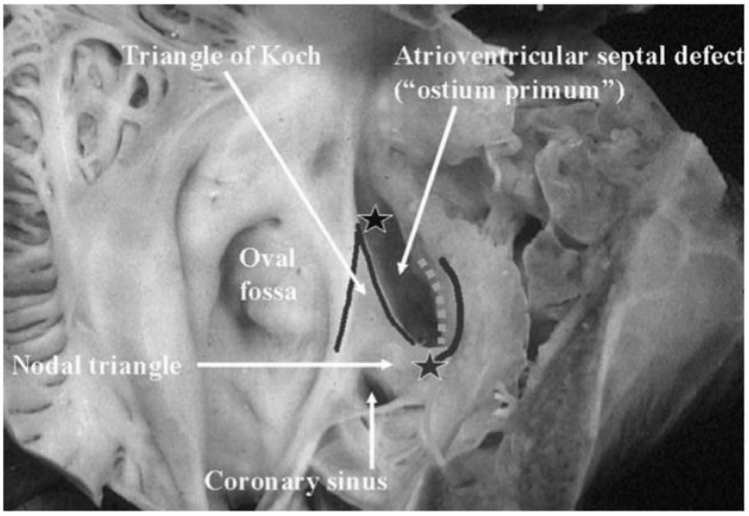

**FIGURE 66-17** The position of the conduction axis in atrioventricular septal defects. The view is from the opened right atrium. The margins of the triangle of Koch are indicated; the superior black star indicates where one would normally expect to find the atrioventricular node (i.e., at the apex of the triangle). However, in this defect, the node has been displaced to the area between the coronary sinus and the crux of the heart (inferior black star). From here, the conduction axis runs along the proximal part of the ventricular crest (dotted line).

## CLINICAL FEATURES

Aside from synchronous congenital malformations, the presentation and clinical findings of patients with AVSD are determined by several factors, among which are the level of shunt and the competence of the left AV valve. Both variables may be the cause of acute and severe presentation.

In the presence of isolated atrial shunting and minimal valvar regurgitation, the presentation is often delayed, akin to a defect in the oval fossa. The findings may be made incidentally, or suspicion may be raised by recurrent chest infections or reduced exercise tolerance.

With a common orifice and shunting at both levels, presentation is usually in infancy, with cardiac failure. The child is diaphoretic and short of breath on feeding and fails to thrive. These problems are compounded if there is severe left AV valvar regurgitation. On examination, the child is undernourished, breathless, and tachycardic, with hepatomegaly. There is a hyperactive precordium with a systolic thrill and a pansystolic murmur of variable grade.

## DIAGNOSIS

On CXR, there is variable cardiomegaly, reflected in the cardiothoracic ratio. If the valve is severely regurgitant, the heart is enlarged in the absence of significant shunting. The pulmonary trunk is similarly engorged, with prominence of the pulmonary vascular markings. With persisting pulmonary hypertension, the heart is not as greatly enlarged, but the pulmonary trunk is prominent, with "pruning" of the markings of the vascular tree.

Although superseded by echocardiography,[43] cardiac catheterization is presently reserved for those patients with complex defects where the intracardiac shunt must be calculated and when operability must be determined in the face of raised pulmonary vascular resistance. Information provided includes the anatomy, degree of AV valvar regurgitation, and quantification of the shunt. The diagnostic hallmark is the "gooseneck" appearance of the LVOT in the anteroposterior projection (Fig. 66-18).[22]

### Echocardiography

This has superseded all other modalities as the pre-,[44,45] intra-,[46–48] and postoperative[49] investigation of choice. Doppler interrogation reveals intracardiac shunting, AV valve function, and patency of the LVOT while also determining the pulmonary vascular pressures. It has also, in recent years, been applied for prenatal diagnosis.[50]

There are a number of anatomic hallmarks. On the four-chamber view, the common AV junction causes loss of the normal offsetting of the AV valves (Fig. 66-19, left). Furthermore, the relationship of the leaflets to the crest of the ventricular septum can be appreciated on this view (Fig. 66-19, right). On the long-axis section, the "gooseneck" deformity of the LVOT is also visible; on the short-axis view, the common AV valve annulus is seen (Fig. 66-20). With separate right and left orifices, the trifoliate left AV valve is seen on short-axis with an exclusive orientation of the leaflets.

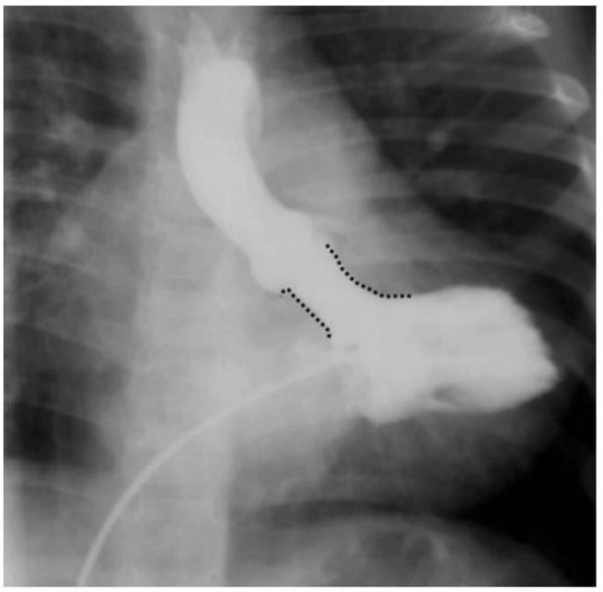

**FIGURE 66-18** An anteroposterior angiocardiographic projection of the heart with an atrioventricular septal defect and common atrioventricular junction. The left ventricular outflow tract is elongated as a "gooseneck" (outlined), since it lies in an unwedged position anterior to the common atrioventricular junction.

The size of the VSD is variable, often being larger beneath the SBL. There will also be variable chordal tethering to its crest. This septal tethering is greatest beneath the IBL, as seen on the four-chamber section. It is therefore important to look for subtle ventricular shunting in the inter-chordal spaces with color-flow Doppler interrogation. Thus, because of this chordal obstruction, the degree of inter-ventricular shunting is greatest with a free-floating SBL.

## NATURAL HISTORY

Without surgical intervention, the natural course will be determined by a number of factors, principally the level and degree of the intracardiac shunting, the pulmonary vascular resistance, and the competence of the left AV valve. It also follows that these factors will affect the timing of surgical intervention and subsequent outcome.

In the absence of significant left AV valvar regurgitation, the natural history of defects with separate orifices will be similar to that of a defect in the oval fossa. Therefore, up to 15 percent of these patients will develop pulmonary hypertension by adulthood, and symptomatic deterioration may coincide with the development of atrial fibrillation.[51]

As predicted, the clinical course of the defect with a common orifice is more pernicious, with early deterioration

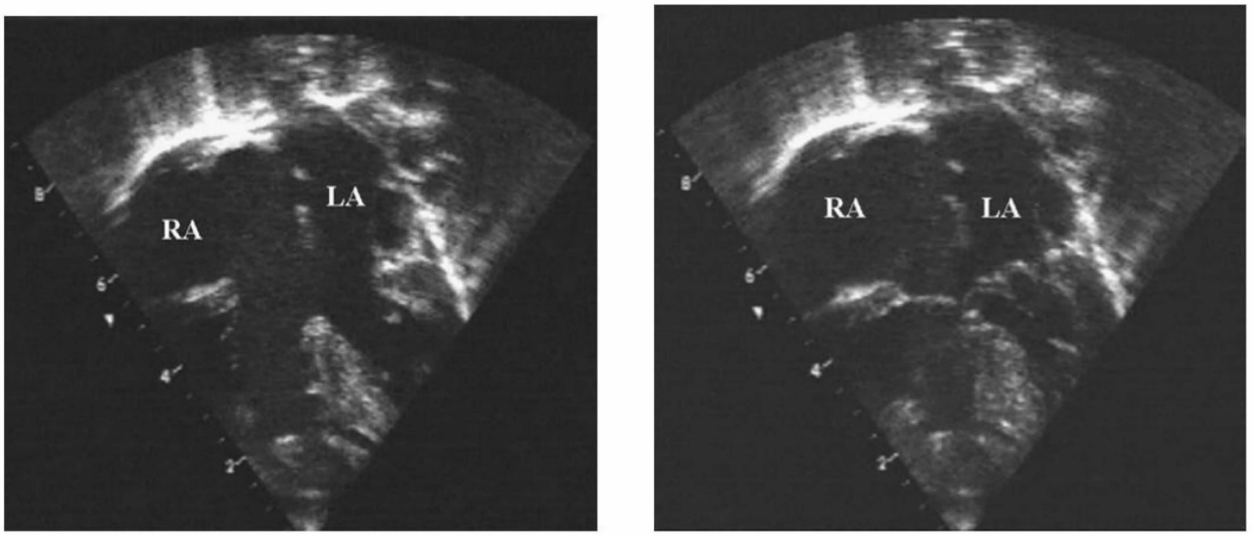

**FIGURE 66-19** Two-dimensional transthoracic echocardiogram of the heart with atrioventricular septal defect in four-chamber view, taken in diastole (left panel) and systole (right panel). Note the tethering of the bridging leaflets to the crest of ventricular septum in systole, as well as the lack of off-setting of the AV valve. LA, left atrium; RA, right atrium.

from pulmonary hypertension, cardiac failure or respiratory infections. It is estimated that up to 80 percent of patients who do not undergo correction die by the age of 2 years.[52]

## SURGICAL MANAGEMENT

Two pivotal events have transformed the surgical repair of AVSDs. The first and most conspicuous was the introduction of cardiopulmonary bypass; this could not have been successful without the other crucial event: mapping of the conduction tissue, by Lev.[53] Up to then, repair was hazardous, even in the best of hands. In 1954, Kirklin and associates successfully closed a defect with separate orifices using the atrial well of Gross. By 1955, defects were being closed under cardiopulmonary bypass using the DeBakey roller pump and wire-mesh screen oxygenator.[54]

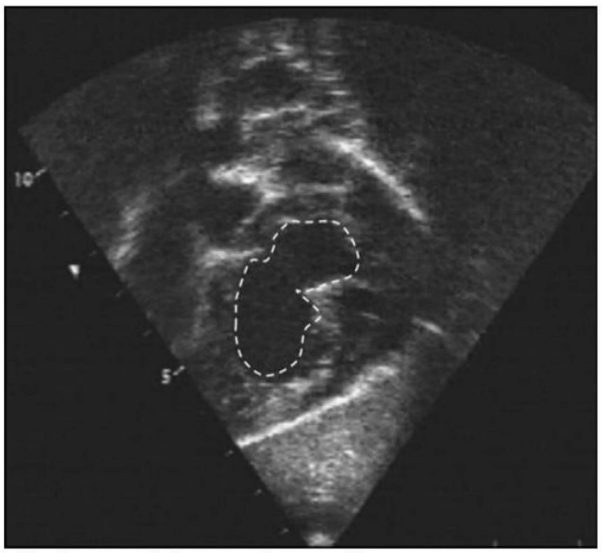

**FIGURE 66-20** The same heart as in Figure 66-18 in short-axis orientation showing the characteristic shape of the common atrioventricular junction (outlined).

Lillehei and associates performed the first repair of the so-called complete defect in 1954 by suturing the inferior rim of the atrial septum directly to the crest of the ventricular septum. Unsurprisingly, this often caused complete heart block, thus worsening valvar regurgitation and subaortic stenosis. It led to the introduction, in 1962,[55] of the single-patch technique as a way of overcoming early mortality. Over the past 4 decades, results have continued to improve, owing to better surgical techniques, more refined bypass circuits, and tailored postoperative care together with the use of permanent pacemaker systems.

### One- Versus Two-Stage Repair

In the modern era, attention has shifted from a two-stage repair [involving initial pulmonary artery (PA) banding - see chapter 62] to complete primary repair in infancy. Two factors have brought about this change of strategy. First, there is greater understanding of the morphology, as mentioned. This also advanced the appreciation of the abnormal pathophysiology. Thus it was recognized quickly that banding was often ineffective in alleviating heart failure in the presence of severe left AV valvar incompetence.[56] Overall, the mortality associated with banding approached 50 percent.[56–58] Within face of these concerns, complete repair before the age

of 2 years was called for, bringing the timing of intervention into line with that of simple VSDs. By the late 1970s, early primary repair had become the norm.[59,60]

Today, initial banding is reserved for complex defects, such as multiple VSDs, concurrent sepsis, and in some cases of the so-called unbalanced AVSDs, when it is possible to delay biventricular repair to a later date.[61,62]

## Timing of Repair

Hand in hand with primary repair is a decline in the age at operation. Independent of age, the timing will also be determined by other factors, such as the pulmonary vascular resistance, size of the intracardiac shunt and the degree of left AV valvar regurgitation. Aside from the protective effects on the pulmonary circulation,[28] earlier age at repair may confer benefits to the competence of the left AV valve. Chronic valvar regurgitation and volume overload lead to progressive annular dilatation with worsening leaflet coaptation. This is accompanied by leaflet dysplasia at the zone of apposition, further affecting the coapting mechanism. This cycle of "regurgitation begets regurgitation" is broken early by timely intervention. As a counterargument to early repair is the possibility of tearing of the sutures at the zone of apposition in patients weighing less than 5 kg at operation.[63]

Until 1973, only six patients below the age of 6 years had undergone attempts to repair defects with a common orifice, with only two survivors. By the late 1990s, the timing had reached the contemporary practice of repair within the first 6 months of life.

With AVSD with separate orifices in the absence of symptoms and left AV valvar regurgitation, repair is performed electively at 3 to 4 years of age, in line with defects in the oval fossa. Surgery is suitably earlier in those presenting with symptoms.

## Principles of Repair

The goals of repair are ventricular septation where there is a common orifice, atrial septation together with repair of the AV valves while avoiding heart block, residual defects, and obstruction of the LVOT. Competence of the left AV valve must be achieved while preventing stenosis of its orifice.

Several techniques have been used to achieve these ends, essentially being variations on the single- or double-patch themes. However, unusual leaflet morphologies add to the complexity.

### APPROACH TO THE HEART, CANNULATION, AND CARDIOPLEGIC ARREST

The technique currently used at Great Ormond Street Hospital is described below. Median sternotomy is used in all cases. After thymectomy, the pericardiotomy is veered slightly to the left of the midline and the pericardium left attached on its right border. The aorta, arterial duct, and caval veins are then mobilized with diathermy. A silk ligature is passed around the arterial duct once this has been identified. In small infants, it may be very delicate, so it is often not ligated until cardiopulmonary bypass is established. This is followed by insertion of 5-0 polypropylene purse-string sutures in the aorta, superior caval vein, and right atrial appendage.

For aortic cannulation, a flexible DLP cannula is used (Medtronic, Grand Rapids, MI). A temporary angled metal Great Ormond Street venous cannula (GU Company, Tricomed, Addiscombe, Surrey, UK) is placed through the right atrial appendage, allowing rapid establishment of cardiopulmonary bypass, followed by ligation of the arterial duct. The superior caval vein is cannulated with a second angled metal cannula appropriate for the caliber of the vessel. Following cannulation of the superior caval vein, the metal cannula is removed from the right atrial appendage and replaced with a vent. The inferior caval vein is then dissected to the first hepatic vein. Once this has been exposed, a 5-0 polypropylene purse-string suture is placed, followed by cannulation. Nylon tape is then used to snare both caval veins.

The patient is cooled to 25°C in the case of the common orifice defect and above 32°C in the defect with separate orifices. The aorta is then cross-clamped and cardioplegia is administered. The right atrium is opened with an incision running parallel to the right AV groove. The left atrium may be vented through either the oval fossa or the right superior pulmonary vein. The latter structure may eventually be used for insertion of a left atrial pressure monitoring line.

### THE DOUBLE-PATCH TECHNIQUE

Irrespective of the patch technique, there are a number of initial stages to be performed prior to septation:

1. **Inspection**: This commences with the position and size of the coronary sinus, proceeding to assessment of the size of the atrial component and patency of the oval fossa. The leaflets of the common AV valve are assessed for accessory orifices. The leaflets are elevated to reveal the ventricular component beneath as well as the state of the subvalvar apparatus. The ventricular septum is also inspected for additional septal defects.
2. **Definition of the "kissing point"** (Fig. 66-21): Bringing together the bridging leaflets over the left side of the ventricular septum allows their natural line of closure to be determined, forming a vital part of valvar repair. Once determined, the kissing point is marked with a 6-0 polypropylene suture.
3. **Closure of the ventricular component** (Fig. 66-22). This is closed with a 0.4-mm polytetrafluoroethylene (Gore-Tex) patch, although other materials may be used. The dimensions of the defect are assessed using silk ties, which are used to fashion out a crescentic patch of Gore-Tex. This is sutured to the right side of the ventricular septum with a continuous 5-0 polypropylene suture. To facilitate

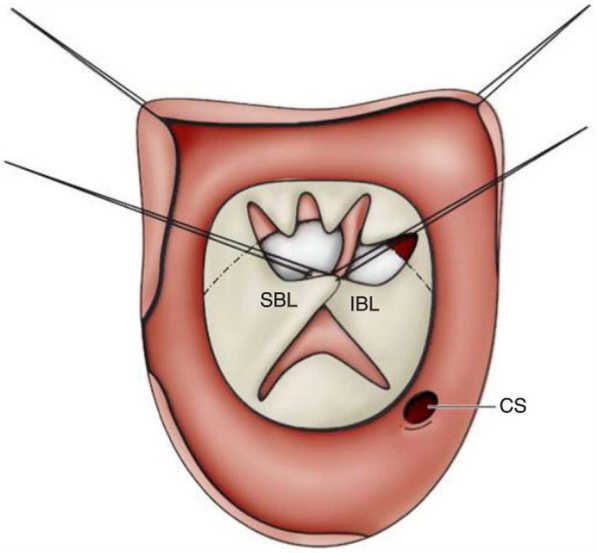

**FIGURE 66-21** Drawing of the surgical repair of the atrioventricular septal defect with a common orifice, using the two-patch technique. The view is in surgical orientation, through the right atrium. The "kissing point" of the superior and inferior bridging leaflets are initially brought together and marked with polypropylene marking sutures. (Modified from Elliott MJ, Jacobs JP. Atrioventricular canal defects. In: Kaiswer LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

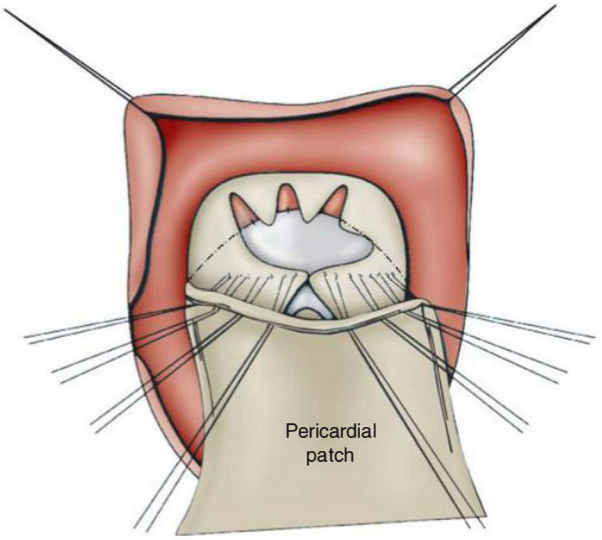

**FIGURE 66-23** Next, the patch of autologous pericardium is secured to the ventricular septal patch and bridging leaflets by a line of double-armed interrupted sutures, released from its pericardial attachment, and slid down into place. (Modified from Elliott MJ, Jacobs JP. Atrioventricular canal defects. In: Kaiswer LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

this, some small secondary chords may have to be sacrificed. The suture line is commenced close to the annulus through the IBL, where it is well away from the position of the bundle. The first one or two bites are placed with the patch outside the heart. Once fixed, the prosthetic patch is slid into position beneath the bridging leaflets. The suture line then runs deeply along the right side of the septum toward the SBL, weaving through the chords. Finally, it is brought through the SBL, avoiding the aortic valve. A rubber-shod clamp is placed on the free end of the suture.

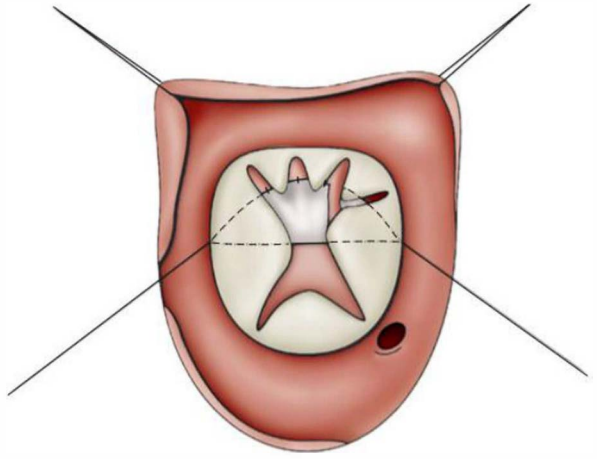

**FIGURE 66-22** The crescentic patch of 0.4-mm Gore-Tex is sutured to the crest of the ventricular septum, keeping the suture line to the right side of the ventricular septum in order to avoid injury to the conduction tissue. (Modified from Elliott MJ, Jacobs JP. Atrioventricular canal defects. In: Kaiswer LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

4. **Atrial septation** (Fig. 66-23). The atria are septated while separating the common valve into right and left components. Interrupted 6-0 polypropylene sutures, double-armed, are placed along the horizontal margin of the ventricular patch. The sutures are then passed through the bridging leaflets and through the edge of the prepared autologous pericardium. This suture line runs from the inferior to the superior margin of the annulus. Thus, the line passes in an axis that bisects the common junction, its axis defined by the kissing point of the bridging leaflets. The sutures are then tied after the right side of the pericardium has been detached.
5. **Closure of the zone of apposition**. To follow, the bridging leaflets are sandwiched between the two septal patches. Once this has been performed, the pericardial patch is swung over, exposing the newly created left AV orifice. The zone of apposition between the bridging leaflets is closed with one or two interrupted 6-0 polypropylene sutures supported with a small patch of pericardium (Fig. 66-24). The left AV valve is tested with a bulb syringe of cold saline. A commisuroplasty or annuloplasty may improve competence if there is persisting central regurgitation. A Hegar dilator ensures that the repaired valve is not stenotic.

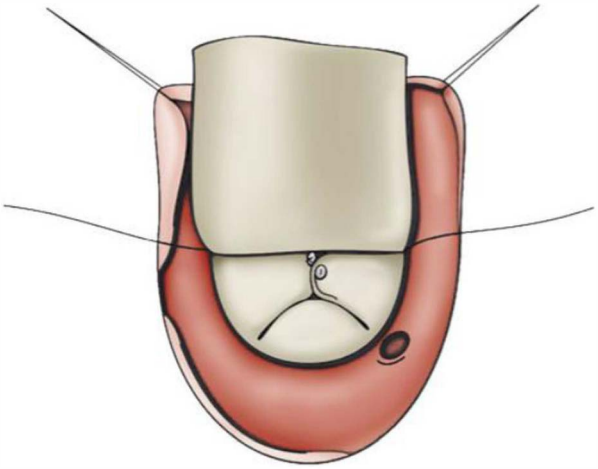

**FIGURE 66-24** Once in place, the pericardial patch is elevated to allow the zone of apposition to be closed with pericardially pledgetted polypropylene sutures. (Modified from Elliott MJ, Jacobs JP. Atrioventricular canal defects. In: Kaiswer LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

6. The atrial patch is sutured in place with continuous 5-0 polypropylene, avoiding the position of the AV node. The coronary sinus may be left on either side of the patch, but it is committed to the right side in the face of a left superior caval vein. The first suture of the atrial patch is the free end of the ventricular patch suture that was held in a rubber-shod clamp. If the coronary sinus is committed to the right side, the suture line passes around the coronary sinus, close to the eustachian valve of the inferior caval vein, well inferior to the bundle. If the sinus is on the left side, the suture line binds the patch to the left AV valve at the annular margin (Fig. 66-25).

Once the heart is septated, the heart is de-aired and the aortic cross-clamp is removed. Once rewarming is complete, cardiopulmonary bypass is weaned.

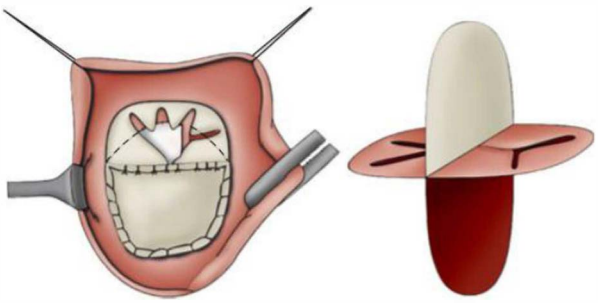

**FIGURE 66-25** The repair is complete when the free edge of the pericardial patch is secured to the leading edge of the atrial septum. In this case, the coronary sinus is committed to the left ventricle. The right-hand panel shows the anterosuperior view of the newly septated heart. (Modified from Elliott MJ, Jacobs JP. Atrioventricular canal defects. In: Kaiswer LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007. With permission.)

## THE SINGLE-PATCH TECHNIQUE

This method has changed little since 1962. In the modern era, a pericardial patch is almost always used to close both ASDs and VSDs. The bridging leaflets are divided in order to accommodate the solitary patch.[64] Given that both bridging leaflets must be anchored to the patch, the suture line is more extensive than with the two-patch technique.

## THE TECHNIQUES COMPARED

Extensive comparisons have been made of the benefits of one technique over the other. The single-patch technique has been hailed as simpler (and therefore superior), with greater exposure of the VSD and subvalvar apparatus[65] and even associated with reduced duration of postoperative ventilator support.[34] However, it has also been criticized for its theoretical effects on valvar competence,[66] since relatively more of the left AV valve is taken up in the suture line, with the risk of dehiscence.[28,67,68] This has caused some to change their technique over time.[28] Furthermore, it has been argued that closure of the zone of apposition may be inappropriate with this technique, since division of the leaflets and resuspension of the valve results in restricted mobility of the SBL.[69] Nevertheless, results are comparable and depend on operator preference.

## THE MODIFIED SINGLE-PATCH TECHNIQUE

This was initially introduced by Rastelli but refined and expanded by Wilcox[70] and the Australian group.[71] Here, the AV valves are sutured directly to the crest of the ventricular septum, simultaneously incorporating a single patch that is anchored to the leaflets and closing the (ASD). Thus, in essence, the defect with the common orifice is converted to one with separate orifices where the valves are bound to the septal crest.

Several centers have adopted it as their standard[76] where it is defended on anatomic principles. Although it is known that the septal scoop is greatest in the setting of a common orifice, this is not the case in 30 to 40 percent of hearts.[19] It follows, therefore, that direct suturing of the leaflets to the septal crest (if the VSD scoop is not of course excessive) is entirely feasible without distortion of the left ventricular outflow or disruption of the natural line of valvar closure. Another argument for this simplified technique is that ventricular septal patches have been getting progressively smaller with time, so that discarding them altogether is the next natural step in the evolution of surgery for AVSD.

## ACHIEVING AND MAINTAINING LEAFLET ATRIOVENTRICULAR VALVAR COMPETENCE

Achievement of a competent left AV valve involves more than closure of the zone of apposition between the bridging leaflets.

Correct sizing of the ventricular patch is the first method, since it supports the annulus. If the patch is too long, the bridging leaflets will fail to coapt. If it is too short, valvar stenosis will ensue.[77]

Despite the observation that the zone of apposition is the most incompetent part of the left AV valve, its closure has not always been advocated. Carpentier[78] has stated that the trifoliate left AV valve is well adapted to its role. Thus, closure of the zone of apposition would reduce valvar opening during diastole and produce undue tension on the suture line.[69,79] Therefore, an integrated trileaflet repair was advocated, based on the native trifoliate appearance.

Nevertheless, others have argued that the zone does not have the characteristic features and support of commissures in the normal AV valves and should therefore be closed.[61]

Some authors have taken the middle ground, repairing only those valves that were incompetent on saline testing[14,80] and not those in the very young because of the risk of tearing the leaflets.[63]

There are certain situations where it is agreed that the zone should be left open to prevent valvar stenosis. One well-recognized situation is that of the solitary left ventricular papillary muscle, or so-called parachute valve. Here, the bridging leaflets have a common papillary muscle insertion, leading to a slit-like valvar orifice. There is a similar risk of stenosis when one is faced with a small left ventricle or in the presence of an accessory left ventricular orifice.[19,81–83] One way of standardizing the decision as to whether or not to close the zone of apposition has called for assessing the size of the left mural leaflet, the angular size of which has been found to be inversely related to the size of the IBL.[19] An angular size of greater than 45 degrees has been used as the determinant of closure.[84]

Commissuroplasty or annuloplasty may also be used to improve competence, either at the commissures or centrally. They have also been used as a "belt and braces" measure in older patients with the defect of separate orifices where there has been chronic annular dilatation.[61,62]

## Atrioventricular Septal Defect with Tetralogy of Fallot

Tetralogy of Fallot is associated with 2.7 to 10 percent of cases of AVSD. Conversely, AVSD is seen in only 1 to 2 percent of cases of ToF.[85] There are a number of issues that must be considered during repair. First is the issue of whether complete primary repair can be carried out at an early stage. Even in the contemporary era, the majority of patients are palliated initially with a systemic-to-pulmonary shunt, the decision being guided by the severity of preoperative cyanosis. However, some have advocated early primary repair, stating that this aggressive strategy negates the risks associated with shunting.[86] However, there is no consensus, so that the age at complete repair varies greatly among different centers, ranging from a few months to several years.

Another issue is the finding that in the combined defect, the SBL is free-floating.[12] This has affected the decision as to whether to use a single- or double-patch strategy.[86,87] Some advocate two-patch repair on the understanding that it reduces the incidence of LVOT obstruction.[88–91] This is because the ventricular septal patch can be easily fashioned into a teardrop shape to accommodate the contour of the deviated outlet septum. Given this and other unresolved issues, such as the impact of both AV and pulmonary valvar dysfunction, mortality is still highly variable, ranging from less than 5 percent[85,88] to 33 percent.[89]

# RESULTS OF REPAIR AND COMPLICATIONS

## Mortality

There has been a striking reduction in the early and late postoperative mortality since the dawn of repair. In the current era, in the situation of a common orifice with no associated defects, balanced ventricles, and in the absence of vascular pulmonary hypertension, the mortality in most reporting centers is less than 5 percent and usually in the order of 1.5 to 3 percent. This is in contrast to 3 decades ago, when mortality was anywhere from 30 to 60 percent. The analysis of these results has also enabled some risk factors to be identified for mortality, some with more consistency than others (Table 66-1).

## Postoperative Complications

Aside from the general risks associated with anesthesia and cardiopulmonary bypass, the following complications are observed with this defect.

**TABLE 66-1: Predictors of Postoperative Mortality in Patients with Complete Atrioventricular Septal Defects**

| Risk Factors for Postoperative | References |
|---|---|
| Preoperative pulmonary hypertension | 35, 88, 89 |
| Preoperative LAVV regurgitation, leaflet dysplasia or dysplastic LAVV | 31, 88, 90–92 |
| Unbalanced ventricles | 15, 90, 93 |
| Double-orifice LAVV or solitary papillary muscle | 28, 31, 64 |
| Additional ventricular septal defects | 31 |
| Early era of operation | 34, 64, 92 |
| Postoperative pulmonary hypertensive crisis | 28 |
| Postoperative LAVV regurgitation | 28, 64 |
| Young age at repair | 29 (before 1976), 92 (before 1990), 89 |
| Low body weight | 35, 89, 90 |
| Long aortic cross-clamp time | 35, 89 |
| Requirement for preoperative inotropic support | 88 |
| Requirement for preoperative ventilatory support | 94 |
| Nonclosure of the zone of apposition | 89, 95 |
| Coarctation of the aorta | 92 |

LAVV, left atrioventricular valve.

### PULMONARY HYPERTENSIVE CRISIS

The incidence of this complication has fallen with the advent of reduced age at primary repair, but the risk is still significant in older patients, those with preoperative pulmonary hypertension, and those with moderate-to-severe preoperative left AV valvar regurgitation. In these cases, concurrent use of both pulmonary artery and left atrial pressure lines is invaluable in the first 24 to 36 h after surgery. Scenarios that may trigger a crisis—such as acidosis, hypoxia, or agitation—must be avoided (see Chapter 60). Thus, older patients are intubated and sedated for longer periods in the postoperative phase. α-Adrenergic blockers, such as phenoxybenzamine, may be used prophylactically, preoperatively, and during rewarming. During a crisis, the patient is sedated and hyperventilated, so that the $Paco_2$ falls to below 3.5 kPa. Paralysis may also be instituted, together with intravenous nitroprusside or inhaled nitric oxide.

### HEART BLOCK

In the modern era, when the position of the conduction bundle has been defined, the prevalence of this complication has fallen to 1 to 2 percent. The key is careful suture placement in the region of the coronary sinus, remembering that the conduction system runs the same course irrespective of the number of orifices. Following operation, in the case of temporary heart block that may occur in the context of regional conduction tissue edema, the patient should leave the operating room with temporary pacing wires.

### LEFT ATRIOVENTRICULAR VALVAR REGURGITATION

This may be considered as an early or late postoperative complication that might require reoperation. It may be recognized as a persistently elevated left atrial pressure and failure to wean from intubation, being confirmed by echocardiography. Early reoperation for regurgitation has been consistently reported in 5 to 7 percent of patients, with little change over the years.[15,64,100] It may be associated with technical factors, such as closing the zone of apposition; but in some series the use of closure of the zone with annuloplasty did not affect the overall incidence of regurgitation.[64] Some have also suggested that the severity of preoperative regurgitation correlated with the degree of postoperative insufficiency,[28] whereas others have found no relationship between the two.[32]

Late regurgitation, measured as freedom from reoperation, ranging from about 80 to 90 percent at 10 years.[93,96,99] The incidence of this complication has similarly shown little change over the years, being more common in such situations as in the setting of a double-orifice valve, nonclosure of the zone of apposition, non-Down patients,[94,100] and a dysplastic left AV valve. Recently, division of the SBL at operation during patch placement has also been associated with an increased incidence of long-term left AV valve regurgitation.[101] Table 66-2 summarizes the risk factors identified in the literature for early and late AV valvar regurgitation.

**TABLE 66-2: Predictors of Postoperative Left Atrioventricular Valve (LAVV) Regurgitation in Patients with Complete Atrioventricular Septal Defects**

| Risk Factors for Postoperative Left Atrioventricular Valvar Regurgitation | References |
|---|---|
| Preoperative LAVVR | 96–98 |
| Nonclosure of the zone of apposition | 61, 90, 96, 99 |
| Non-Down AVSD | 38, 90 |
| Leaflet dysplasia | 100 |
| Double-orifice left atrioventricular valve | 96, 97, 99, 100 |
| Solitary papillary muscle arrangement | 97 |
| Older age at operation | 38 |
| Division of the bridging leaflets at operation | 97 |
| Earlier era of operation | 95 |
| Unbalanced | 90, 100 |
| atrioventricular septal defects | — |
| Preoperative pulmonary hypertension | 100 |

## THE FUTURE

Although, in terms of both mortality and morbidity, surgical repair of this defect has come a very long way, the main issue for the future involves long-term durability of the repair and quality of life. With this in mind, the stagnant incidence of long-term left AV valvar deterioration will be tackled successfully only by thoroughly understanding the form and function of the valve, with all of its morphologic nuances.

## ATRIOVENTRICULAR SEPTAL DEFECTS BOARD REVIEW QUESTIONS (CHAPTER 66)

1. Which is correct regarding anatomy and morphology of AVSD?
   A. The hinges of the mitral valve are anchored by muscle throughout the right AV junction.
   B. The disparity between the muscular AV junction and the valvar annulus is most clearly seen at the tricuspid valve.
   C. The mitral annulus lies at a more apical position than the tricuspid annulus.

D. The AV septum refers to the AV component of the fibrous membranous septum.
E. The common AV junction is not seen in the absence of septal deficiency.

2. Which is true regarding leaflet arrangement and subvalvar apparatus in AVSD?
   A. The SBL is analogous to the tricuspid anterior leaflet.
   B. The IBL is analogous to the mitral anterior leaflet.
   C. The left-sided papillary muscles are located in the same vertical plane.
   D. The degree of bridging of the IBL across the VSD is the basis of the Rastelli classification.
   E. The Rastelli type C defect has the greatest prevalence.

3. Which is correct regarding morphology of AVSD?
   A. The pattern of blood flow between the chambers is largely determined by chordal and leaflet anatomy.
   B. The degree of ventricular septal "scooping" is less extensive in hearts with a common orifice.
   C. The connecting leaflet "tongue" over the ventricular septal crest is a continuation of the common annulus.
   D. Obstruction of the subaortic outflow tract is common.
   E. The nodal triangle is displaced anteriorly and superiorly.

4. Which is correct regarding surgical technique for repair of AVSD?
   A. The VSD patch is sutured to the left side of the ventricular septum.
   B. Secondary chordae may need to be sacrificed during VSD closure.
   C. The atria are septated before separating the common valve orifice.
   D. Annuloplasty is not useful if there is persisting central regurgitation.
   E. The coronary sinus should be placed on the left side in the setting of a left superior caval vein.

5. Which of the following is true for results of surgical repair of AVSD?
   A. Operative mortality is 5 to 10 percent.
   B. Pulmonary hypertensive crisis is more common in younger patients.
   C. Heart block occurs in 3 to 5 percent.
   D. Closing the zone of apposition is associated with early reoperation for insufficiency.
   E. Late regurgitation is more common in patients with Down syndrome.

## ANSWERS

1. **Answer: D.** The AV septum is a term that is reserved for the AV component of the fibrous membranous septum. The hinges of the tricuspid valve are anchored by muscle throughout the right AV junction. The disparity between the muscular AV junction and the valvar annulus is most clearly seen at the mitral valve. The tricuspid annulus lies at a more apical position than the tricuspid annulus. The common AV junction is the fundamental feature of AVSD and is seen even in the absence of septal deficiency.
2. **Answer: C.** The left-sided papillary muscles are located in the same vertical plane. The SBL and the IBL have no counterparts to the normally septated heart. The degree of bridging of the SBL across the VSD forms the basis of the Rastelli classification. The Rastelli type A defect is the most common, occurring in 50 to 75 percent of cases.
3. **Answer: A.** The pattern of blood flow between the chambers is largely determined by chordal and leaflet anatomy. The degree of ventricular septal "scooping" is more extensive in hearts with a common orifice. The connecting leaflet "tongue" over the ventricular septal crest is not a continuation of the common annulus and has a variable extent. Obstruction of the subaortic outflow tract is uncommon. The nodal triangle is displaced posteriorly and inferiorly.
4. **Answer: B.** Small secondary chordae may need to be sacrificed to facilitate VSD closure. The VSD patch is sutured to the right side of the ventricular septum. The atria are septated during at the same time the common valve is separated into right and left components. Annuloplasty or commissuroplasty are useful if there is persisting central regurgitation. The coronary sinus should be committed to the right side in the setting of a left superior caval vein.
5. **Answer: D.** Closing the zone of apposition has been associated with early reoperation for insufficiency. Current operative mortality is less than 5 percent. Pulmonary hypertensive crisis is more common in older patients, existing preoperative pulmonary hypertension, and in patients with moderate or severe left AV valve regurgitation. Postoperative heart block occurs in 1 to 2 percent of patients. Late regurgitation is more common in patients with a double-orifice valve, nonclosure of the zone of apposition, those without Down syndrome, and a dysplastic left AV valve.

# 67 Aortopulmonary Window

*Victor O. Morell*
*Ergin Kocyildirim*

**KEY CONCEPTS**

- Epidemiology
  - Aortopulmonary (AP) window is a rare congenital anomaly, representing 0.2 to 0.5 percent of all cases of congenital heart disease.
- Pathophysiology
  - An abnormal communication between the ascending aorta and main or branch pulmonary artery results in severe left-to-right shunting. The degree of pulmonary overcirculation, pulmonary hypertensive vascular changes, congestive heart failure, and failure to thrive depend on associated anomalies and the size of the defect, which is often large enough to allow equalization of pulmonary and aortic pressures. Associated malformations are present in 50 to 60 percent of cases and include interrupted aortic arch, tetralogy of Fallot and anomalous origin of the right pulmonary or coronary artery.
- Diagnosis
  - Two-dimensional echocardiography provides accurate identification and localization of AP window as well as definition of associated lesions.
- Treatment
  - Surgical closure of large defects is indicated at the time of diagnosis in order to avoid early development of fixed pulmonary hypertension. Patch repair using a transaortic, transpulmonary, or "sandwich" approach has excellent outcomes. Small defects can be ligated or approached by percutaneous techniques.
- Outcomes/prognosis
  - Operative mortality is reported at less than 10 percent, with long-term prognosis largely dependent on the development of pulmonary hypertensive changes.

## INTRODUCTION

Aortopulmonary (AP) window is a rare congenital anomaly, accounting for 0.2 to 0.5 percent of all congenital heart defects.[1] It consists of a communication between the aorta and the pulmonary artery or its branches. Although closely related to AP window, pulmonary artery origin from the ascending aorta (also erroneously termed "hemitruncus") is classified as a separate defect.

AP window was first described by Elliotson in 1830 in an autopsy study.[2] In 1948, Robert Gross successfully ligated an AP window in a patient undergoing a thoracotomy for closure of a patent ductus arteriosus (PDA).[3] In 1957, Cooley and associates described the first successful repair of AP window using cardiopulmonary bypass.[4]

## PATHOPHYSIOLOGY

The pathophysiology of AP window is similar to that of a ventricular septal defect, PDA, or truncus arteriosus consisting of a left-to-right shunt. The amount of left-to-right shunting is related to the size of the defect and the pulmonary vascular resistance. Patients with small defects can be completely asymptomatic. With large defects, and as the pulmonary vascular resistance decreases in the first weeks of life, symptoms of congestive heart failure develop rapidly, and irreversible pulmonary vascular disease can occur as early as during the first 12 months of life. If untreated, 40 percent of patients will die of intractable heart failure during the first year of life, and survivors will succumb to the sequelae of congestive heart failure and severe irreversible pulmonary vascular disease during childhood (Fig. 67-1).[5]

## EMBRYOLOGY AND MORPHOLOGY

This defect has also been called AP septal defect; however, in terms of the structure of the postnatal heart and beyond the initial few months of gestation, there is no such thing as an AP septum. Almost as soon as the aortic and pulmonary pathways become separate entities within the developing heart, each of the intrapericardial arterial trunks develops its

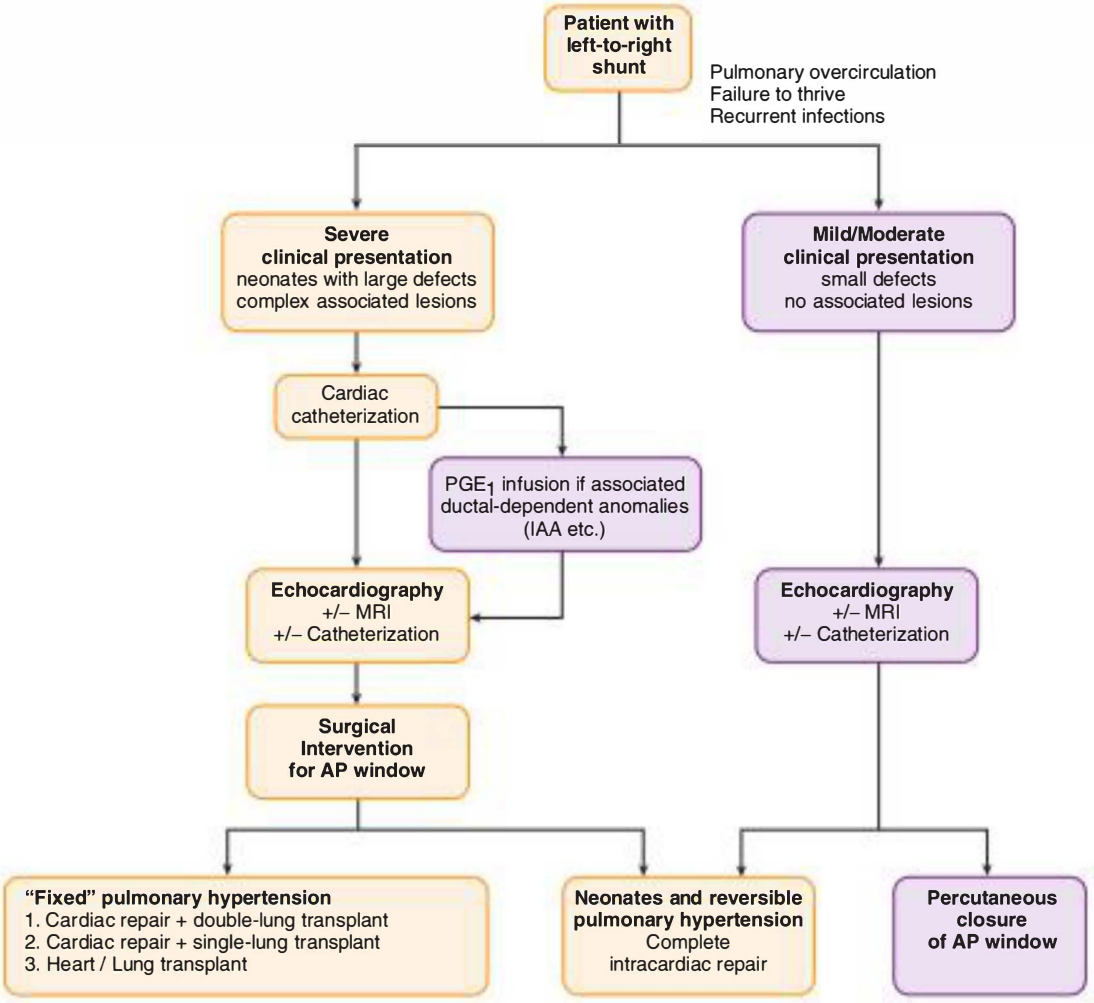

**FIGURE 67-1** Decision-making flowchart.

own discrete arterial wall. AP window is the failure of formation of the separate adjacent walls of the intrapericardial arterial trunks, with persistence of the AP foramen that certainly does exist during embryological development.[6] This defect can be differentiated from common arterial trunk by the presence of two separate arterial valves arising from separate subarterial ventricular outflow tracts.

AP window was classified by Mori et al.[7] into three types (Fig. 67-2):

- *Type I*: The most common type; involves proximal defects located between the semilunar valves and the pulmonary bifurcation.
- *Type II*: Distal defects located in the uppermost portion of the ascending aorta, with the posterior border of the defect formed by the pulmonary bifurcation.
- *Type III*: The defect is posterior in the aorta, creating a communication with the right pulmonary artery.

The Congenital Heart Surgery Nomenclature and Database project uses a classification system that is similar to the one just described.[8] A *Type 1 proximal defect* involves an AP window located just above the sinus of Valsalva, a few millimeters above the semilunar valves, with a superior rim but little inferior rim separating the AP window from the semilunar valves. *Type 2 distal defect* is located in the uppermost portion of the ascending aorta, with a well-formed inferior rim but little superior rim. *Type 3 total defect* involves the majority of the ascending aorta, with little superior and inferior rims. The *intermediate type* is a defect similar to the Type 3 but with well-defined superior and inferior rims. Interrupted aortic arch (IAA) is one of the most common associated cardiovascular lesions seen in patients with an AP window; the ventricular septum is usually intact and type A interruption is most commonly encountered.

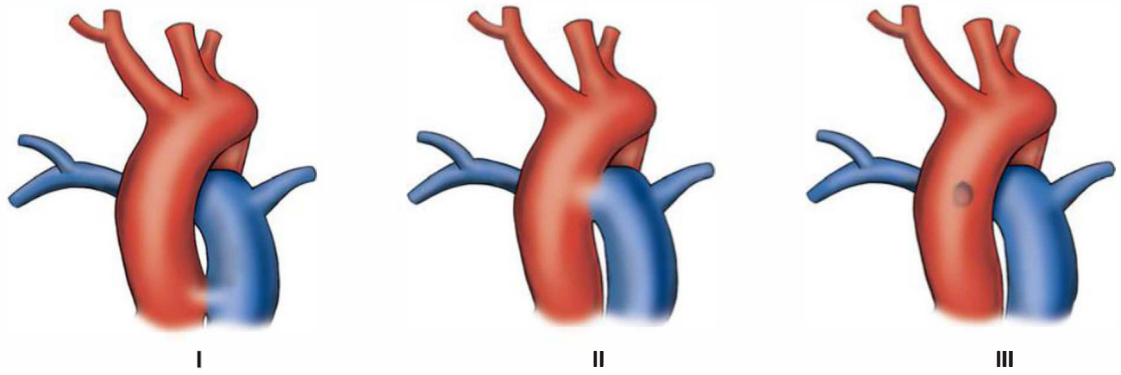

**FIGURE 67-2** Mori's classification of AP window.

AP window is also associated with VACTERL syndrome, which involves vertebral anal, tracheoesophageal renal and limb anomalies. Other associated lesions include tetralogy of Fallot, ventricular and atrioventricular septal defects, anomalous origin of the either coronary arteries from the pulmonary artery, transposition of the great arteries, and double aortic arch.

## CLINICAL FEATURES

The clinical presentation is related to the magnitude of the left-to-right shunt. In early life patients present with signs and symptoms of congestive heart failure, including failure to thrive and frequent respiratory tract infections. The smaller size defects are associated with minimal or no symptoms. On cardiac ausculation a systolic murmur is usually heard. Cyanosis is a late finding, presenting with the development of severe pulmonary vascular obstructive disease. When associated malformations are present, the clinical presentation can change to reflect the combined hemodynamic features, with IAA usually presenting with metabolic acidosis and poor perfusion after PDA closure, making the clinical diagnosis of AP window more challenging.

## DIAGNOSIS AND IMAGING

Depending on the magnitude of the shunt, chest x-ray commonly shows cardiomegaly with increased pulmonary vasculature markings. Electrocardiography may show biventricular hypertrophy. Echocardiography can demonstrate the defect, as well as most associated cardiac malformations, in the majority of the patients. Cardiac catheterization is usually not needed, unless significant associated defects are present that cannot be reliably assessed by echocardiography and other noninvasive imaging methods such as cardiac computed tomography (CT) or magnetic resonance imaging.

## SURGICAL MANAGEMENT AND OUTCOMES

The author's approach usually involves surgical repair as soon as the lesion is diagnosed. These patients will typically have significant left-to-right shunting and demonstrate signs of rapid diastolic aortic runoff. The key aspect of preoperative management is optimization of the $Q_p/Q_s$ in order to avoid low systemic blood flow (Chapter 60). Given the excellent surgical results in young infants (especially in the absence of associated lesions) delaying surgery in clinically symptomatic patients is usually not indicated even in low-birth-weight infants and neonates.

Since the first successful repair by Gross over 5 decades ago, a variety of different techniques have been reported. The currently preferred surgical approach involves repair via a median sternotomy with the use of cardiopulmonary bypass with mild or moderate hypothermia. Both branch pulmonary arteries need to be controlled with tourniquets as soon as cardiopulmonary bypass is established in order to prevent excessive pulmonary runoff. Under cardioplegic arrest the AP window is entered by a vertical incision and occluded (septated) with a patch (Fig. 67-3). Another option is to completely divide the AP window, separating the aorta from the pulmonary artery and repairing both great vessels with separate patches, or to perform an aortotomy and repairing the window through the aorta. This is particularly useful in case of communication between the aorta and the right branch pulmonary artery. Some cases of percutaneous closure have been reported with favorable results in specific situations, such as a small (3–4 mm) defect without any associated lesions.[9,10] In the early postoperative phase, hemodynamic management focused on the prevention of pulmonary hypertensive crisis is crucial, especially in patients in whom the defect is diagnosed late.

The operative morbidity and mortality rates for repair of an isolated AP window are very low.[11–14] The late results are also excellent, with an actuarial survival rate reported between 70 to 90 percent at 10 years. The outcome of

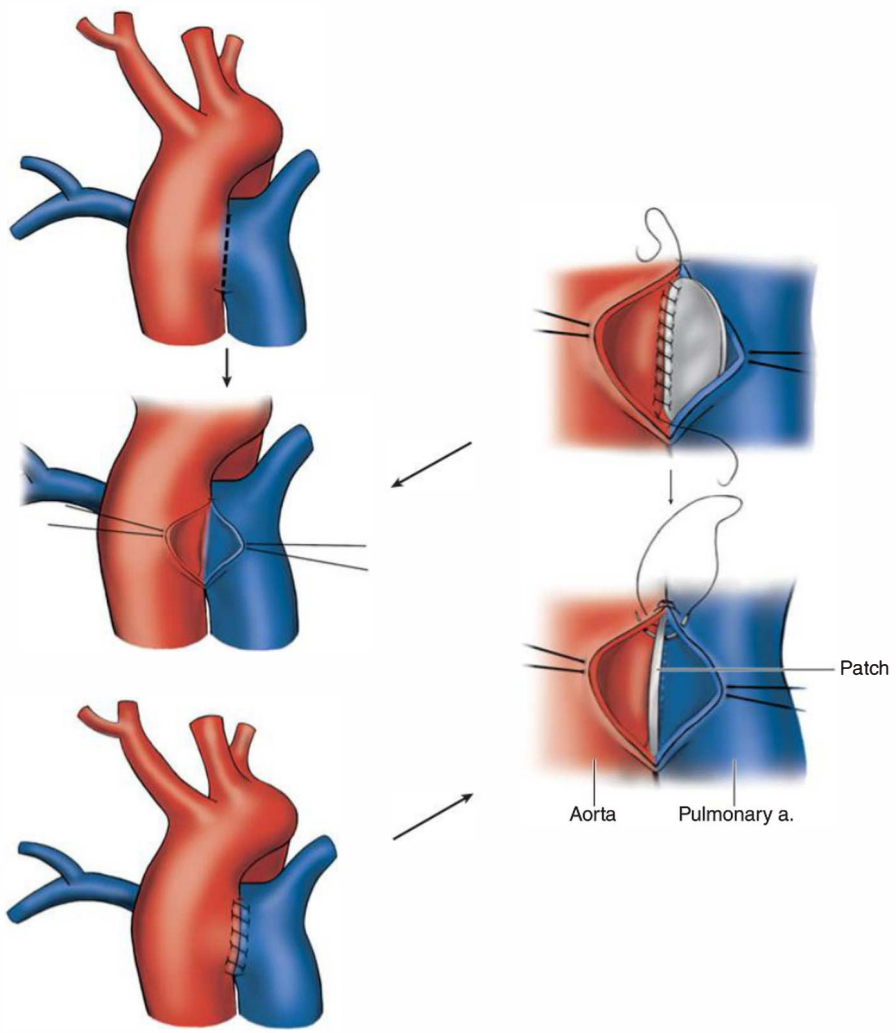

**FIGURE 67-3** Repair of AP window with a prosthetic patch. The anterior wall of the "window" is opened and the patch is sewn to the edges of the defect.

patients with significant associated malformations is determined primarily by the severity of associated lesions rather than by the mere concomitant diagnosis of AP window. The simultaneous presence of IAA (Chapter 79) has been found to be an independent risk factor for mortality.[11] The adverse outcomes in this particular group of patients, including reintervention and mortality, are directly related to the arch repair.[15]

## AORTOPULMONARY WINDOW BOARD REVIEW QUESTIONS (CHAPTER 67)

1. Which is true regarding pathophysiology of AP window?
   A. It is similar to truncus arteriosus with a right-to-left shunt.
   B. Small defects may be asymptomatic.
   C. Large defects become symptomatic as pulmonary vascular resistance increases.
   D. Irreversible pulmonary vascular disease can occur as early as 3 months of life.
   E. Untreated, 80 percent of patients will die within the first year.

2. Which is correct regarding classification of AP window according to the Congenital Heart Surgery Nomenclature and Database project?
   A. Type 3 defect = located just above the sinus rim
   B. Type 1 defect = located at uppermost portion of ascending aorta
   C. Type 2 defect = majority of ascending aorta
   D. Intermediate defect = similar to type 1 defect with well-defined rims
   E. Type A IAA is a common association.

3. Which is not associated with AP window?
   A. VACTERL syndrome
   B. Tetralogy of Fallot
   C. Atrioventricular septal defect
   D. Hypoplastic left heart syndrome
   E. Double aortic arch

4. Which of the following is correct regarding surgical repair of AP window?
   A. Deep hypothermic circulatory arrest is the preferred approach.
   B. Branch pulmonary arteries are not mobilized to prevent distortion.
   C. The window is repaired through the pulmonary artery.
   D. Percutaneous closure can be performed for small defects.
   E. Postoperative pulmonary hypertensive crisis is unusual.

5. Which is true regarding outcomes after repair of AP window?
   A. Operative mortality rates are 10 to 15 percent.
   B. Late survival is 50 percent at 10 years.
   C. Outcome is primarily determined by the severity of the defect.
   D. Presence of concomitant interrupted arch is an independent risk factor for mortality.
   E. Adverse outcomes are not related to concomitant repair of an interrupted arch.

## ANSWERS

1. **Answer: B.** Small defects may be entirely asymptomatic. The shunting is left-to-right, similar to truncus arteriosus. Large defects become symptomatic as pulmonary resistance falls, and irreversible pulmonary vascular disease occurs as early as 1 year of age. Untreated, 40 percent of patients will die within the first year.
2. **Answer: E.** Type A IAA is a common association. A type 1 defect is located at just above the sinus rim, a type 2 defect is at the uppermost portion of the ascending aorta, and a type 3 defect is the majority of the ascending aorta. An intermediate defect is similar to a type 3 defect and has well-defined rims.
3. **Answer: D.** Hypoplastic left heart syndrome is not associated with AP window. The remaining conditions are associated with this defect.
4. **Answer: D.** Defects less than 3 to 4 mm and without associated anomalies can be successfully closed with a percutaneous approach. Deep hypothermic circulatory arrest is not usually necessary, and the branch pulmonary arteries are mobilized and controlled to prevent excessive runoff. The window is repaired through the aorta. Postoperative pulmonary hypertensive crisis is common, especially in patients with a delayed diagnosis.
5. **Answer: D.** Presence of concomitant interrupted arch is an independent risk factor for mortality, and adverse outcomes in these patients are directly related to the arch repair. Late outcomes are primarily determined by associated anomalies rather than the specific type of AP window. Operative mortality rates are low and late survival is 70 to 90 percent at 10 years.

# 68

# Tetralogy of Fallot

*Osami Honjo*
*Glen S. Van Arsdell*

## KEY CONCEPTS

- Epidemiology
  - The prevalence of tetralogy of Fallot (TOF) is 0.21 to 0.36 per 1000 live births, accounting for approximately 7 to 10 percent of all congenital heart disease (CHD). 22q11 deletion is seen up to 20 percent of patients with TOF.
- Morphology
  - The essence of TOF anatomy is the anterocephalad deviation of the muscular outlet septum, which causes right ventricular outflow tract (RVOT) obstruction, override of the aorta, and malaligned ventricular septal defect (VSD). As a result of RVOT obstruction (RVOTO), the patients with TOF have various degree of right ventricular (RV) hypertrophy. The pulmonary valve (PV) is commonly bicuspid and has variable hypoplasia and dysplasia. TOF hearts commonly have multi-level obstruction: at infundibulum, PV, main and branch pulmonary arteries (PAs). Coronary artery anamalies occur in up to 5 percent of patients with TOF.
- Pathophysiology
  - The pathophysiology of TOF largely depends on the degree of RVOTO: mild RVOTO results in a predominant left-to-right shunt ("pink" TOF), whereas severe RVOTO results in right-to-left shunt and cyanosis. Some neonates with severe RVOTO are dependent on the presence of a patent ductus arteriosus (PDA) for pulmonary perfusion.
- Clinical features
  - Patients with very mild RVOTO have symptoms of congestive heart failure due to the left-to-right shunt. Those with moderate or severe RVOTO have various degree of cyanosis, that can be episodic (cyanotic spells). In the extreme form of RVOTO, neonates with duct-dependent pulmonary circulation become profoundly cyanotic as the PDA closes.
- Diagnosis
  - Typically, CXR shows decreased pulmonary vascular markings, upturned apex of the heart, and a pulmonary concavity at the upper left heart border, forming a "boot-shaped heart." Electrocardiogram shows rightward QRS axis and various degree of RV hypertrophy. Echocardiography is the most important diagnostic modality for delineating anatomy, including nature and degree of RVOTO, aortic override, type of VSD, PV and PAs. Cardiac catheterization, computed tomography (CT), and magnetic resonance imaging (MRI) can be useful in selected cases with unclear anatomy.
- Treatment
  - Prostaglandin $E_1$ ($PGE_1$) infusion is administered in patients with severe RVOTO and duct-dependent pulmonary circulation. Indication for surgery in the presence of the lesion. Symptomatic neonates are treated with early repair or stenting of RVOT. Patients with no or mild-to-moderate cyanosis typically undergo surgery at 4 to 6 months of age, or when cyanosis gets progressive. In the current era, primary repair is a preferred approach over palliation, with focus on preserving the PV annulus.
- Outcomes
  - Outcomes are excellent, with operative mortality below 3 percent in contemporary series. One-third of patients require late reintervention for residual RVOTO or VSD, and PV implantation. Late survival is 85 to 87 percent at 30 years after repair.

## INTRODUCTION

Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart disease (CHD). The anatomical essence of TOF is the anterocephalad deviation of the infundibular septum, which causes various degree of right ventricular outflow tract (RVOT) obstruction and subsequent right ventricular (RV) hypertrophy.[1–3] The malalignment of the infundibular septum results in a biventricular connection of the aortic valve, i.e., aortic override, and a subaortic ventricular septal defect (VSD) (Fig. 68-1). Although the characteristics of the intracardiac anomalies are predominantly determined by the anterocephalad deviation of the infundibular septum,[3] the subsequent degree of RVOT obstruction (RVOTO) varies significantly, yielding a wide spectrum of anatomy and physiology within the entity. The reported natural history of untreated tetralogy discloses survival rates of approximately 75 percent and 30 percent at 1 and 10 years of age, respectively.[4] The major causes of death in patients with unrepaired TOF include severe hypoxia (62 percent) and cerebrovascular events (30 percent).[5] Surgical strategies for management have evolved from staged repair with an initial systemic-to-pulmonary shunt and subsequent late repair to primary intracardiac repair in early infancy. Clinical outcomes have dramatically improved along with the evolution of surgical strategy.[6] In this chapter, clinical presentation, diagnosis, and current therapeutic strategies for TOF with pulmonary stenosis are discussed. TOF with pulmonary atresia is discussed in Chapter 69. Two important subgroups, namely TOF with absent pulmonary valve (PV) and TOF with atrioventricular septal defect (AVSD) are discussed in the latter part of this chapter.

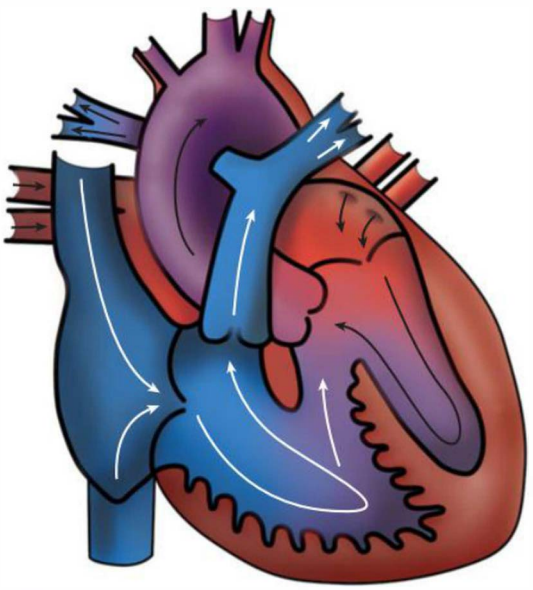

**FIGURE 68-1** Diagram of typical tetralogy of Fallot. The presence of right ventricular outflow tract obstruction and VSD allows right-to-left shunting at the ventricular level.

## EPIDEMIOLOGY AND ETIOLOGY

The prevalence of TOF is 0.21 to 0.36 per 1000 live births as reported in the Baltimore-Washington Infant Study and other large cohort studies,[7,8] accounting for approximately 7 to 10 percent of all forms of CHD. The exact etiology is largely unknown. Most cases are sporadic, although rare familial cases with a missense mutation in JAG1 (jagged 1 gene) have been reported.[9] The risk of recurrence in siblings is approximately 1 to 3 percent.[10,11] Microdeletion of chromosome 22q11 is strongly related to some forms of CHD including TOF. 22q11 deletion is seen in 12 to 20 percent of the patients with TOF.[12]

## ANATOMY

The unifying anatomic feature for TOF is the anterocephalad deviation of the muscular outlet septum relative to the limbs of the septomarginal trabeculation. The subpulmonary stenosis is caused by the deviated outlet septum combined by the hypertrophied septoparietal trabeculations and results in a "squeeze" effect. Anterocephalad deviation of the outlet septum can also be seen in the absence of significant subpulmonary stenosis. This clinical condition is also known as "pink" tetralogy and the septal defect as an "Eisenmenger VSD."[13] The infundibulum is generally longer than that of normal hearts,[14] although there is a significant variability in infundibular length. The infundibulum can also be completely absent.[2] Additional subpulmonary stenosis can be caused by a hypertrophied moderator band or infundibular trabeculations. RV hypertrophy is generally mild at birth, and becomes prominent over time.

As a result of the deviated infundibular septum, the aorta is shifted anteriorly toward the RV, thus overriding the interventricular septum. The degree of aortic override varies from 15 to 95 percent.[2] If there is more than 50 percent override of the aorta, the lesion is referred to as tetralogy-type double outlet RV (Chapter 71).[15] The anatomical features of those hearts are essentially the same as those observed in typical tetralogy.

The VSD in tetralogy is located just beneath the overriding aorta and is usually large and unrestrictive. It can rarely be restricted by tricuspid valve tissue or septal hypertrophy.[16] The majority of VSDs are perimembranous (80 percent), but they can occasionally be subarterial or doubly committed.[2] In a typical TOF VSD, the defect is cradled by the anterior–superior rim (that inserts to the deviated outlet septum) and the posterior–inferior rim of the septomarginal trabeculation. The anterior–superior margin of the defect is the muscular outlet septum and the ventriculo-infundibular fold (the roof of the outlet septum). The inferior–posterior margin of

the defect is muscular. Separating these two limbs is an area of fibrous continuity between aortic and tricuspid valve leaflets, which incorporates the remnant of perimembranous septum (membranous flap). The VSD can also be called a conal septal malalignment defect, and differs from the typical perimembranous defect in that it is rare for chords of tricuspid valve to attach to the margins. The atrioventricular (AV) conduction axis is located around the apex of the triangle of Koch and penetrates the central fibrous body in the area of the remnant of the perimembranous septum. Approximately one-fifth of tetralogy patients have a muscular margin along the entire perimeter of the VSD, a feature most frequently seen in the Asian population.[17] In this defect, the posterior–inferior rim of the septomarginal trabeculation inserts on the outlet septum and the perimembranous region is entirely intact. The rarest type of VSD is the doubly committed juxta-arterial defect, which is more common among patients from the Far East, South America, and Mexico. Unlike the vast majority of the VSDs in tetralogy, this form of tetralogy is characterized by the fact that the anterior–superior rim of the defect is a fibrous raphe between the leaflets of the aortic and PVs. The muscular outlet septum is deficient.

The PV in patients with TOF is most commonly bicuspid and characterized by a small annulus and thickened, dysplastic leaflets. There can occasionally be a tricuspid arrangement of the leaflets but they are usually small and dysplastic as well. PV leaflets are sometimes absent, and this is frequently associated with markedly dilated main pulmonary artery (PA) and its branches, resulting in a completely different physiology (absent PV syndrome).[18] Stenosis is also common in the left PA, main PA, and the branch PA bifurcation.[19] The left PA often originates more distally from the main PA and takes off with an abnormal acute angle, which may result in left PA stenosis. The left PA can be isolated and supplied by an arterial duct (discontinuous branch pulmonary arteries). Major aortopulmonary collateral arteries (MAPCAs) can coexist but are more common in the setting of TOF and pulmonary atresia (see Chapter 69).

A patent oval foramen or atrial septal defect is the most commonly associated lesion seen in patients with tetralogy (also known as pentalogy of Fallot). Other associated lesions include additional muscular VSDs, straddling of the tricuspid valve, common AV valve (TOF with AVSD), and right aortic arch. It is not uncommon to have coronary artery anomalies, including anomalous origin of the anterior descending coronary artery from the right coronary artery (2–3 percent), the presence of an accessory left anterior descending artery from the right coronary artery (5–6 percent), and a single coronary artery.[20] These coronary artery abnormalities may have surgical implications in terms of RVOT reconstruction.

## PATHOPHYSIOLOGY

The pathophysiology of TOF largely depends on the particular anatomical features and, most importantly, on the degree of RVOTO. Neonates or infants with TOF who do not have established RVOTO may have a moderate to large left-to-right shunt through the large VSD. The physiology in this situation is similar to that of an isolated VSD with pulmonary overcirculation. As RVOT muscle obstruction develops over time, the direction of the shunt at the VSD level may become bidirectional. In neonates with severe RVOTO, the direction of the shunt across the VSD can be exclusively or predominantly from right to left. For severe forms of TOF, pulmonary blood flow can be entirely duct-dependent.

The direction of the shunt at the atrial level is typically from left to right or bidirectional. The shunt can be bidirectional or predominantly from right to left if pulmonary vascular resistance is still high in the neonatal period, or if the RV has reduced compliance due to progressive RV hypertrophy.

## DIAGNOSIS

### Clinical Presentation

Neonates with severe RVOTO may present with significant persistent cyanosis at birth. Profound cyanosis may result in metabolic acidosis, compensatory tachypnea, and respiratory alkalosis. Pulmonary perfusion is, in this context, often duct-dependent. If the arterial duct is widely open, patients may not disclose intense cyanosis in spite of the presence of RVOTO. Infants with moderate RVOTO may present with cyanosis in the first few weeks of life with a systolic murmur. Development of cyanosis is usually correlated with the development of infundibular stenosis and RV hypertrophy. Infants with mild or minimal RVOTO may present with nonspecific symptoms of congestive heart failure because of a large left-to-right shunt. Possible symptoms include feeding, poor weight gain and tachypnea. There is generally no cyanosis but may become prominent as RVOTO develops. Older patients may have clubbing of fingers, although it is rarely observed in developed countries in the current era.

Patients with significant RVOTO may experience cyanotic spells, which are common among unrepaired patients who are older than 6 months. Many physiologic changes, such as dehydration, fever with resultant tachycardia and decrease in systemic vascular resistance may decrease relative pulmonary blood flow and trigger a cyanotic spell. Although infundibular spasm has been thought to cause cyanotic spells, this hypothesis is currently not supported. A cyanotic spell typically lasts 15 to 60 min. A long-lasting spell may result in brain damage or even death. Administration of vasoconstrictors, β-blockers, volume and sedation may be critical for stabilization. Older patients with severe cyanosis may assume a typical "squatting" position. The physiologic consequence of this posture is the increase in systemic vascular resistance with subsequent improvement in pulmonary perfusion and with left-to-right shunting across the VSD.

## PHYSICAL EXAMINATION

The presence of cyanosis and a systolic ejection murmur along the left upper sterna border is the common characteristics of moderate-to-severe form of TOF in neonates and infants. A shorter ejection murmur may indicate severe RVOTO, which may correlate with the severity of cyanosis. The second heart sound is typically single and of normal intensity. A continuous murmur may be audible when the arterial duct is patent. The parasternal RV impulse may be increased and a thrill may be palpable. Patients will usually have a normal growth pattern, although growth may be delayed if patients with associated syndromes such as DiGeorge syndrome, 22q11 deletion and trisomy 21. In such circumstances, various degrees of facial dysmorphism are also common. Infants with TOF who have minimal or mild RVOTO may have clinical features of congestive heart failure, such as tachypnea, hepatomegaly, and poor weight gain. The parasternal impulse may be increased.

**FIGURE 68-2** Chest radiograph showing a "boot-shaped heart," with upturned apex of the heart and pulmonary concavity at the upper left heart border.

## DIAGNOSTIC INVESTIGATIONS

Radiographic findings in patients with moderate-to-severe forms of TOF include decreased pulmonary vascular markings, upturned apex of the heart and pulmonary concavity of the upper-left cardiac border. The latter two features form a "boot-shaped heart" on a chest radiograph (Fig. 68-2). A right aortic arch can be found in up to 15 percent of the patients with TOF. In acyanotic infants with TOF CXR may be normal or may have signs of increase in pulmonary blood flow, such as cardiomegalyand increase in pulmonary vascular markings. The electrocardiogram usually shows normal sinus rhythm, rightward QRS axis, and various degrees of RV hypertrophy.

Echocardiography is by far the most important and effective diagnostic modality for detailing anatomic features of TOF. Nature and degree of RVOTO and deviated infundibular septum can be well documented by the subcostal right anterior oblique view (Fig. 68-3). The degree of aortic override and presence or absence of straddling of the mitral or tricuspid valve apparatus can be assessed in the parasternal long-axis view (Fig. 68-4A). Type of the VSD and presence or absence of additional muscular VSDs should be screened by multiple views (Fig. 68-4B). Other important structures to be assessed include size and morphology of the PV, size of main and branch PAs, and the presence or absence of an arterial duct. Detection of an anomalous coronary artery (anomalous origin of the left anterior descending artery or a large coronal branch of the right coronary artery crossing the RVOT) is

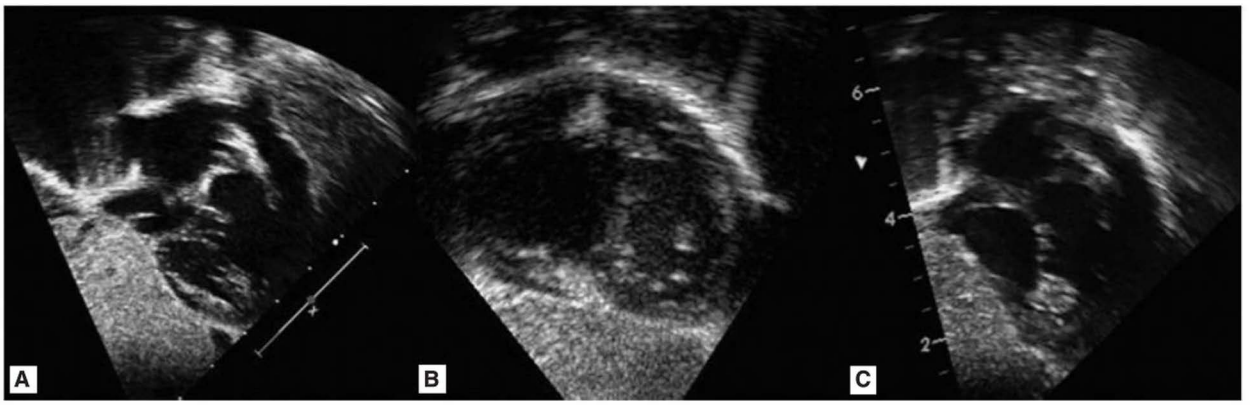

**FIGURE 68-3** **A.** Subcostal right anterior oblique echocardiographic view in a patient with mild form of tetralogy of Fallot. The anterior deviation of the infundibular septum is mild. This patient underwent repair with sparing of the pulmonary valve. **B.** Significant anterior deviation of the infundibular septum, resulting in highly obstructed subpulmonary chamber; the pulmonary valve annulus is, however, of adequate diameter. This patient underwent repair with a main pulmonary artery and infundibular patch and preservation of the PV. **C.** Diffusely hypoplastic right ventricular outflow tract and pulmonary valve with significant anterior deviation of the infundibular septum. This patient required a transannular patch at the time of surgical correction.

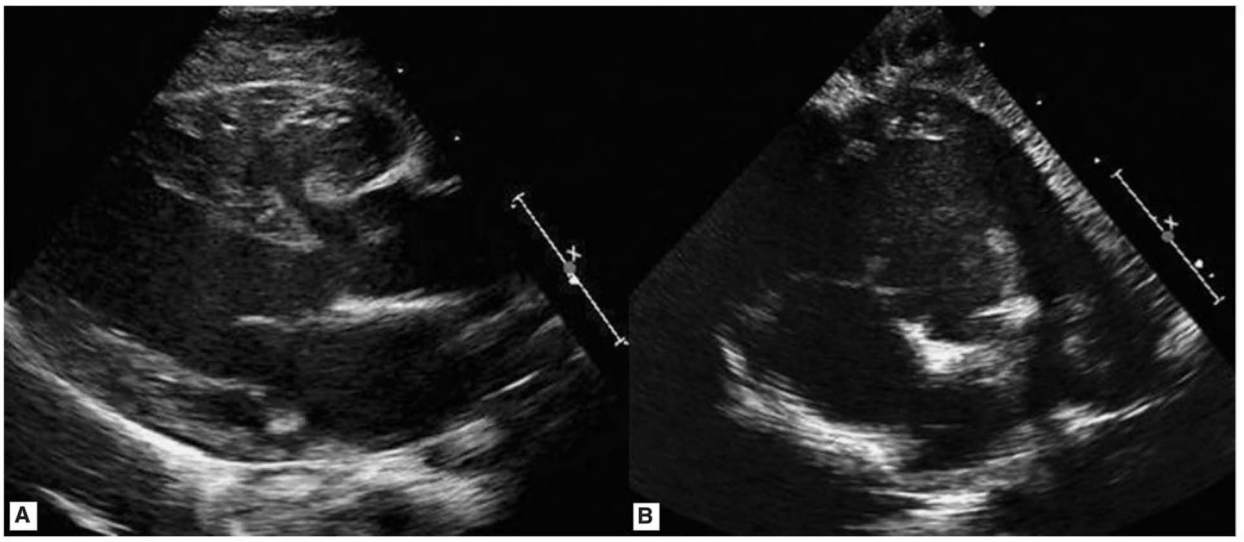

**FIGURE 68-4** **A.** Parasternal long-axis echocardiographic view showing aortic override and VSD. **B.** A large perimembranous VSD with a long infundibular chamber in a short-axis view.

of great importance for surgical decision-making and can be usually achieved by echocardiography. Aortopulmonary collateral arteries may be visualized if they are present and relatively large in size, but require delineation by angiography or computerized tomography if suspected.

Since echocardiography can provide detailed anatomic and physiologic information, the role of cardiac catheterization in the diagnosis TOF is currently somewhat limited. Cardiac catheterization may be useful when the presence of large aortopulmonary collateral arteries is suspected or to delineate the PA size if they appear small on echocardiography. Cardiac catheterization has, however, an important role if percutaneous intervention is contemplated or if the branch PAs cannot be completely assessed echocardiographically or if other imaging modalities are unsuccessful or unavailable.

## MEDICAL MANAGEMENT

The major role of medical management is to stabilize or optimize the patient's condition until palliation or definitive surgical treatment is undertaken. Severely cyanotic neonates with TOF require administration of $PGE_1$ and/or intubation with mechanical ventilation. Prostaglandin may or may not be helpful in increasing pulmonary blood flow, depending on the presence or absence of a patent arterial duct. Prompt surgical or catheter-based management is required in this situation. Infants with TOF who have progressive cyanosis with or without cyanotic spells require β-blocker administration, which is usually effective to prevent recurrence. Early elective surgery is indicated if a patient requires therapy with β-blockers for progressive cyanosis or experiences a persistent fall in arterial saturation below 80 percent. Spelling patients may require intensive treatment with sedation, systemic vasoconstriction, volume repletion and β-blockade followed by urgent surgery. Acyanotic patients with TOF may not require any medical management until surgery. Patients with TOF who have minimal RVOTO and have pulmonary overcirculation may require diuretic therapy.

## SURGICAL MANAGEMENT

The diagnosis of the lesion is per se indication for surgery. There have been significant paradigm shifts in the surgical strategy for this entity over time. In the current era, there are still, however, considerable differences in surgical management among different institutions. We highlight to follow the evolution of the surgical approach to this malformation, and describe our current management strategy.

## EVOLUTION OF THE SURGICAL APPROACH TO TETRALOGY

The presence of TOF had been uniformly lethal until the introduction of the systemic-to-pulmonary shunt by Alfred Blalock in 1944 (see Chapter 58).[21] This, other forms of shunts, and closed valvotomy procedures represented the only form of therapy until C. Walton Lillehei performed the first intracardiac repair under direct vision.[22] The repair was achieved then with a large vertical right ventriculotomy (Fig. 68-5). The VSD was closed with direct suture closure technique and RVOT muscle bundle resection was performed with a specifically designed infundibulectomy scissor.

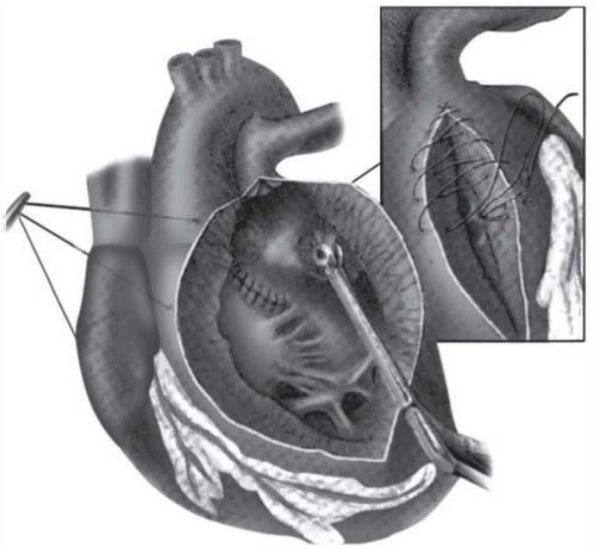

**FIGURE 68-5** Operative drawing from the original description of the first intracardiac repair of tetralogy of Fallot by the team at University of Minnesota led by C. Walton Lillehei.[22] The repair was accomplished through a large vertical right ventriculotomy under cross-circulation.

Remarkably, six of ten patients undergoing repair of TOF with parental cross-circulation survived. The role of cross-circulation was soon replaced by the heart–lung machine[23] but the fundamental concept of TOF repair through a right ventriculotomy remained. Given the early excellent results with this approach, many believed that intracardiac repair of TOF with a transannular patch and a transventricular VSD repair was a definitive repair. Over time, these patients went, however, on to develop RV dilatation, tricuspid insufficiency, atrial and ventricular arrhythmias, dysfunction and sudden death.[24,25]

A transatrial approach for repairing TOF was first reported by Hudspeth in 1963.[26] This approach was later popularized by Edmunds[27] and Kawashima,[28] who reported successful early survival, superior pulmonary competence and RV performance in a substantial number of patients. These excellent results were reproduced in high-volume centers and extended to include patients with additional anatomical abnormalities such as abnormal coronary arteries.[29]

The transatrial approach to VSD closure may better preserve RV geometry by avoiding a large right-ventriculotomy even if the pulmonary annulus is crossed. Residual mild-to-moderate RVOT stenosis with a preserved PV annulus and PV competency may be better at preserving long-term RV performance in those patients with favorable anatomic substrate. RV hypertrophy in the setting of residual stenosis may play a protective role against the dilatation associated with significant pulmonary insufficiency, thereby preserving long-term RV geometry and function.

## TREATMENT ALGORITHM—THE HOSPITAL FOR SICK CHILDREN, TORONTO

Our current management algorithm is shown in Figure 68-6. Asymptomatic patients with TOF are electively operated at 5 to 6 months of age. Earlier repair is indicated when arterial saturation ($SaO_2$) falls below 80 percent, or if the patient experiences one or more cyanotic spells. The strategy for critically cyanotic neonates is based on body weight and on the presence or absence of risk factors that may preclude neonatal repair. Neonates whose body weight is greater than 2.3 kg undergo primary repair unless a contraindication is present. The contraindications for primary neonatal repair include body weight less than 2.3 kg, prematurity below 36 weeks, pathologic biventricular hypertrophy, intracranial hemorrhage, sepsis/infection, and significant end-organ dysfunction. The neonates who are not suitable for primary repair are assessed for possible catheter-based intervention. Balloon dilatation and/or placement of RVOT stent are performed in these cases if feasible. Patients who are palliated by RVOT dilation or stent placement undergo elective repair at 3 to 6 months of age, or earlier if $SaO_2$ decreases below 80 percent. The patients who are not suitable for surgery or catheter-based intervention are kept on $PGE_1$ until the patients' growth approaches 2.5 kg or the factor(s) precluding surgery are no longer present. Our policy is to avoid the placement of a Blalock-Taussig shunt in the neonatal period or in early infancy because of the known incidence of significant pulmonary overcirculation, PA distortion, shunt thrombosis, and seromas.[30] In our experience and with this approach, primary repair has resulted in less than 1 percent morality over the past 15 years.

### Surgical Techniques

The operation is performed under mild hypothermic cardiopulmonary bypass with bicaval venous cannulation. A transatrial and transpulmonary repair[29] is our preferred approach. A right atriotomy is made parallel to the AV groove and the VSD and RVOT are exposed through the tricuspid valve orifice. The moderator band is identified. The abnormal muscle bundles crossing from the "10 o'clock" position on the tricuspid valve annulus and extending to the PV are divided and resected to increase the infundibular chamber size (these are known as the parietal muscle bundles) (Fig. 68-7A). Care is taken that the resection area does not get too close to the infundibular septum or aortic valve. Once the muscle resection is completed, the subpulmonary area is inspected to see if there is adequate volume. The VSD is closed with a Dacron patch (Fig. 68-7B). Glutaraldehyde-treated autologous or bovine pericardium or polytetrafluoroethylene can also be used as patch materials. If the infundibular chamber size is small but the PV size is adequate, an infundibular outflow patch is added to achieve an unobstructive sub-valvar outflow tract. The size of the

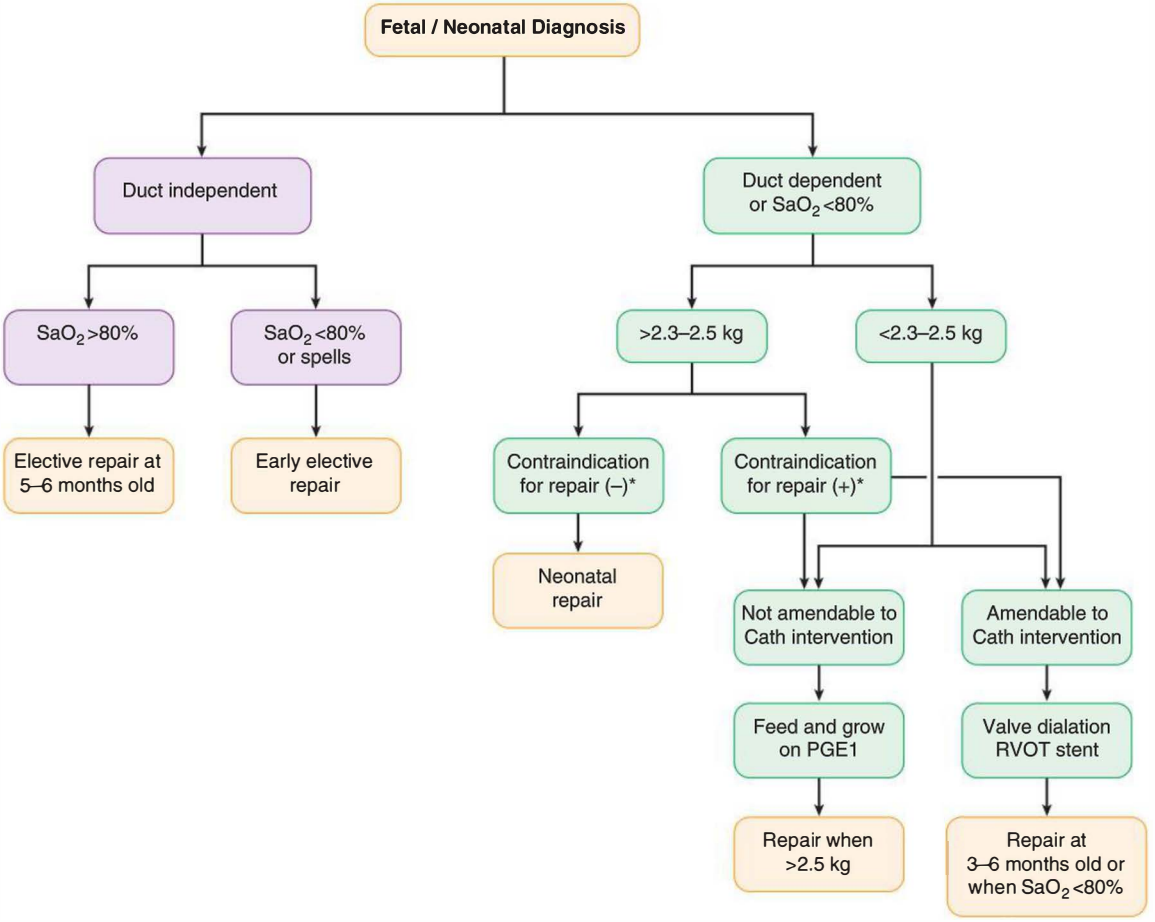

**FIGURE 68-6** The treatment algorism for patients with tetralogy of Fallot at The Hospital for Sick Children in Toronto. $PGE_1$, prostaglandin $E_1$; $SaO_2$, arterial saturation.*Contraindications: body weight less than <2.3 to 2.5 kg, significant prematurity, pathologic ventricular hypertrophy, intracranial hemorrhage, sepsis/infection, and significant end-organ dysfunction.

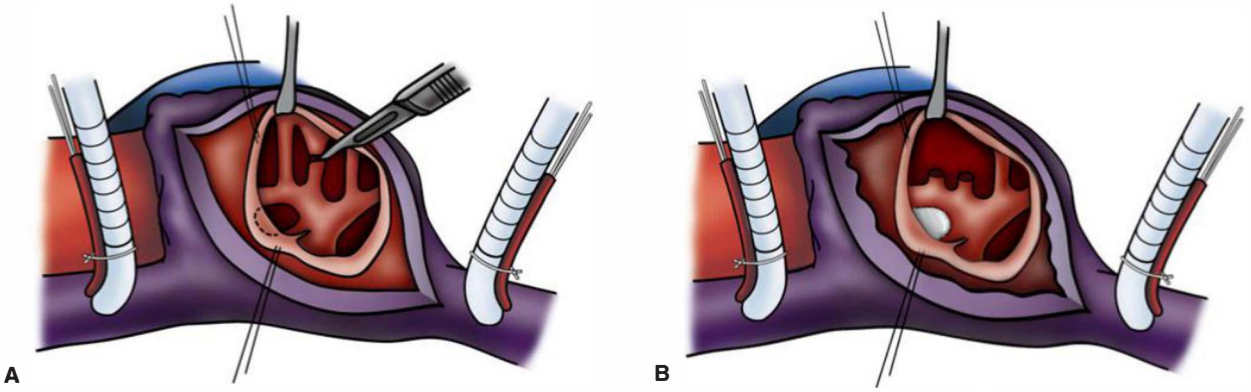

**FIGURE 68-7** **A.** Right ventricular outflow tract muscle resection in tetralogy of Fallot repair. The septomarginal trabeculation and moderator band are identified. The septoparietal trabeculations that arise from the septomarginal trabeculation to RV free wall should be resected. In addition, hypertrophied RV free wall can be resected. **B.** The VSD is closed with a continuous suture technique. Suspension stitches placed on the anterior and septal leaflets of the tricuspid valve facilitate exposure.

ventriculotomy is kept small, typically, so that it would not allow for VSD closure via the incision.

### PULMONARY VALVE PRESERVATION STRATEGY

In general, the PV can be preserved if the annulus size is more than 70 to 80 percent of normal. Our strategy to maximize the possibility of PV preservation is to perform a stepwise RVOT construction. A valvotomy and commissurotomy are performed on the PV through a vertical main pulmonary arteriotomy and the main PA and two PV sinuses are enlarged with a patch (Fig. 68-8A and B). The functional assessment of residual RVOTO is performed after weaning from cardiopulmonary bypass by intraoperative transesophageal echocardiogram and direct needle pressure measurement. An RV systolic pressure less than 75 percent of systemic pressure is accepted (for a 5–6-month old this is usually around a systolic RV pressure of 50–55 mm). If the RV systolic pressure is subsystemic and there is infundibular stenosis, an additional infundibular patch is placed (Fig. 68-8C and D). If a significant obstruction remains at the level of the PV annulus after placing the infundibular patch, a limited transannular patch is placed (Fig. 68-8E and F). With this approach, the PV annulus is preserved in approximately 80 percent of the patients. Other strategies (including intra-operative balloon pulmonary anuloplasty) have been recently introduced to preserve function of the PV.[31]

## Controversies in Surgical Strategy

Acyanotic infants with TOF undergo elective surgical repair between 5 and 6 months of age (Fig. 68-6); this approach is based on the notion that infants <6 months of age generally have good physiologic tolerance to surgical intervention, can have their atrial defect closed, and are proven to have prompt postoperative recovery with less inotropic and fluid requirement when compared to small infants less than 3 months of age.[32] Timing of surgery for asymptomatic patients in other centers varies from the neonatal period to around 1 year of age.[33,34] The surgical strategy for cyanotic neonates with TOF varies more markedly among different centers. We[6] and other centers[35,36] advocate primary repair for symptomatic neonates unless contraindicated. Dilation or stenting of the RVOT is the second option if infants have risk factors precluding primary neonatal repair (Figs. 68-6 and 9).[30,37] Some centers will routinely place a modified Blalock-Taussig shunt in the neonatal period followed by complete repair.[34] A recent series showed equivalent survival between the two strategies in symptomatic neonates with TOF.[38]

Many centers, including ours, advocate a transatrial transpulmonary approach, although some still prefer transventricular approach. The major advantage of a transatrial approach is the potential avoidance of a ventriculotomy and of a large transannular patch. Potential advantages of transventricular approach include better exposure and ability to enlarge the hypoplastic infundibulum without extensive muscle resection, which may result in extensive endocardial scar formation.[39]

Less than 2 percent of infants have insufficient PA size for complete repair. In these infants shunts, transannular patches and/or percutaneous interventions are used to induce PA growth prior to repair.[40,41]

# EARLY OUTCOME

Operative mortality of TOF repair was as high as 25 percent in the 1960s and 1970s, improving to less than 10 percent by the 1980s.[42,43] In the current era, primary repair for acyanotic TOF can be done with a mortality of less than 1 percent.[6,34] Even among symptomatic neonates or small infants undergoing primary repair, the hospital mortality ranges from 1 to 3 percent in contemporary series.[35,36] Classic risk factors for operative death included small PV and annular size, high postrepair RV/LV pressure ratio and young age at repair[43]; these risk factors have largely been overcome in the current era. Most patients undergoing elective repair will quickly recover, with prompt weaning from mechanical ventilation and intensive care unit stay of less than 48 hours.[32] Up to one-third of the patients will, however, have significant low cardiac output state due to the restrictive physiology of the RV.[44]

## Restrictive Physiology of the Right Ventricle

Some postrepair TOF patients develop poor diastolic relaxation of the RV that causes the ventricle to function as a passive conduit in diastole rather than as a compliance chamber. This can lead to a low cardiac output state, requiring significant fluid resuscitation. This situation is known as restrictive physiology and is characterized by the presence of antegrade late diastolic flow in the PA as seen by pulse Doppler echocardiography (Fig. 68-10). This indicates that the atrial contraction is directly transmitted to the PA. Systolic function is usually maintained. Treatment includes spontaneous ventilation or minimal airway pressure ventilation with minimal airway pressure. This in turn facilitates blood flow through the RV, as does maintaining a high preload with a central venous pressure of up to 15 mm Hg or more; additional therapeutic measures include complete drainage of both pleural spaces and the abdominal cavity and, in severe cases, reopening of the chest to improve diastolic filling. Inotropic support should be minimized. The phenomenon is common in patients who had a transannular patch repair.[45] Although restrictive physiology is associated with significant early postoperative morbidity, it paradoxically is related to less late QRS prolongation, less cardiomegaly and improved exercise tolerance at late follow-up.[45,46]

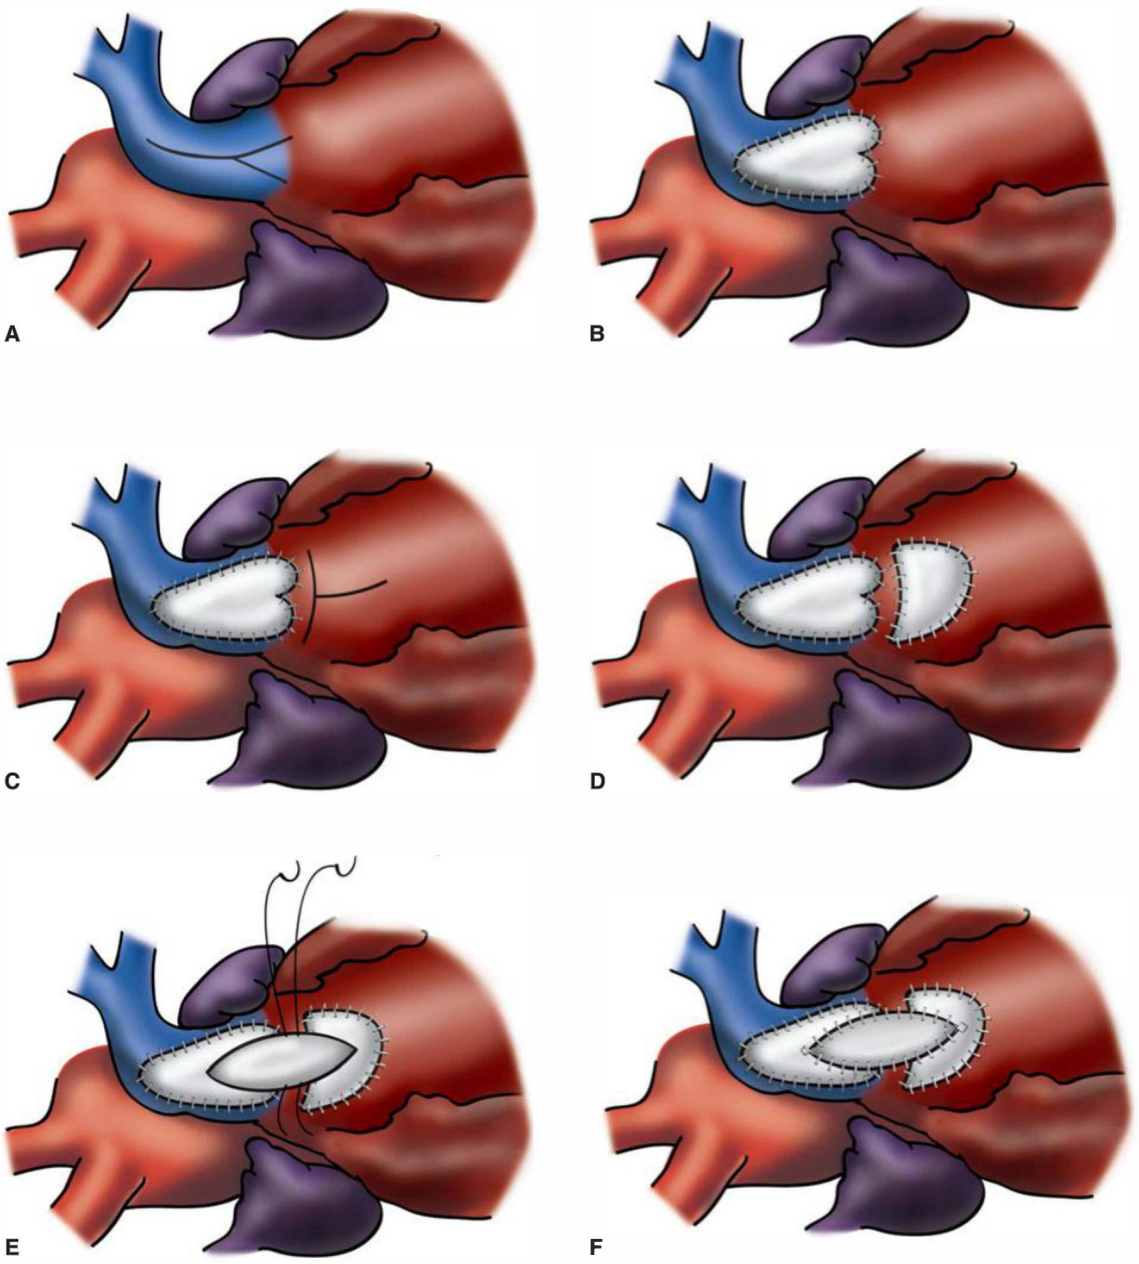

**FIGURE 68-8** **A.** The first step of right ventricular outflow tract reconstruction. A vertical incision on the main pulmonary artery is extended into two pulmonary sinuses. **B.** The main pulmonary artery and two pulmonary sinuses are enlarged either with a fresh pericardial or a polytetrafluoroethylene patch. **C.** If residual right ventricular outflow tract obstruction persists after main pulmonary artery patch repair, the infundibular chamber is enlarged with a limited infundibular incision. **D.** A polytetrafluoroethylene patch is placed just below the pulmonary valve annulus. **E.** If significant obstruction remains at the annulus level after two-patch repair, a limited transannular patch is placed by cutting across the patches and the annulus. **F.** A polytetrafluoroethylene patch is placed across the pulmonary valve annulus.

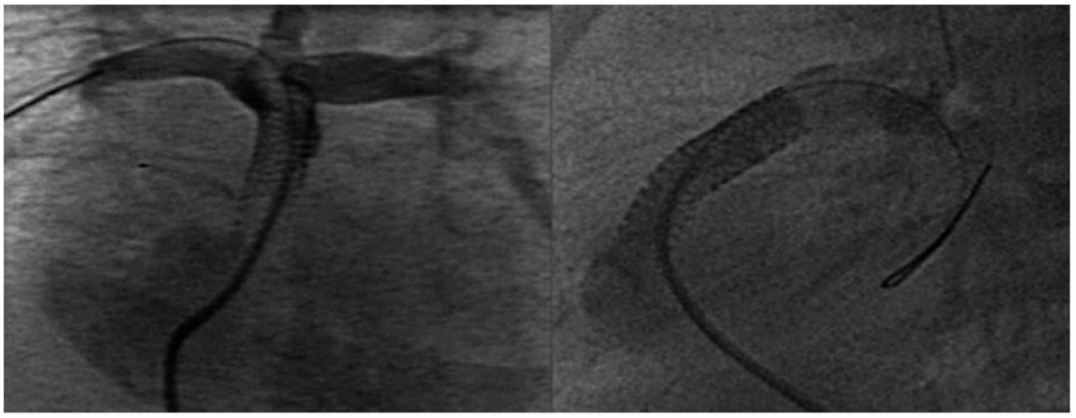

**FIGURE 68-9** Stent placement across the stenotic right ventricular outflow tract and pulmonary valve annulus in a severely cyanotic neonate with tetralogy of Fallot. (Courtesy of Dr. Lee Benson in The Hospital for Sick Children, Toronto.)

## LATE OUTCOME

Large surgical series from several centers as well as from our institution have shown an overall 85 to 87 percent survival rate at 30 years after repair.[42,47,48] The constant risk of death is approximately 0.3 percent/year in the first 30 years after repair. The Mayo clinic group showed older age at operation and a high postrepair RV/LV systolic pressure ratio as independent risk factors for late mortality on multivariate analysis.[47] Conflicting results have been reported regarding the impact of transannular patch on long-term survival: data from the Toronto group showed no difference in late survival between transannular patch and valve-sparing repair,[42] whereas others suggested a negative impact of a transannular patch on long-term outcomes.[48] The most common mode of late death is cardiac-related sudden death, followed by congestive heart failure and death related to reoperations. In the current era of very low early mortality, 40-year survival can be estimated to be nearing 90 percent.[42]

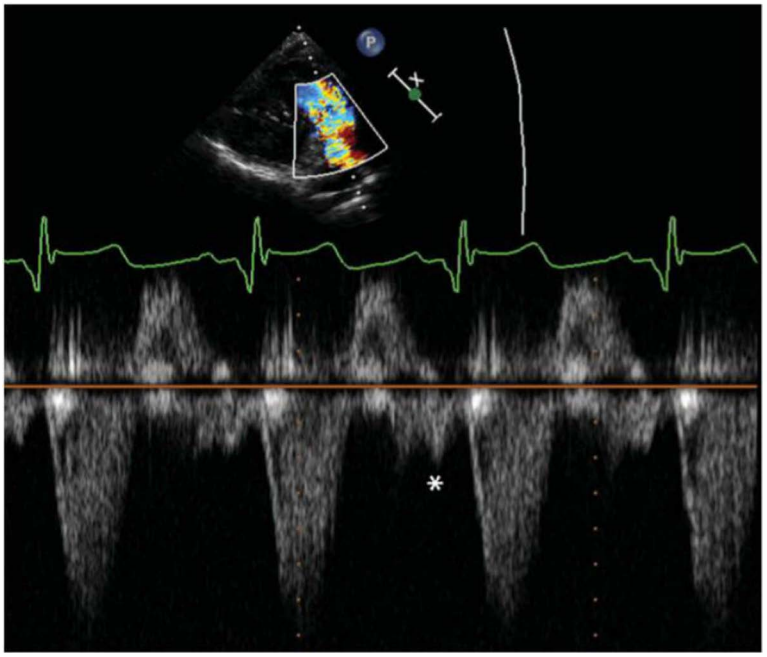

**FIGURE 68-10** The restrictive pattern of the RV seen by pulse Doppler echocardiography. Antegrade late diastolic flow in the pulmonary artery is shown.

The functional status of the long-term survivors is reasonable: approximately 80 percent of patients are in New York Heart Association (NYHA) functional class I, and less than 10 percent are in class III at median follow-up of 30 years.[47] Nonetheless, exercise capacity of these patients is markedly impaired. Maximal oxygen consumption among postrepair TOF patients whose are in NYHA class I is approximately two-thirds of the predicted value. Decrease in exercise capacity is strongly related to the magnitude of pulmonary insufficiency[49] as well as with the degree of biventricular dysfunction.[50]

## Late Problems and Management

Patients with TOF will still have life-long residual anatomic and functional problems (see Chapter 90). The major possible residual lesions include significant pulmonary insufficiency and subsequent RV dilatation and dysfunction, residual VSD or atrial septal defect, tricuspid valve regurgitation, residual RVOTO or aneurysm formation, branch PA stenosis and atrial and/or ventricular arrhythmias. This patient group therefore necessitates long-term follow-up by a comprehensive team that is well versed in the specific care of adults with CHD. Up to one-sixth of patients will at some point require reoperation. Indications for reoperation, as summarized by the Canadian Cardiovascular Society[51] are shown in Table 68-1.

**TABLE 68-1: Indication for Reoperation in Patients with Repaired TOF**

**Indication for reoperation**

1. Free pulmonary regurgitation associated with
   - Progressive or moderate-to-severe RV enlargement (RV end-diastolic volume >170 mL/m²)
   - Moderate-to-severe RV dysfunction
   - Important TR
   - Atrial or ventricular arrhythmias
   - Symptoms such as deteriorating exercise performance
2. Residual VSD with $Q_p/Q_s$ > 1.5:1
3. Residual pulmonary stenosis with RV pressure at least >2/3 systemic pressure
4. Significant AI with symptoms and/or progressive LV dysfunction
5. Aortic root enlargement >55 mm
6. A large RVOT aneurysm or evidence of infection or false aneurysm
7. Sustained atrial flutter or fibrillation, or sustained ventricular tachycardia
8. Combination of residual VSD and/or residual pulmonary stenosis and regurgitation

Data from Silversides CK, Kiess M, Beauchesne L, et al. Canadian Cardiovascular Society 2009 Consensus Conference on the management of adults with congenital heart disease: Outflow tract obstruction, coarctation of the aorta, tetralogy of Fallot, Ebstein anomaly and Marfan syndrome. *Can J Cardiol* 2010 Mar;26(3): e80–e97.

### PULMONARY INSUFFICIENCY, RIGHT VENTRICULAR DYSFUNCTION AND PULMONARY VALVE REPLACEMENT

As the clinical significance of pulmonary insufficiency increases overtime following TOF repair, so does RV chamber size and compliance.[52] Progressive dilatation can result in a decrease in systolic function. At a certain point, these changes become irreversible even if volume overload is eliminated by pulmonary valve replacement (PVR). The risk of requiring PVR is constant and is approximately 0.8 percent/year over 30 years.[42] Our series of PVR in patients with severely dilated (mean RV end-diastolic volume index of 227 mL/m²) and dysfunctional RVs showed that PVR failed to reverse RV dilatation and RV systolic function.[53] No RV that had an end-diastolic volume >180 mL/m² had remodeling to a normal size subsequent to PVR.[54] It is therefore important to timely intervene with PV implantation while RV dilatation and dysfunction are still reversible. As shown in Table 68-1, our current criteria for PVR include RV end-diastolic volume >170 mL/m², moderate-to-severe RV dysfunction, QRS duration >180 msec, and/or decrease in exercise tolerance. A decision for borderline patients who meet some but not all of these criteria is still subjective. We prefer to see at least two criteria met. When performed before irreversible dysfunction occurs, PVR improves symptoms and decreases RV end-diastolic and end-systolic volumes. Ejection fraction of the RV generally does not change significantly after PVR.[54] RV remodeling surgery, that is, surgical plication of the noncontractile portion of RV at the time of PVR may improve RV ejection fraction in these patients.[55] There is some but not strong evidence to show improved exercise tolerance after PVR.[56] There is no clear benefit of PVR on survival, and recent studies show that PVR does not reduce the risk of ventricular tachycardia and death compared to matched controls.[57] Percutaneous PV insertion is an alternative option, but is currently limited to patients whose PV annulus is 22 mm in diameter or smaller.[51] Survival after PVR is 92 to 95 percent at 5 years and 76 to 86 percent at 10 years.[54,58]

### ANATOMIC RESIDUAL LESIONS

Up to 15 to 20 percent of patients who require late reoperation do so for reasons other than pulmonary regurgitation.[47] The next most frequent lesions are residual VSD and recurrent/residual RVOTO.[42,47,48] Indication for residual VSD closure is a $Q_p/Q_s$ > 1.5:1 or the presence of residual VSD with $Q_p/Q_s$ <1.5:1 with significant pulmonary stenosis or regurgitation. Surgical indication in case of RVOTO is an RV systolic pressure chronically greater than two-thirds of the systemic (Table 68-1). Branch PA stenosis is also common in repaired patients, and is typically managed by balloon angioplasty and/or stent placement. It is rare for isolated branch PA stenosis to require surgical intervention; patch enlargement for stenotic branch PA is, however, undertaken as a concomitant procedure at the time of PVR or intervention for RVOTO. Severe symptomatic tricuspid regurgitation (TR) can be an isolated

indication for surgery. More importantly, TR that is more than mild-to-moderate should be treated at the time of PVR.

### ARRHYTHMIAS AND SUDDEN DEATH

The incidence of arrhythmias late after TOF repair is substantial: Forty-three percent of patients have sustained arrhythmias at 30 years after complete correction.[59] Atrial arrhythmias are present in 20 percent of patients and are mainly represented by atrial reentrant tachycardia, followed by atrial fibrillation. Predictors for the development of atrial arrhythmias on multivariate analysis include reduced left ventricular ejection fraction, older age, number of cardiac surgical interventions, hypertension and right atrial enlargement.[59] Pharmacological therapy including β-blocker, digoxin, and amiodarone is the first line of therapy. Surgical cryoablation or right-sided Maze procedure[60] at the time of PVR or other reoperations is an effective means to reduce the risk of recurrence of atrial arrhythmias.[61]

Ventricular tachycardia occurs in 15 percent of patients during the same time interval. They are mainly treated with amiodarone and β-blockers. Approximately 10 percent of patients will subsequently require placement of an implantable cardioverter defibrillator for ventricular tachycardia refractory to medical treatment. Independent risk factors for ventricular tachycardia on multivariate analysis include number of cardiac surgeries, long QRS duration and reduced left ventricular diastolic function. Intraoperative electrophysiological mapping and surgical ablation is an option in patients with ventricular arrhythmias associated with pulmonary insufficiency and RV dilatation/dysfunction.[61] As mentioned above, PVR transiently shortens the QRS interval if the preoperative QRS duration is <180 msec; this effect is usually not long-lasting. Overall incidence of sudden cardiac death is <0.2 percent. Prolonged QRS (greater than 180 ms) has been implicated as a risk factor for sudden death;[62] however, large studies have failed to show that QRS duration was an independent risk factor for sudden death due to relatively small number of events.

A permanent pacemaker for late conduction disturbance is necessary in 2 to 3 percent of patients.[48,59] Indications for implantation include AV block (66 percent), sinus node dysfunction (18 percent) and tachycardia/bradycardia syndrome (16 percent).[59]

Cardiac resynchronization therapy may improve RV function, and clinical studies have shown improved right and left ventricular function following institution of biventricular pacing.[63]

## TETRALOGY OF FALLOT WITH ABSENT PULMONARY VALVE SYNDROME

A minority of patients (3 percent) with TOF have only rudimentary or absent PV leaflets. This anatomical feature of the PV is usually associated with markedly dilated main and branch PAs.[18,64] Such massively dilated PAs frequently cause bronchial compression and bronchomalacia.[65] The intracardiac anatomic features are essentially similar to typical TOF. Patients with TOF/absent PV do also typically not have an arterial duct at birth.[66,67] Two clinical forms of TOF/absent PV have been described: (1) patients who present predominantly with respiratory distress in early infancy; (2) patients who present with cyanosis similar to classic TOF. About two-thirds of the patients have respiratory symptoms due to bronchial compression, and 40 percent of them will do so in early infancy, requiring urgent surgical intervention.[65] Some patients need preoperative mechanical ventilation or even extracorporeal membrane oxygenation (ECMO).[68] Transthoracic echocardiography is sufficient enough to visualize the intracardiac structures and abnormalities; however, additional tomographic or magnetic resonance imaging (MRI) demonstrates the degree and extension of bronchial compression and its relation to the PAs.

Early primary repair is indicated when neonates and infants present with moderate or severe respiratory symptoms. Patients with minimal or mild respiratory symptoms are treated according to standard TOF treatment algorithms. The goals of surgical repair for symptomatic infants are to relieve bronchial compression by aggressive reduction of the dilated branch and main PA and to reestablish competency of the PV. During surgical correction, a strip of the dilated PAs is resected from hilum to hilum. Transection of the ascending aorta helps to expose the entire central PA.[69] Mobilization, suspension, and even anterior translocation (Lecompte maneuver) may be necessary in addition to PA size reduction to relieve bronchial compression.[70] Our preference is to use a homograft or bovine jugular vein valved conduit to achieve PV competency, whereas some centers routinely use a transannular patch as a method of RVOT reconstruction. Our clinical experience with 61 patients with TOF/absent PV operated between 1982 and 2006 has shown a survival of 93 percent at 5 years and 87 percent at 10 years after repair. All three operative deaths in this series (5 percent) occurred in neonates with severe bronchial compression. Reoperation is common (up to 40 percent at 10 years), and is mainly required because of structural failure of the RV-PA conduit or somatic overgrowth of the conduit by the patient.

## TETRALOGY OF FALLOT WITH ATRIOVENTRICULAR SEPTAL DEFECT

Up to 2 percent of patients with TOF have anatomic features of AVSD (see Chapter 66). In addition to anterior deviation of the infundibular septum and RVOTO, these hearts disclose ventricular inlet abnormalities, namely common AV junction with a common AV valve.[71] A large VSD with inlet extension is present. The inlet abnormality makes the left ventricular outflow unwedged and narrowed ("goose neck" appearance on the angiogram). Approximately 80 percent of patients with TOF/AVSD will have trisomy 21.[72] The direction of the shunt at the ventricular level can be from left to

right, bidirectional, or predominantly right to left depending on the degree of RVOTO. The direction of shunt at the atrial level through the ostium primum defect is typically from left to right, but it can be bidirectional because of hypertrophy and diminished compliance of the RV. Most patients with TOF/AVSD present with cyanosis rather than congestive heart failure.[71,72]

The classic surgical strategy utilized in infants with TOF/AVSD has been a staged repair, with initial placement of a systemic-to-pulmonary shunt and subsequent late repair. The systemic-to-pulmonary shunt improves saturation and may facilitate growth of both AV valves by inducing volume overload.[73] However, it may potentially worsen AV valve insufficiency as well as ventricular hypertrophy, which may complicate definitive repair. Our current approach is to perform primary repair after 3 or 4 months of age, although we would prefer for the infant to reach 6 to 8 months of age if possible. The left AV valve in a cyanotic infant with TOF/AVSD can be quite small due to low $Q_p/Q_s$. If there are additional anatomic risk factors, such as unbalanced ventricles and AV valve orifice, poorly formed or narrowly spaced papillary muscles or preoperative significant left AV valve regurgitation, catheter-based intervention as a temporary palliation may be preferred.

The repair can be accomplished either by transventricular[72] or transatrial–transpulmonary approach.[74] The same surgical principles outlined above are applied to relieve the RVOTO; given the high prevalence of a hypoplastic infundibulum in this subgroup, up to 70 percent of the patients will require a transannular patch.[72] Our preferred approach is that of repairing the AVSD with a two-patch technique (See Chapter 66). We also prefer to maintain pulmonary competency by insertion of an RV-to-PA conduit if the native PV is of insufficient size. Intermediate-term competence can also be obtained by insertion of a polytetrafluoroethylene monocusp valve. Between 1981 and 1997, we have corrected 38 patients with this particular combination of anomalies with an early mortality of 6 percent.[72]

## SUMMARY

With appropriate understanding of the anatomy and with an appropriately aggressive treatment algorithm, most patients with TOF including symptomatic neonates survive intracardiac repair in infancy without the need for a staged approach to correction. Preservation of long-term RV function is and PV competency is of prime importance for this population in order to achieve long-term freedom from complications and need for reintervention.

## TETRALOGY OF FALLOT BOARD REVIEW QUESTIONS (CHAPTER 68)

1. What is the essential underlying anatomic feature of tetralogy of Fallot?
   A. Anterior deviation of the infundibular septum
   B. VSD
   C. RV hypertrophy
   D. Aortic override
   E. Pulmonary stenosis

2. Which is not a correct treatment strategy for a critically cyanotic neonate with tetralogy of Fallot?
   A. Administration of $PGE_1$
   B. Intubation and mechanical ventilation
   C. Prompt surgical intervention
   D. Balloon atrial septostomy
   E. Ductal stenting

3. What is the best treatment strategy for a 1-month-old infant with TOF without cyanosis?
   A. Immediate definitive surgical repair
   B. Immediate stent placement in the RV outflow tract
   C. Observe and electively operate at 5 to 6 months of age
   D. Administration of β-blocker
   E. Creation of a systemic to PA shunt

4. What are the treatment strategies for restrictive physiology of the RV following TOF repair?
   A. Spontaneous ventilation with minimal airway pressure
   B. Volume infusion to maintain high preload
   C. Adequate drainage from pleural and peritoneal spaces
   D. Avoid inotropes
   E. All of the above

5. What is not a late problem among the long-term survivors following surgery for tetralogy of Fallot?
   A. Mitral insufficiency
   B. RV dysfunction
   C. Arrhythmias
   D. Sudden death
   E. Pulmonary stenosis

## ANSWERS

1. **Answer: D.** The anatomy of TOF is essentially determined by the anterior deviation of the infundibular septum, which results in other features such as VSD, aortic override, and RVOT obstruction. Pulmonary stenosis and RV hypertrophy are also common anatomic features of this entity.

2. **Answer: E.** Ductal stenting will increase the amount of intracardiac mixing, which does not alleviate the cyanosis. Neonates with TOF who present with critical cyanosis often have duct-dependent pulmonary circulation. Administration of $PGE_1$ is the first line treatment for this condition. If the arterial duct is not patent, urgent surgical or catheter-based intervention is required.

3. **Answer: C.** Acyanotic patients with TOF do not require immediate intervention. Elective surgery can be done at 4 to 6 months of age or when cyanosis develops. Shunting is not indicated, as the patient is not cyanotic. β-blockade is useful in patients with cyanotic spells.

4. **Answer: E.** Restrictive physiology of the RV should be treated by minimizing afterload to the RV and by maintaining adequate preload. It is important to drain pleural and peritoneal cavities. Severe cases may need chest opening to improve diastolic filling of the RV.

5. **Answer: A.** Tricuspid, not mitral, insufficiency is a late complication. Other common problems among the long-term survivors mainly stem from chronic pulmonary insufficiency and subsequent RV dilatation and dysfunction. Significant RV dilatation and dysfunction are often related to arrhythmias and sudden death.

# Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals

*Malcolm J. MacDonald*
*Frank L. Hanley*

**KEY CONCEPTS**

- Epidemiology
  - Pulmonary atresia (PA) with ventricular septal defect (VSD) and major aortopulmonary collaterals (MAPCAs) is a complex lesion with great morphologic variability that represents approximately 2 percent of congenital heart defects, with a prevalence of 0.07 per 1000 live births.
- Morphology
  - This particular malformation entails the association of atresia of the pulmonary valve, a tetralogy-type VSD, and pulmonary collateral vessels that usually originate from the descending thoracic aorta.
- Clinical features
  - Neonates born with PA, VSD, and MAPCAs may have very unpredictable presentation owing to the anatomic variability of the lesion. Patients may be minimally symptomatic or severely cyanotic, or may develop congestive heart failure (CHF) from pulmonary overcirculation.
- Diagnosis
  - Diagnostic evaluation includes echocardiography, cardiac catheterization, and, in selected cases, computed tomographic angiography (CTA) to clarify the anatomy of the MAPCAs.
- Treatment
  - Definitive treatment is surgical. The ultimate goal of surgical therapy is creation of separated, in-series pulmonary and systemic circulations. Achievement of this goal requires unifocalization of the vascular systems, VSD closure, and reconstruction of the right ventricular outflow tract (RVOT). "Single-stage" unifocalization with or without concurrent VSD closure is favored by the authors.
- Outcomes
  - In over 460 patients managed by the authors' protocol, complete unifocalization via median sternotomy was achieved in 76 percent of patients. Intracardiac repair (VSD closure) was possible at initial operation in 56 percent. Ninety-five percent of patients were completely repaired by 5 years of age. Recent operative mortality was 2.3 percent, with a 5-year actuarial survival of 85.5 percent.

## INTRODUCTION AND BACKGROUND

Pulmonary atresia (PA) with ventricular septal defect (VSD) and major aortopulmonary collateral arteries (MAPCAs) is a complex lesion with great morphologic variability. The lesion is characterized by atresia of the pulmonary valve, a tetralogy of Fallot-type VSD, and pulmonary collateral vessels originating from the aorta. The major variability occurs in the pulmonary vascular circulation. Development of the pulmonary arterial system occurs by fusion of the left and right sixth dorsal aortic arches with the plexus of systemic arteries carried by the lung buds from the foregut. Failure of the normal fusion process results in PA. Development of the true pulmonary arteries (PAs) is variable and depends on the point in gestation at which connection of the lumen of the true PAs with the right ventricle (RV) is lost.[1] True central

PAs vary from normal size to absent. The mean diameter of the central PAs in the author's series of over 300 patients was 1.5 mm. A small central confluence is usually present. When confluent PAs are present, there is typically no ductus arteriosus. When the right and left main PAs are discontinuous, bilateral ducti may exist with the right typically originating from the innominate or subclavian artery.

Persistent connections from the aorta (MAPCAs) probably originate from splanchnic vessels. Collaterals vary widely in origin, course, size, and histologic appearance. The mean number of collaterals in the author's series was 3.8 ± 1.4. Most commonly, aortopulmonary collaterals originate from the proximal descending aorta. There is great variability in the way in which MAPCAs connect to the pulmonary circulation. A given lung segment may have its blood supply uniquely derived from the true PA system, MAPCAs, or both; collateral vessels may supply anything from a small proportion of the total lung parenchyma to the majority of the pulmonary vascular bed. Variable degrees of obstruction of the collateral vessels may occur, and obstructions may be inconsistent in their location—proximally or distally—within the vessels. Diffuse collateralization from the systemic circulation, especially the chest wall, is common, particularly after surgical intervention.

The pulmonary microcirculation is the healthiest at birth, and declines progressively afterward. The natural history of the MAPCAs is to frequently progress to stenosis, which may in turn result in distal microvascular hypoplasia. In the absence of stenosis, the systemic pressure within the pulmonary vasculature may cause pulmonary vascular obstructive disease (PVOD). Surgical interventions requiring the use of systemic-to-PA connections (e.g., Blalock–Taussig shunt or aortopulmonary window) may also result in PVOD due to the persistence of pulmonary vascular flow at systemic pressure.

The intracardiac anatomy is typified by an anteriorly malaligned VSD (hence the alternative designation as tetralogy of Fallot with PA). Although the ventricles are typically normally developed, the infundibulum of the RV may be quite small. There are normal atrioventricular and ventriculoarterial connections (Fig. 69-1).

## EPIDEMIOLOGY, MORPHOLGY, AND ASSOCIATED ANOMALIES

PA with VSD represents approximately 2 percent of congenital heart defects. In the Baltimore–Washington Infant Study, a prevalence of 0.07 per 1000 live births was reported.[2] PA with VSD accounted for 1.4 percent of all forms of congenital heart disease, and 20.3 percent of all forms of tetralogy of Fallot. Of patients with PA and VSD, approximately 60 percent have a ductus arteriosus and normal branch PAs, and 40 percent have MAPCAS. Infants of overtly diabetic mothers are at approximately 10-fold risk of developing PA with VSD. Genetic factors are considered likely to be etiologically contributory, since an increased risk of occurrence to siblings (2.5–3 percent) or to children of parents with tetralogy of Fallot (1.2–8.3 percent) has been observed.

Associated cardiac and extracardiac anomalies may occur. Commonly associated cardiac anomalies include secundum atrial septal defects, coronary anomalies, and multiple VSDs. Other less common cardiac anomalies may also occur.

A significant proportion of patients with PA and VSD have associated syndromes or extracardiac anomalies. Such associations include the VATER syndrome, Alagille syndrome, DiGeorge (velocraniofacial) syndrome, and trisomy 21 among others. There may be an unusually high incidence of tracheobronchial anomalies, particularly the origin of the right upper lobe bronchus from the trachea, which may result in postoperative respiratory complications involving the right upper lobe.

## CLINICAL FEATURES

Children born with PA, VSD, and MAPCAs may have very unpredictable presentation due to the anatomic variability of the lesion. Approximately 80 percent are minimally symptomatic, and have only mild cyanosis. The VSD is typically unrestrictive. Patients with valvar atresia but little collateralization may be severely cyanotic. Patients with severe atresia and/or hypoplastic true PAs but extensive collateralization may be minimally symptomatic and plethoric. Such patients may eventually develop congestive heart failure (CHF) due to pulmonary overcirculation, or may develop progressive cyanosis. Cyanosis occurs due to paucity of pulmonary flow because of inadequate collaterals, stenosis of the collaterals, or pulmonary microvascular obstructive disease. Development of these complications may occur at very variable rates, resulting in unpredictably delayed presentation. Cyanotic spells may occur. In patients with PA these occur due to decreases in systemic vascular resistance resulting in markedly decreased pulmonary blood flow [rather than due to RV infundibular spasm, as is usual in tetralogy without atresia]. Late presentation may occur[3] and may include polycythemia, "clubbing," cerebral embolism, and cerebral abscesses.

## DIAGNOSTIC EVALUATION

Following presentation with the symptoms described above, patients require complete diagnostic investigation. Pulse oximetry is a useful indicator of adequacy of pulmonary blood flow. Patients with oxygen saturation greater than 85 to 90 percent will typically have well-developed collateral systems and are at risk for CHF. Patients with oxygen saturations of less than 75 to 80 percent may have poorly developed pulmonary vascular and collateral systems.

Chest radiographs may demonstrate pulmonary plethora or hypoperfusion of the lung fields. The electrocardiogram is

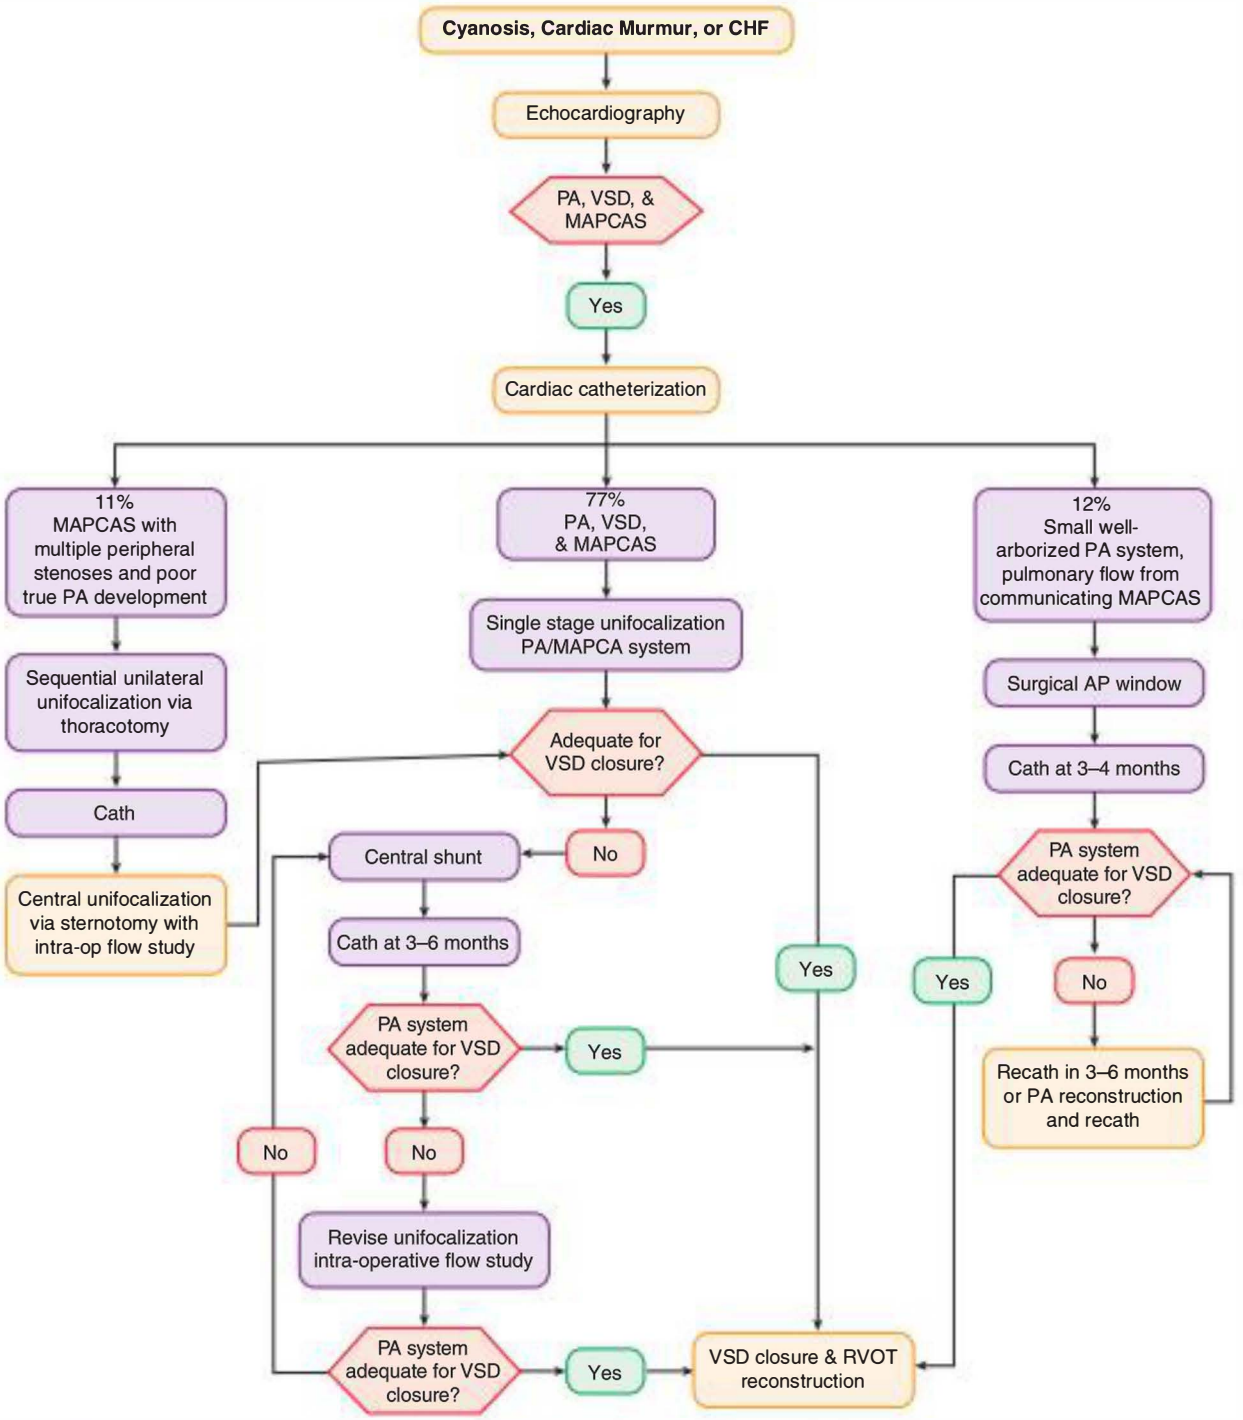

**FIGURE 69-1** Clinical decision-making algorithm in pulmonary atresia with VSD and multiple aortopulmonary collaterals. PA, pulmonary atresia; VSD, ventricular septal defect; MAPCA, major aortopulmonary collateral arteries.

typically normal at birth but will gradually develop evidence of RVH comparable to tetralogy of Fallot. Echocardiography is highly reliable in making the diagnosis of PA, VSD, and MAPCAs, but is typically inadequate for complete evaluation. Echocardiography is sensitive for detection of aortopulmonary collaterals, but inadequate for complete delineation, which is essential for surgical management. The intracardiac anatomy is well delineated by echocardiography. Echocardiography may also show other associated cardiac lesions including ASD or a patent foramen ovale (PFO), multiple VSDs, and coronary anomalies.

Cardiac catheterization is essential in evaluation of the true PAs and aortopulmonary collateral system (Fig. 69-2). It is particularly important to clarify the complete true pulmonary arterial and aortopulmonary collateral distribution. Evaluation of the true PA system may be difficult unless there is duct-dependent pulmonary circulation or a connection between a collateral and the true PA system. Retrograde venous wedge angiography may be needed to evaluate the true PA system in the absence of a ductus or connections between collateral and true PAs. The true central PA system appears as a "seagull"— like vascular structure best visualized in the left lateral or left anterior oblique view. Following intervention, repeated cardiac catheterization is essential to assess results and to plan for subsequent interventions when staged repair is necessary. In addition to imaging, acquisition of hemodynamic data is important. Presence of elevated distal pressure within collateral vessels (mean pressure greater than 20–25 mm Hg) suggests significant PVOD within the affected lung segments. Evaluation of RV pressure may be helpful when planning VSD closure in patients who have been managed by complete unifocalization and placement of an RV–PA conduit without VSD closure, as is advocated by some authors. RV pressure less than 50 percent systemic (under optimal circumstances) or, at most, up to 75 percent systemic suggests that the VSD can be closed. After unifocalization and right ventricular outflow tract (RVOT) reconstruction without VSD closure, the presence of a left-to-right shunt at the ventricular level indicates adequacy of the pulmonary vasculature to tolerate at least one full cardiac output and suitability for VSD repair.

Computed tomographic angiography (CTA) and magnetic resonance imaging are gaining prominence in evaluation of anatomy of complex collaterals in selected circumstances such as in neonates and in older postoperative patients. Due to difficulty in evaluation of angiograms, three-dimensional CTA and MRI reconstructions may be helpful for detailed anatomic assessment and operative planning.

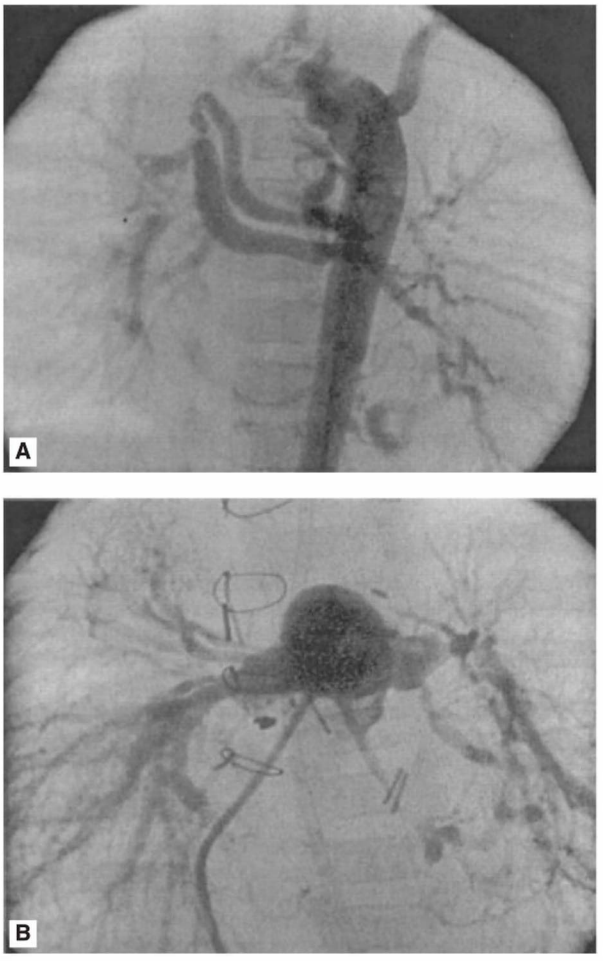

**FIGURE 69-2** Aortic arch angiogram before (**A**) and main pulmonary arteriogram after (**B**) one-stage complete unifocalization in a 2-month-old infant with five MAPCAs and 1.5-mm confluent PAs. VSD was left open. Postoperative angiogram demonstrates complete perfusion of both lungs. (Reproduced with permission from Reddy VM, McElhinney DB, Amin Z, et al. Early and intermediate outcomes after repair of pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries: Experience with 85 patients. *Circulation* 2000;101:1826.)

## GOALS AND PRINCIPLES OF THERAPY

The initial management of patients presenting with PA, VSD, and MAPCAs is based on medical stabilization of the patient so that full evaluation and proper therapeutic planning can be undertaken. Some patients with excessive pulmonary blood flow may require management of CHF. Interventional cardiac catheterization is important in both short- and long-term management. Interventional procedures may include coil occlusion of collaterals providing duplicate flow to individual pulmonary segments and balloon dilatation of stenoses. Pulmonary valve perforation and dilatation may be performed in the very rare instance of PA with VSD and an adequately developed main pulmonary arterial system.

The ultimate goal of surgical therapy is the creation of separated in-series pulmonary and systemic circulations. Ideal age for repair of this lesion is unknown. If the patient is well balanced physiologically, we prefer to perform the repair

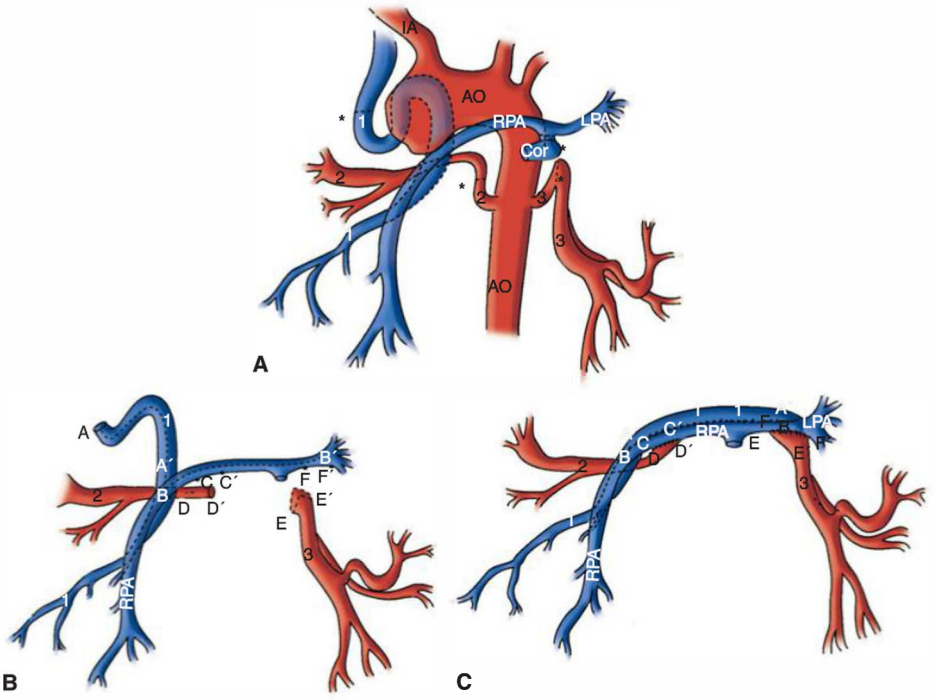

**FIGURE 69-3** Anatomy of pulmonary blood supply and unifocalization in a 3.5-month-old child who underwent one-stage complete unifocalization and repair of tetralogy of Fallot with MAPCAs. **A.** Illustration of pulmonary blood supply with left pulmonary artery (LPa) and right pulmonary artery (RPa), a coronary collateral (COR) connecting to the true pulmonary artery, and three MAPCAs (1–3) from the Innominate artery (IA) and descending aorta (AO). **B.** MAPCAs are opened along the dashed lines A–A′, D–D′, and E–E′, whereas the true pulmonary arteries are filleted open from hilum to hilum (B–B′). **C.** Complete unifocalization and reconstruction of the pulmonary artery is completed with full native tissue continuity. Collateral 1 A–A′ is anastomosed side to side to the incision B–B′ in the true pulmonary artery as a long onlay. Collateral 2 is anastomosed end to side to the undersurface of the RPA from D–D′ to C–C′. Collateral 3 is anastomosed end to side to the undersurface of the LPA from E–E′ to F–F′. (Reproduced with permission from Reddy VM, Liddicoat JR, Hanley FL. Midline one-stage complete unifocalization and repair of pulmonary atresia with ventricular septal defect and major aorto-pulmonary collaterals. *J Thorac Cardiovasc Surg* 1995;109:832–845.)

when the patient is between 3 and 6 months of age, and perform then a single-stage repair. There are many advantages of early one-stage repair. Cardiovascular physiology is normalized and cyanosis is corrected. The patient is protected against pulmonary hypertension related to high flow either through collaterals or through systemic shunts. The number of operations is reduced, reducing the complexity and morbidity of reoperative surgery. The major problem in management is the natural and intervened history of the MAPCAs and the complexity of surgical intervention on the pulmonary vascular bed (Fig. 69-3).

Reconstruction must achieve unobstructed flow from the RV to the PA system. Achieving this goal requires "unifocalization" of the vascular systems, recruiting as much of the true PA- and MAPCA-supplied systems as possible and, eventually, closure of the VSD. The most important physiologic factor indicating favorable ultimate outcome is postrepair RV pressure, which depends on the number of lung segments included in the pulmonary vascular bed and the status of the pulmonary microvasculature. The goal of early intervention is to incorporate as many lung segments in the pulmonary vascular circuit as possible, and to close the VSD; this in turn maximizes the possibility that the pulmonary circulation is exposed to normal pulmonary arterial pressures.

Surgical approaches have included staged reconstruction via thoracotomies with subsequent pulmonary arterial centralization and ultimate VSD closure via sternotomy, staged reconstructions via sternotomies, and single-stage reconstruction.[4–9]

"Single-stage" unifocalization with or without concurrent repair of the VSD is favored by the authors.[10–12] The operation is achievable via sternotomy in most patients, avoiding possible long-term complications of thoracotomy. In patients whose pulmonary arterial system is inadequate to support a full cardiac output due to distal stenosis or hypoplasia unifocalization of the collaterals and creation of a shunt from the ascending aorta to the unifocalized PA system is performed

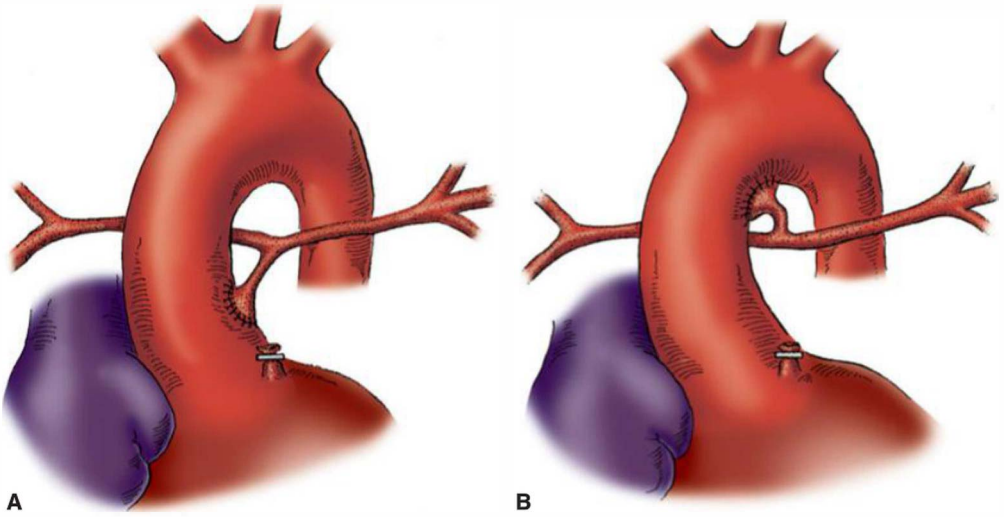

**FIGURE 69-4** Surgical aortopulmonary window. Ideal location for anastomosis varies according to patient-specific anatomic variables and may be dictated not only by pulmonary artery anatomy but also by aortic size and position. **A.** Most common anastomotic position at left posterolateral aspect of ascending aorta, just above sinotubular junction. **B.** Less commonly, the pulmonary artery confluence has better positional lie when located superiorly to the undersurface of the aortic arch. (Reproduced with permission from Rodefeld MD, Reddy VM, Thompson LD, et al. Surgical creation of aortopulmonary window in selected patients with pulmonary atresia and with poorly developed aortopulmonary collaterals a nd hypoplastic pulmonary arteries. *J Thorac Cardiovasc Surg* 2002;123:1147.)

whenever possible. The VSD is left open and early follow-up and reintervention is planned.

In a small minority of patients minute, centrally-confluent true PAs are present with a relatively complete arborization pattern to most or all lung segments. Pulmonary blood flow is, however, from MAPCAs which share dual supply vascular distribution with the true PAs. In these patients, we construct a neonatal "aortopulmonary window" by transecting the main PA close to the infundibulum and anastomosing the small main PA to the ascending aorta to encourage pulmonary vascular growth (Fig. 69-4).[13] Important MAPCAs are ligated. These patients are evaluated for intracardiac repair at 3 to 6 months of age. In a few patients, the majority of MAPCAs have multiple stenoses at the segmental and subsegmental branches. True PAs may or may not be present. This small subgroup of patients with PA, VSD, and MAPCAs are managed by sequential staged thoracotomies.

Patients who have severe cyanosis and inadequate collateralization or a pulmonary vascular bed that is not amenable to reconstruction, or patients who fail unifocalization and complete correction may eventually require pulmonary or heart–lung transplantation. Patients who have had bilateral thoracotomies who require pulmonary transplantation due to failure of unifocalization are very difficult subjects for transplant due to severe cyanosis and development of extensive collateral vessels from the chest wall. Thoracotomy approaches to pulmonary vascular reconstruction are therefore only used when unavoidable.

## SURGICAL THERAPY

The primary objective of surgery is to completely unifocalize the pulmonary arterial and MAPCA complex. Our current approach is to perform first intervention at 3 to 6 months of age (median age of first operation in the authors' series was 8 months). Complete bilateral unifocalization via median sternotomy can usually be achieved (85 percent in the authors' series). Intracardiac repair is achieved as early as possible (56 percent at first operation and 83 percent within 2 years in the authors' series). In patients who are severely cyanotic or over-shunted, earlier intervention is feasible and may be necessary. Customizing the therapeutic approach to the individual patient and creative, meticulous, surgical techniques are essential in achieving good surgical outcomes.

Timing of the VSD closure may be a significant challenge.[14] Patients who have previously undergone PA reconstruction and unifocalization who have demonstrated satisfactory pulmonary vascular growth on follow-up angiography are typically amenable to VSD closure and RV–PA conduit RVOT reconstruction. When there is a question regarding the adequacy of the pulmonary bed to accommodate a full cardiac output, an intraoperative flow study has been used by the authors. When the VSD is closed, a PFO is left to allow for right-to-left shunt in the event of elevated RV pressure in the early postoperative period.

Other authors have advocated using an "adjustable VSD."[15] The VSD is closed with a patch, leaving a deliberate defect in the superior portion of the patch which is encircled with a

purse-string suture. The RVOT is reconstructed, and a pressure-monitoring cannula is placed in the RV. Occlusion of the deliberate "residual" VSD is then attempted. If the VSD can be occluded with resulting RV pressure half or less of the systemic pressure the defect is completely closed. Otherwise the defect is maintained patent to allow for right-to-left shunt. The purse string suture is enclosed in a tourniquet snare and brought to the subcutaneous tissue where it may be easily located and exposed later.

## Operative Technique

The surgical approach to the mediastinum favored by the authors is via a wide midline incision and a median sternotomy. Subtotal thymectomy is performed. The right pleura is widely opened anterior to the phrenic nerve, the right lung is lifted out of the pleural cavity, and the right-sided collaterals are identified and dissected. Similarly, the left pleura is opened and the left-sided collaterals are identified and dissected. Collaterals are rerouted by opening the pleura on both sides posterior to the phrenic nerves. The descending aorta is exposed in the posterior mediastinum and all the collaterals from it are identified, dissected, and controlled. The pericardium is then opened, partial anterior pericardiectomy is performed and the excised portion of pericardium is preserved in glutaraldehyde (0.6 percent). The native PAs, if present, are completely mobilized from hilum to hilum. Any further collaterals from the upper descending aorta are identified and dissected in the subcarinal space between the tracheobronchial angle and the roof of the left atrium by an approach between the right superior vena cava and the aorta. The floor of the pericardial reflection in the transverse sinus is opened and the posterior mediastinal soft tissues are dissected to expose the aortic segment and the collaterals in this region. This is an important maneuver for gaining access to collaterals, which quite often arise from this location (Fig. 69-5). Opening this space also provides the most direct avenue for collateral rerouting for direct tissue-to-tissue anastomosis. In patients in whom collaterals originate from the aortic arch or the neck vessels the vessels are exposed and mobilized. All collaterals are controlled with snares or neurovascular clips before cardiopulmonary bypass is instituted.

As many collaterals as possible are permanently ligated at their origin, mobilized, and unifocalized without cardiopulmonary bypass. When the patient's oxygenation reaches an unacceptably low level, cardiopulmonary bypass is instituted, and the remainder of the collaterals are unifocalized at mild-to-moderate hypothermia with the heart beating. A calcium-supplemented blood prime is used in the cardiopulmonary bypass pump circuit to maintain normal cardiac function. During unifocalization, emphasis is placed on avoiding synthetic or allograft conduits in the periphery and on achieving unifocalization by native tissue-to-tissue anastomosis. Surgical techniques used to achieve native tissue-to-tissue continuity may include side-to-side anastomosis of collaterals to the central PAs (thus augmenting the hypoplastic true PAs),

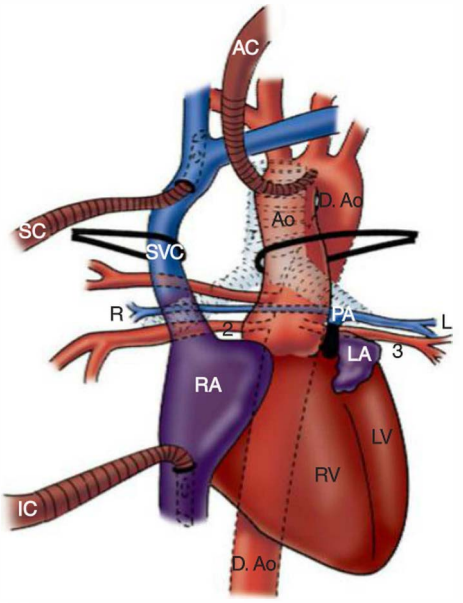

**FIGURE 69-5** The transverse sinus is an important avenue for dissecting, routing, and unifocalizing the collaterals that arise from the descending aorta in the region of the subcarinal space. In this diagram, the MAPCAs are depicted anterior to the tracheobronchial tree. However, collaterals in this region have a variable relation to the extraparenchymal airways and esophagus, and the technique of rerouting and unifocalization must be individualized to optimize the lie of each collateral. side-to-side anastomosis of collateral-to-collateral- or of collateral-to-peripheral true PAs, end-to-side anastomosis of collateral-to-collateral or of collateral-to-true PA, anastomosis of a button of aorta (giving rise to multiple unobstructed collaterals) to the native PAs, end-to-end- or end-to-side anastomosis of collateral-to-central conduit, allograft patch plasty of stenotic distal segments of the collaterals or allograft patch augmentation of the reconstructed neo-central PAs. These anastomoses are achieved directly by bringing collaterals either through the transverse sinus, below the hilum of the lung, or above the hilum to achieve the optimal anatomic result, and by making use of as much of the collateral length as possible. Tension-free tissue-to-tissue anastomosis is essential and collateral length is therefore critically important and consequently given the highest priority. If a discrete stenosis is present in the midportion of a collateral, the collateral is used and the stenosis is managed by side-to-side reconstruction at the stenotic area or, if that is not possible,

by patch augmentation. Collaterals that provide a dual supply to a lung segment together with the true PA supply are unifocalized in order to build up the size of the reconstructed PAs. Particularly difficult aspects of unifocalization may occasionally be completed after aortic cross-clamping and cardioplegic arrest is induced, at moderate hypothermia. If use of patch material is unavoidable we use it noncircumferentially so that the growth potential of the native tissue is preserved. We limit the use of circumferential nonviable conduits to the central mediastinum. Essential concepts necessary to achieve this type of unifocalization are flexibility regarding reconstruction, aggressive mobilization, maximizing the length of the MAPCAs and creative rerouting.

In a total of over 1500 unifocalized collaterals in our experience, only a small number have been reconstructed with circumferential nonviable conduit (expanded polytetrafluoroethylene). In patients with absent or string-like true PAs, a non-valved allograft conduit may sometimes be necessary to reconstruct the central left and right PAs. In such patients, in whom growth potential is an issue, the hilar regions are reconstructed only with native tissue (using the techniques described) and the conduit serves as the main left and right PAs with the graft limited to the pericardial cavity.

Following completion of the unifocalization (when indicated) the VSD is closed. Suitability for closure of the VSD may be determined by preoperative studies, or may require an intraoperative flow study to assess the total resistance of the pulmonary vascular bed. The flow study is performed while on cardiopulmonary bypass. The recreated main PA supplying the entire pulmonary vascular bed is cannulated and perfused using a calibrated pump head from the cardiopulmonary bypass pump. Flow from the pump head is progressively increased up to the equivalent of at least one cardiac output. A pressure catheter is placed in the PA system, and the left atrium is vented. If the mean PA pressure is less than 25 mm Hg, the VSD can be closed. If the mean pulmonary pressure is greater than 25 mm Hg a central shunt or a restrictive right-ventricle-to- PA conduit is created.

If VSD closure is indicated, a longitudinal ventriculotomy is made in the RV infundibulum and hypertrophied muscle bundles are resected. The VSD is closed with a glutaraldehyde-fixed autologous pericardial patch or a polyester (Dacron) patch. The right atrium is opened to inspect the atrial septum. An atrial septal defect or PFO, if present, is closed leaving a small unidirectional interatrial communication as a "pop-off" valve for right-to-left shunt of venous blood in case of postoperative RV dysfunction. In occasional cases with an intact atrial septum a small one-way interatrial communication is created. A homograft-valved conduit is tailored and used to connect the RV to the reconstructed neopulmonary arterial system. A valved bovine jugular vein conduit (Contegra®) may provide a useful alternative.[16] The distal conduit is anastomosed to the reconstructed PAs using a 6-0 or 7-0 monofilament nonabsorbable suture. The distal anastomosis may be performed prior to cardioplegic arrest in order to minimize ischemic time when the decision has been made to close the VSD. If needed, a distal extension of the conduit tissue can be shaped to augment the reconstructed central branch PAs. The proximal RV-to-conduit anastomosis is made with a continuous monofilament nonabsorbable suture by directly anastomosing the conduit around a portion of its circumference, and augmenting the anastomosis with a "hood" of either pericardium or homograft tissue to complete the anastomosis. The proximal anastomosis may be made after removal of the aortic cross-clamp and reperfusion of the heart during the rewarming period. A pressure-monitoring catheter is placed into the PAs across the RVOT. Following adequate rewarming, the patient is weaned from cardiopulmonary bypass with constant monitoring of the systemic arterial pressure, pulmonary arterial pressure, and atrial pressures. After separation from bypass, these pressures are measured continuously and transesophageal echocardiography is performed to ensure that there are no significant residual defects.

Bilateral pleural and mediastinal drains are placed and the sternum is closed. If bleeding or ventilation is a significant concern, we electively leave the sternum open and close the chest incision with a siliconized rubber (Silastic®) patch. Secondary sternal closure is performed on the second or third postoperative day once the patient is physiologically stable.

## POSTOPERATIVE MANAGEMENT

Postoperatively patients are ventilated, kept well sedated and, if necessary, pharmacologically paralyzed until hemodynamically stable and on minimal ventilatory support. Inotropic support is provided using dopamine, milrinone, calcium chloride, and epinephrine infusions as needed. Important postoperative problems include pulmonary parenchymal reperfusion injury, pulmonary hemorrhage, bronchospasm, and phrenic nerve injury. Reperfusion injury most typically occurs in pulmonary segments that are severely hypoperfused preoperatively. Bronchospasm may occur due to extensive hilar and intraparenchymal dissection. Phrenic nerve injury is uncommon and can be avoided by meticulous attention during dissection. Splanchnic organ dysfunction has previously been described and was a problem in the early experience of the authors. The problem typically presents as acute hepatic dysfunction or, rarely, intestinal necrosis. It is now not common; maintaining perfusion pressure over 40 mm Hg during cardiopulmonary bypass appears to have been significantly contributory in resolving the problem.

### Postoperative Follow-up and Evaluation

After repair all patients are closely followed clinically. Routine echocardiography and nuclear pulmonary flow scans are performed at least every 3 months. In patients in

whom the VSD is left open or a shunt is made to the unifocalized pulmonary arterial system, a cardiac catheterization is performed approximately 3 months postoperatively. If the $Q_p/Q_s$ ratio is over 2:1 the VSD is closed. If less than 2:1 the pulmonary arterial system is assessed for stenotic lesions that may be amenable to percutaneous catheter based or surgical intervention. Following VSD closure, the status of the conduit and of the peripheral PAs are closely followed by serial clinical and echocardiographic evaluation in order to evaluate for stenosis or insufficiency. Cardiac catheterization is performed electively approximately 1 year following complete repair.

## CURRENT OUTCOMES

Reddy et al. reported 85 patients with PA, VSD, and MAPCAs.[12] Fifty-six underwent complete one-stage unifocalization and intracardiac repair. In 23 patients the VSD was left open at the time of complete unifocalization. There were six early deaths and seven late deaths. Actuarial 3-year survival was 80 percent.

Rodefeld et al.[13] reported on patients with diminutive PAs who require creation of an aortopulmonary window. In the series of 18 patients with confluent diminutive PAs who underwent the procedure there was 100 percent early survival and 2 late deaths unrelated to the procedure. Follow-up angiography demonstrated excellent development of the true PAs.

Hanley et al. have now accumulated data on 462 patients with VSD and MAPCAs who were managed as described.[17] The cohort includes the patients previously described by Reddy et al. Median age at first surgery was 7.7 months. Initial operation was complete unifocalization via median sternotomy in 76 percent. Intracardiac repair was achieved at initial operation in 56 percent,. Ninety percent of patients were completely repaired at 5 years. Operative mortality for the most recent 9 years was 2.3 percent. Mortality for the entire series was 5.9 percent, with actuarial survival at 5 years of 85.5 percent. Surgical reintervention for PA reconstruction was required in 22.6 percent of patients.

## PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT AND MAJOR AORTOPULMONARY COLLATERALS BOARD REVIEW QUESTIONS (CHAPTER 69)

1. Which is correct regarding anatomy of pulmonary atresia with ventricular septal defect and major aortopulmonary collaterals (PA–VSD with MAPCAs)?
   A. A large central confluence of the main PAs is usually present.
   B. The MAPCAs probably originate from the splanchnic vessels.
   C. Most MAPCAs originate from the distal descending thoracic aorta.
   D. The VSD is typically posteriorly malaligned.
   E. The defect is not associated with the VATER syndrome.

2. Which is a correct clinical presentation of PA–VSD with MAPCAs?
   A. Over 80 percent are symptomatic at birth
   B. The VSD is usually restrictive
   C. Patients with extensive collaterals may have minimal symptoms
   D. Cyanosis is caused solely by pulmonary microvascular obstructive disease
   E. Cyanotic spells are due to RV infundibular spasm

3. Which is not required during cardiac catheterization for preoperative evaluation of PA–VSD with MAPCAs?
   A. Delineation of true PA anatomy
   B. RV pressures
   C. Assessment of collateral distribution
   D. Venous wedge angiography
   E. Selective coronary angiography

4. Which is correct regarding surgical technique for repair of PA–VSD with MAPCAs?
   A. Collaterals are rerouted by opening the pleurae anterior to the phrenic nerves.
   B. The native PAs should not be mobilized.
   C. Opening the floor of the pericardial reflection in the transverse sinus provides the most direct avenue for collateral rerouting.
   D. Collaterals should be controlled after instituting cardiopulmonary bypass.
   E. The majority of the collaterals are unifocalized after cross-clamping.

5. Which of the following is true for outcomes after surgical repair of PA–VSD with MAPCAs?
   A. Early mortality is 50 percent in patients requiring creation of an aortopulmonary window.
   B. About 75 percent of patients can undergo complete unifocalization at the initial operation.
   C. Intracardiac repair is achieved in less than 30 percent.
   D. Overall operative mortality is 10 to 15 percent.
   E. Surgical reintervention for PA reconstruction is required in less than 10 percent.

## ANSWERS

1. **Answer: B.** The MAPCAs probably originate from the splanchnic vessels. A small central confluence is usually present, and most of the MAPCAs originate from the proximal descending thoracic aorta. The VSD is typically anteriorly malaligned. The defect is associated with the VATER, Alagille, DiGeorge, and trisomy 21 syndromes.
2. **Answer: C.** Patients with extensive collaterals may have minimal symptoms. About 80 percent of patients have minimal symptoms and mild cyanosis. The VSD is usually unrestrictive. Cyanosis may be caused by pulmonary microvascular obstructive disease, inadequate collaterals, or collateral stenosis. Cyanotic spells are caused by decreases in systemic vascular resistance that result in markedly decreased pulmonary blood flow.
3. **Answer: E.** Selective coronary angiography is not necessary for evaluation of these patients. Delineation of both true PA and collateral anatomy is critical, with retrograde venous wedge angiography used in patients without connections between the collaterals and the true PAs. Assessment of RV pressures helps plan VSD closure strategy.
4. **Answer: C.** Opening the floor of the pericardial reflection in the transverse sinus provides the most direct avenue for collateral rerouting. Collaterals can also be rerouted by opening the pleurae posterior to the phrenic nerves. The native PAs should be extensively mobilized. Collaterals should be controlled prior to instituting cardiopulmonary bypass, and as many as possible should be unifocalized without cardiopulmonary bypass.
5. **Answer: B.** About 75 percent of patients can undergo complete unifocalization at the initial operation. All patients requiring creation of an aortopulmonary window survived the operation. Intracardiac repair is achieved in over 50 percent of patients at the initial operation. Overall current operative mortality is approximately 5 percent. Surgical reintervention for PA reconstruction is required in about 20 percent of patients.

# Pulmonary Stenosis and Pulmonary Atresia with Intact Ventricular Septum

*Cara L. Lawrence*
*Deborah J. Kozik*
*Mark D. Plunkett*

**KEY CONCEPTS**

- Pulmonary stenosis
  - Right ventricular outflow tract (RVOT) obstruction at the level of the pulmonary valve
  - Pulmonary annulus may be stenotic or normal.
  - Treatment is often with balloon valvotomy versus surgical valvotomy.
  - Recurrent stenosis and insufficiency is common with surgical or balloon valvotomy.
- Pulmonary atresia (PA) with intact ventricular septum (IVS)
  - Complex defect with complete absence of communication between right ventricle (RV) and pulmonary arteries
  - Characterized by varying degrees of RV and tricuspid valve hypoplasia
  - Multiple surgical interventions common in childhood
  - Surgical treatment strategies based on size and development of RV and tricuspid valve

## INTRODUCTION

**Pulmonary stenosis** (PS) at the valvar level accounts for 8 to 10 percent of all congenital heart defects. In most patients, the pulmonary valve is found to be dome-shaped, with commissural fusion and variable subvalvar right ventricular outflow tract (RVOT) obstruction. The pulmonary annulus may be normal in size or smaller than predicted, and a patent foramen ovale (PFO) or atrial septal defect (ASD) is usually present. Clinical presentation is variable. Although severe PS may present in the newborn period, most of these lesions do not manifest significant signs and symptoms until later in childhood. Clinical findings are directly related to the severity of the RVOT obstruction and the degree of shunting across the atrial septum. Timing of intervention is based on severity of clinical findings and is indicated when an RVOT gradient exceeds a mean of 50 mm Hg. Although balloon valvotomy has become the initial therapeutic intervention in most patients, surgical valvotomy still remains an important form of intervention in a subset of these patients. Both catheterization with balloon valvotomy and surgical valvotomy are associated with low morbidity and mortality and excellent long-term survival.

**Pulmonary atresia (PA) with intact interventricular septum (IVS)** is an uncommon defect, representing between 1 and 3 percent of all congenital heart lesions. By definition, there is no communication between the right ventricle (RV) and the pulmonary arteries and no antegrade pulmonary blood flow through the RVOT. Consequently, a patent ductus arteriosus (PDA) is essential for early survival. The defect presents with varying degrees of hypoplasia of the RV and tricuspid valve, and often involves RV-to-coronary artery fistulas (45 percent). In addition, the tricuspid valve may have an Ebstein malformation (10 percent), and a right ventricle-dependent coronary circulation (RVDCC) is found in 10 to 15 percent of patients.

In neonates with PA/IVS, surgical classification of RV hypoplasia into mild (more than two-thirds of normal), moderate (one-third to two-thirds of normal), and severe (less than one-third of normal), as well as accurate assessment of the TV annular diameter, is useful in directing surgical management. A similar classification strategy is used for surgical management in older children. This allows patients to be stratified into those who will most likely achieve a biventricular repair and those who are best suited for a single ventricle pathway.

# PULMONARY STENOSIS

## Definition

PS with IVS is characterized by RVOT obstruction at the level of the pulmonary valve. The pulmonary valve is typically dome-shaped, with commissural fusion of the leaflets and a small central orifice. The pulmonary annulus may be either normal in size or smaller than predicted by the patient's weight. The RV is usually of normal size and morphology but may develop RV hypertrophy very early in life. This progression of RV hypertrophy may lead to further obstruction of the RVOT at the infundibular level.

## Historical Note

The initial pathologic description of PS is credited to Morgagni in 1761. The first attempt at surgical treatment of this lesion is attributed to Doyen in 1913. In his report, Doyen described a transventricular valvotomy using a tenotomy knife with an unsuccessful outcome.[1] In 1948, Sellors and Brock reported successful blunt valve dilatation using a transventricular approach.[2] Several successful cases of open pulmonary valvotomy using systemic hypothermia and ventricular fibrillation also followed. Open pulmonary valvotomy with the use of cardiopulmonary bypass was successfully introduced in 1955. This remained the primary treatment for patients with PS until the technique of balloon valvotomy was introduced by Semb and associates in 1979. In 1982, Kan and associates at the Johns Hopkins Hospital first reported successful percutaneous balloon valvotomy in a patient with PS.[3] Balloon valvotomy has since become the mainstay of initial therapy for PS and has succeeded surgical therapy as a primary intervention in most patients.

## Epidemiology

Obstructive lesions of the RVOT are found in 25 to 30 percent of children with congenital heart disease. Isolated PS at the level of the pulmonary valve with an intact IVS accounts for approximately 8 to 10 percent of all congenital heart defects, with a slightly higher incidence in females. Without intervention, the onset of hypoxia and heart failure in neonates carries an extremely high mortality. There is a reported increased incidence of 2 to 4 percent in siblings of patients with this particular defect.

## Etiology and Pathogenesis

The etiology of this lesion is unknown. Failure of the pulmonary valve leaflets to form and separate adequately during embryonic development results in limited mobility and stenosis of the valve. The consequent turbulence of blood flow across this region during subsequent growth and development leads to dysplasia and fibrous distortion of the valve leaflets and further increases the degree of stenosis. RV hypertrophy develops secondarily and is directly related to the severity of the obstruction. Rarely, neonates may present with enlarged RVs and cardiomyopathy, associated with a very poor prognosis despite early intervention.

## Clinical Features

Neonates who present with critical PS in the newborn period develop severe cyanosis and congestive heart failure. The clinical findings are directly related to the severity of the stenosis as well as to the degree of right-to-left shunting across the interatrial septum. On physical examination, most children with PS present with a harsh holosystolic ejection murmur, an ejection click, and a palpable thrill over the pulmonic valve region. These neonates often appear irritable, tachypneic, and cyanotic due to shunting at the atrial level. Although severe PS may present in the newborn period, most of these lesions do not manifest significant clinical findings until later in childhood. The timing of intervention is usually determined by the severity of clinical findings and is indicated for a documented mean gradient of 50 mm Hg or greater across the RVOT. The results of treatment and long-term outcomes are directly related to the size of the RV and the patient's age at presentation.

## Laboratory and Diagnostic Features

In patients with PS, an electrocardiogram typically reveals right-axis deviation, prominent P waves, and RV hypertrophy. On the chest radiograph, prominent pulmonary artery (PA) shadows secondary to poststenotic dilatation may be observed. The cardiac shadow is usually normal except in severe cases with associated congestive heart failure. Transthoracic echocardiographic examination establishes the severity of the stenosis, the gradient across the RVOT, and the size of the ASD. Cardiac catheterization is performed to obtain additional diagnostic information, and in many patients to perform therapeutic intervention with a balloon valvotomy.

## Differential Diagnosis

The differential diagnosis includes all congenital heart defects that have RVOT obstruction as an anatomic finding. They include defects such as tetralogy of Fallot, PS with ventricular septal defect (VSD), PA/IVS, and all morphologic cardiac abnormalities characterized by infundibular obstruction. Echocardiography can easily delineate these defects in most patients and identify those with isolated PS with an IVS.

## Therapy

The medical management of these patients is similar to that for any neonate or child with RVOT obstruction. In the neonate with severe PS and cyanosis, ductal patency must be

maintained with prostaglandin infusion, and pulmonary vascular resistance must be reduced to ensure adequate pulmonary blood flow. Systemic hypotension is avoided as it may result in reduced ductal flow to the pulmonary arteries and lead to increased hypoxemia. These patients may also have dynamic obstruction in the infundibular region secondary to RV myocardial hypertrophy. Inotropic agents must therefore be used with caution as increased contractility may, in turn, worsen functional obstruction across the RVOT. This will result in further compromise of pulmonary blood flow. After initial stabilization, percutaneous intervention with balloon valvotomy is often performed. If this is unsuccessful in relieving the obstruction, surgical valvotomy can be then performed as either an open technique using cardiopulmonary bypass or with a transventricular approach using a dilator without bypass.

### OPERATIVE PROCEDURES

***Open Pulmonary Valvotomy Using Cardiopulmonary Bypass.*** Open pulmonary valvotomy is performed through a median sternotomy using cardiopulmonary bypass and bicaval cannulation. If present, the PDA is ligated or snared prior to the initiation of cardiopulmonary bypass. An aortic cross clamp is applied, and antegrade cardioplegia is administered through the aortic root to achieve myocardial arrest. If no ASD is present, cardioplegic arrest may be omitted and the procedure performed with the heart beating. Otherwise, the PFO or ASD is closed through a right atriotomy, either with primary suture closure or with a patch of autologous pericardium. A vertical pulmonary arteriotomy is then performed on the anterior wall of the main PA and extended down to the level of the pulmonary valve. The stenotic valve is inspected, and the fused commissures are carefully identified and incised with a No. 11 scalpel or fine vascular scissors. The incisions in the valve tissue should extend to the edge of the annulus (Fig. 70-1). Any valvular adhesions to the PA wall are sharply incised. A partial valvectomy may be necessary to remove thickened valve tissue or dense fibrous scarring on dysplastic leaflets. The infundibulum is then inspected through the valve for any subvalvular stenosis, and sharp infundibular resection may be performed if necessary. A dilator may be used to size the valve annulus and dilate the annular tissue. A transannular patch may be required if the annulus is small. The arteriotomy may be closed primarily or with a patch of autologous or bovine pericardium to reduce the risk of any residual obstruction.

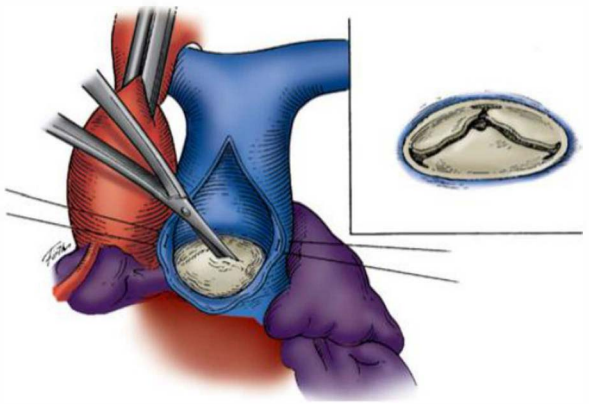

**FIGURE 70-1** Open pulmonary valvotomy using cardiopulmonary bypass. The pulmonary valve is approached through a vertical arteriotomy and the fused commissures are incised with a No. 11 scalpel or fine scissors.

***Off-Pump Transventricular Pulmonary Valvotomy.*** If no ASD is present, a pulmonary valvotomy may be performed through a median sternotomy using an off-pump transventricular technique. A purse-string suture is placed in the anterior wall of the RV. An angiocatheter connected to a pressure transducer is first introduced through the purse-string suture into the RV and then into the PA. Using the same technique, progressively larger metal dilators are then introduced through the RV wall and across the valve membrane. If the valve does not dilate easily, a long vascular clamp can be used to initially disrupt the valvar tissue. After adequate dilation is achieved, the purse string is tied and reinforced. If adequate relief of obstruction is not achieved, then open valvotomy may be performed with cardiopulmonary bypass, while a systemic-to-pulmonary shunt may be added to augment pulmonary flow for persistent cyanosis.

## Results

Most patients with PS are operated on electively and require routine pre- and postoperative care. In neonates, the management of acidosis, electrolyte derangements, and congestive heart failure should be aggressively pursued prior to surgery. Following surgical correction, there is often a residual gradient across the RVOT. Inotropic support should be used cautiously in the postoperative phase in order to avoid exacerbation of any residual infundibular obstruction. Mild and moderate residual gradients often resolve with age and the patient's growth.

Both balloon valvotomy and surgical valvotomy are associated with low morbidity and mortality rates and excellent long-term survival. Each has a significant incidence of recurrent stenosis, requiring additional early or late intervention. There is also a significant incidence of pulmonary valve insufficiency following both procedures. Mild-to-moderate pulmonary insufficiency is tolerated remarkably well by most patients, and its long-term clinical importance is a current topic of investigation. Although early mortality is not reportedly increased in patients with significant pulmonary insufficiency, the development of RV enlargement, RV dysrhythmias, and abnormal RV response to exercise may lead to increased long-term morbidity and mortality in these patients. Although overall survival following surgical treatment of isolated PS remains excellent, many patients undergo late reintervention after 30 years of follow-up.[4]

Therefore, these patients should be followed in the long term for the need of possible late reintervention or pulmonary valve replacement.

A multi-institutional study by Hanley and associates reported a 30-day survival of 89 percent and a 4-year survival of 81 percent for all modes of intervention in neonates with critical PS.[5] Of note, 26 percent of these patients required reintervention within 2 years for residual stenosis (defined as a gradient greater than or equal to 30 mm Hg). Following successful pulmonary valvotomy (after either initial intervention or reintervention), RV size approaches normal in more than 90 percent of these patients.

A report by Rao and associates on 80 patients treated initially with balloon valvotomy with follow-up between 3 and 10 years showed a freedom from repeat balloon valvotomy or surgery of 88 and 84 percent at 5 and 10 years, respectively.[6] Furthermore, surgical reintervention in older children is associated with minimal morbidity and mortality and excellent short- and long-term outcomes.

## PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

### Definition

PA/IVS is a congenital defect characterized by lack of communication between the RV and pulmonary arteries (PAs), resulting in no antegrade blood flow from the RVOT to the pulmonary arteries. A PDA is essential for maintaining adequate pulmonary blood flow and for early survival. Unlike PA with VSD, aortopulmonary collateral arteries are rarely found in patients with PA/IVS. The defect presents with varying degrees of hypoplasia of the RV and tricuspid valve and often involves fistulas from the RV cavity to the coronary arteries. Morphologically and functionally, the hypoplastic tricuspid valve usually varies in direct correlation with the size of the RV chamber. Coronary artery fistulas are present in up to 45 percent of cases and are more common in patients with severely hypoplastic RVs and small but competent tricuspid valves.[7] In addition, it should be noted that an Ebstein's malformation of the tricuspid valve might be present in 10 percent of cases.[8] These patients may present with marked cardiomegaly due to right atrial (RA) enlargement, severe tricuspid regurgitation, and a relatively large RV size.

### Historical Note

Surgical treatment of this PA/IVS was historically associated with very high morbidity and mortality. The low incidence of this defect combined with its extreme morphologic variability delayed the development of a standardized approach to surgical therapy.

The original Greenwold classification[9] of PA/IVS described this defect by two types of RVs: Type I with a hypoplastic RV and Type II with a normal or dilated RV. A further refinement of this classification was offered by Goor and Lillihei who described the tripartite morphology of the RV (a sinus inlet part, a trabecular part, and a conus or outlet portion) and used this as a basis for surgical therapy.[10] Bull and associates introduced as part of the pre- and intraoperative decision-making process the actual annular diameter of the tricuspid valve.[11] More recently, the surgical approach to PA/IVS has been based on a quantitative *Z*-score assessment of the tricuspid valve diameter.[12] The *Z*-score is determined by comparing the estimated diameter of the tricuspid valve (as measured by echocardiography) to the expected "normal" size and calculating the difference of the two values in standard deviations. In 1989, Billingsley and associates from UCLA introduced a surgically oriented classification of mild, moderate, and severe hypoplasia of the RV that is used today by many centers.[13]

Current surgical approaches to patients with PA/IVS are primarily based on the degree of RV hypoplasia and the degree of TV hypoplasia. In most patients, the degree of hypoplasia of these two structures correlate quite well and this facilitates the classification of these patients for purposes of surgical management. With a more systematic approach to this defect, increasing surgical experience, and improved diagnostic modalities, long-term outcomes have steadily improved.[14,7,15]

### Epidemiology

In contrast to other forms of RVOT obstruction, PA/IVS is an uncommon congenital cardiac malformation, representing between 1 and 3 percent of all congenital heart defects.[16] Without early surgical intervention, children with PA/IVS have an extremely high mortality rate. The natural history in untreated patients is a 50 percent mortality rate at 2 weeks of life and a mortality of approximately 85 percent at 6 months.[17] Death occurs as a consequence of severe hypoxemia and progressive metabolic acidosis secondary to closure of the ductus arteriosus and subsequent loss of pulmonary blood flow. In general, most children with PA/IVS will require multiple surgical interventions beginning in the neonatal period and continuing to one or more interventions later in life.

### Etiology and Pathogenesis

The etiology of this defect remains unknown. A failure of formation of a patent pulmonary valve during embryonic development results in a completely obstructed RVOT. The obstruction varies in form and may be a relatively thin tissue membrane at the end of a well-formed infundibulum or a thick muscular wall with a poorly formed, or absent outflow tract. Since the ventricular septum remains intact, forward blood flow through the RV is precluded. The growth and development of the RV and tricuspid valve (TV) in utero are severely compromised by this lack of forward flow. Both structures tend to follow a similar pattern of hypoplasia,

which is reflected by the TV annular size and the reduced size and volume of the RV chamber. RV-to-coronary artery fistulas are present in 45 percent of cases and are more common in those patients with a severely hypoplastic RV and a small competent TV.[13] In 10 percent of patients, the coronary circulation may be dependent on RV pressure for perfusion by way of fistulous communications associated with severe proximal coronary artery stenosis. Pulmonary blood flow in the neonate is dependent almost entirely on a PDA, as aortopulmonary collaterals are uncommon with this defect. Ebstein's malformation of the TV is seen in 10 percent of patients, adding significantly to the severity of the defect. Although no specific genetic pattern of inheritance has been identified, PA/IVS has been reported in siblings and associated with trisomy 18 or 21.[8]

## Clinical Features

Although prenatal diagnosis is increasing for this defect, most neonates with PA/IVS are still diagnosed shortly after birth. The diagnosis is often prompted by varying degrees of hypoxia and cyanosis within the first week of life. Physical examination is often remarkable for prominent venous pulsations. A significant systolic murmur may be indicative of tricuspid regurgitation. This must be differentiated from the continuous machinery murmur of a PDA. Prostaglandin $E_1$ ($PGE_1$) therapy should be initiated as early as possible to maintain ductal patency. Neonates with hypoxia and poor perfusion in spite of medical management should be evaluated for the presence of a restrictive ASD. In this case, balloon septostomy should be performed urgently to relieve the obstruction at the atrial level. Neonates with severely hypoplastic RVs may also require open atrial septostomy. Classification of the defect is determined by echocardiography. Cardiac catheterization and an appropriate operative procedure are selected based on assessment of RV morphology, TV size, the development of the RVOT, and the coronary circulation.

## Laboratory and Diagnostic Features

In neonates with PA/IVS, an electrocardiogram usually shows progressive evidence of RA enlargement with prominent P waves. The pattern of RV hypertrophy that is present in most neonates is absent. A chest radiograph is usually unremarkable at birth but may later reveal an increased heart shadow secondary to RA and left ventricular (LV) enlargement. The lung fields are usually clear with normal to diminished vascular markings. Echocardiography remains the initial diagnostic study to identify the anatomic abnormalities and assess RV morphology. The size of the ventricular cavity, valve dimensions and function, and the nature of the RVOT obstruction are also evaluated. Because of the complexity and morphologic variability of PA/IVS, the anomaly must be defined by both echocardiography and right/left heart catheterization. Catheterization should determine the size and competency of the TV, the degree of RV hypoplasia, the size of the pulmonary arteries, the coronary anatomy and presence of coronary sinusoids and fistulas, and ventricular function. Selective coronary injections and an injection into the RV are also required for a complete evaluation. RV-to-coronary artery fistulas are frequently accompanied by the development of fibrous intimal hyperplasia, resulting in stenosis or complete obstruction of the native coronary circulation. The presence of obstructive lesions in the proximal coronaries may produce a RVDCC. Such patients are at high risk for myocardial ischemia as desaturated blood from the RV perfuses a significant portion of the myocardium. An even greater risk of myocardial ischemia is incurred by the reduction of diastolic aortic pressure resulting from the creation of a systemic-to-PA shunt. In such patients, decompression of the RV by either an outflow tract patch or a pulmonary or tricuspid valvotomy is poorly tolerated and may lead to acute myocardial infarction and intraoperative demise. The presence or absence of a RVDCC by catheterization must be established in a neonate prior to determining the operative strategy.

## Differential Diagnosis

The differential diagnosis encompasses all congenital heart defects with PA. This includes such defects as PA with VSD and single-ventricle defects associated with PA. Echocardiography can easily delineate these defects in most patients and correctly identify those with isolated PA/IVS. Cardiac catheterization is performed in almost all neonates with PA/IVS to confirm the diagnosis and to define and evaluate the anatomy.

## Therapy

Previous surgical experience has indicated that the surgical management of patients with PA/IVS should be based primarily on an anatomic classification system that specifically defines the degree of RV hypoplasia and the TV annular size. A variety of surgical strategies has been proposed in the past for the treatment of these infants.[18–23] We and others have found classification of the RV hypoplasia to be an accurate and consistent approach to surgical therapy.[24,7,25–27] Using this approach, neonates with PA/IVS are initially separated into three groups of mild, moderate, and severe RV hypoplasia.

In patients with mild RV hypoplasia, the TV and RV cavity are approximately two-thirds or greater of the calculated normal size and the RVOT is well developed. This usually correlates with a *Z*-score for the TV between 0 and –2. In patients with moderate RV hypoplasia, the TV and the RV cavity are approximately one-half of calculated normal size (with a range of one-third to two-thirds of normal) and the pulmonary outflow tract is usually developed enough to perform an effective pulmonary valvotomy. This usually

correlates with a *Z*-score for the TV of −2 to −4. In patients with severe RV hypoplasia, the TV and RV cavity are one-third or less of calculated normal size and the pulmonary outflow tract is not amenable to an effective pulmonary valvotomy. This usually correlates with a *Z*-score for the TV of −4 to −6. This approach is not based on any single anatomic component such as RV volumes or the size of the tricuspid annulus but instead assesses the overall RV morphology and the degree of both TV and RV hypoplasia.

During the initial evaluation of patients with PA/IVS, special attention must be paid to the anatomy of the coronary circulation. Abnormalities of the coronary circulation are often found in the severely hypoplastic group and dictate which surgical management options are indicated.[28,14] During fetal development, RV hypertension may cause intramyocardial sinusoids to develop. These sinusoids may branch extensively into blind channels or communicate by fistulas with the coronary artery circulation. The morphology of these sinusoids and their specific communications are extremely variable and can change over time. Proximal coronary artery stenoses or obstructions may develop in a coronary artery supplied by these intramyocardial sinusoids. If the distal coronary artery flow is dependent on these sinusoids for adequate myocardial perfusion, they are termed RVDCC.[29] Decompression of the RV in these patients is contraindicated and may lead to acute myocardial ischemia and death. The preferred management strategy for these patients is single-ventricle palliation to a Fontan procedure.[30]

**TABLE 70-1: Surgical Management of Pulmonary Atresia with Intact Ventricular Septum in Neonates**

| Classification of RV Hypoplasia | RV Morphology | Treatment |
|---|---|---|
| Mild | RV cavity more than two-thirds normal size<br>TV *Z*-score 0 to −2<br>Well-developed RVOT | Pulmonary valvotomy with transannular patch and shunt or valvotomy only |
| Moderate | RV cavity one-third to two-thirds normal size<br>TV *Z*-score −2 to −4<br>Moderately hypoplastic RVOT | Pulmonary valvotomy with transannular patch and shunt |
| Severe | RV cavity less than one-third normal size<br>TV *Z*-score −4 to −6<br>Severely hypoplastic or absent RVOT | Shunt only or shunt and tricuspid valvotomy |

## SURGICAL MANAGEMENT OF NEONATES

Almost all neonates with PA/IVS will require surgical intervention early in life in order to survive. Treatment with $PGE_1$ maintains pulmonary flow through the PDA and allows time for medical stabilization, diagnostic evaluation, and surgical decision-making. Once the anatomy and morphology of the defect is defined by echocardiography and right/left cardiac catheterization, classification is determined and an appropriate operative strategy initiated. Delay in surgical treatment is hazardous and will reduce early survival.

The surgical approach to most patients is based on the degree of RV hypoplasia and TV measurements (Table 70-1). Initial surgical management of most neonates with PA/IVS involves the establishment of a reliable and adequate source of pulmonary blood flow while optimizing the potential for growth and development of the RV and TV in order to achieve a biventricular repair later in life.

***Neonates with Mild Right Ventricular Hypoplasia.*** Neonates with PA/IVS and mild RV hypoplasia with a TV *Z*-score of 0 to −2 are best treated with a pulmonary valvotomy, insertion of an aorta-to-PA shunt, and ligation of the ductus arteriosus. Occasionally, there are patients in whom a pulmonary valvotomy alone will restore adequate pulmonary blood flow. Experience has shown that initial valvotomy alone often fails to produce effective palliation despite favorable anatomy. In most instances, it is preferable to perform a small shunt to ensure adequate pulmonary blood flow and promote subsequent growth of the branch PAs.

***Neonates with Moderate Right Ventricular Hypoplasia.*** Neonates with PA/IVS and moderate RV hypoplasia with a TV *Z*-score of −2 to −4 are best treated with a pulmonary valvotomy, patch augmentation of the pulmonary outflow tract, insertion of an aorta-to-PA shunt, and ligation of the ductus arteriosus. Pulmonary valvotomy and augmentation of the pulmonary outflow tract relieves RV hypertension, reduces tricuspid regurgitation, and potentiates the growth of both the tricuspid annulus and the RV cavity. In many patients with moderate RV hypoplasia, this may allow for a subsequent biventricular repair as the definitive procedure. A transannular pericardial patch (native or bovine) or Gore-Tex patch may be used to augment the RVOT.

***Neonates with Severe Right Ventricular Hypoplasia.*** Neonates with PA/IVS and severe RV hypoplasia with a TV *Z*-score less than −4 are more difficult to manage surgically. Balloon atrial septostomy is recommended at the time of cardiac catheterization, and stenting of the ductus arteriosus may be considered. Pulmonary valvotomy is usually not effective in relieving RV hypertension and augmenting pulmonary blood flow. If stenting of the ductus is not an option, these neonates are best treated with an aorta-to-PA shunt or a subclavian artery-to-PA (modified Blalock–Taussig) shunt. If there are no RV sinusoids or there are tortuous, narrow sinusoids without broad coronary artery fistulas, RV decompression by tricuspid valvotomy may be considered. This can be performed using a closed technique or with an open technique using cardiopulmonary bypass. In

most cases, decompression of the RV results in regression of the narrow, tortuous type of sinusoid and does not result in myocardial ischemia (if the native proximal coronary circulation is intact). If broad fistulas from the coronary arteries to the RV can be identified on the epicardial surface of the heart they can be directly ligated at the time of the shunt procedure.

## SPECIFIC OPERATIVE PROCEDURES FOR NEONATES

Below are described some specific surgical techniques utilized in patients with PA/IVS. Details on systemic-to-pulmonary shunts are presented in Chapter 68.

***Insertion of a Transannular Right Ventricular Outflow Tract Patch via Sternotomy.*** A transannular patch can be placed with relative ease on cardiopulmonary bypass, with aortic and RA cannulation and ligation of the ductus arteriosus. Advantages of performing a transannular patch with the use of cardiopulmonary bypass include better visualization of the annular area, more accurate placement of the edges of the patch, and little blood loss during opening of the RVOT with the RV decompressed.

In some cases with moderate RV hypoplasia, the infundibulum is long and narrow but reaches the pulmonary valve membrane. In these cases, a pericardial transannular patch may be inserted "off pump" without cardiopulmonary bypass (Fig. 70-2A–C). A median sternotomy incision is used. A pediatric cross clamp is placed immediately beneath the bifurcation of the PA. The ductus is kept open to provide pulmonary blood flow. A vertical incision is made in the main PA down to the RV junction. A partial-thickness incision is made over the RV for a distance to bring the incision over the RV cavity. Part of the muscle is resected to a depth of 2 to 3 mm to thin out the RV. A pericardial patch is then sutured to the pulmonary arteriotomy with running polypropylene down to the RV junction. The suture line is continued to the edges of the RV incision leaving the sutures loose inferiorly. A scalpel is then used to incise the valve membrane and to cut into the RV cavity under the pericardial patch. The sutures are pulled up to control bleeding, and the cross-clamp is removed. If the RV pressure is not adequately reduced, a rhizotomy knife is introduced through a purse-string suture in the pericardial patch, and the RV muscle is further incised until an adequate outflow tract has been created to reduce the RV pressure to an acceptable level. Advantages of this technique are the avoidance of cardiopulmonary bypass and also of systemic anticoagulation, although hemodynamic instability can limit the applicability of this technique to only very selected patients.

***Off-Pump Pulmonary Valvotomy via Left Thoracotomy.*** A pulmonary valvotomy may also be performed using a closed technique through a left thoracotomy. The approach is through the fourth intercostal space, with the lung retracted to expose the hilar region. The overlying pericardium is incised and the left PA identified. The main PA and PDA are then identified and the main PA is dissected from the surrounding tissue. Care is taken to avoid dissection of the PDA to maintain its patency during the procedure. The main PA is cross-clamped immediately below the bifurcation, allowing pulmonary perfusion to continue via the ductus arteriosus. The artery is then incised longitudinally and retracted to expose the valve. The fused commissures are identified and incised sharply with a No. 11 scalpel. A thin-bladed vascular C clamp is applied to the incision in the PA, and the cross clamp is removed. A Gore-Tex shunt can then be sutured to the main PA and to the subclavian artery using techniques similar to those used for a modified Blalock–Taussig shunt. The ductus arteriosus is ligated prior to releasing flow into the shunt. Pressure measurements can be obtained to assess the adequacy of the valvotomy and the potential need for further intervention to relieve the RV pressure.

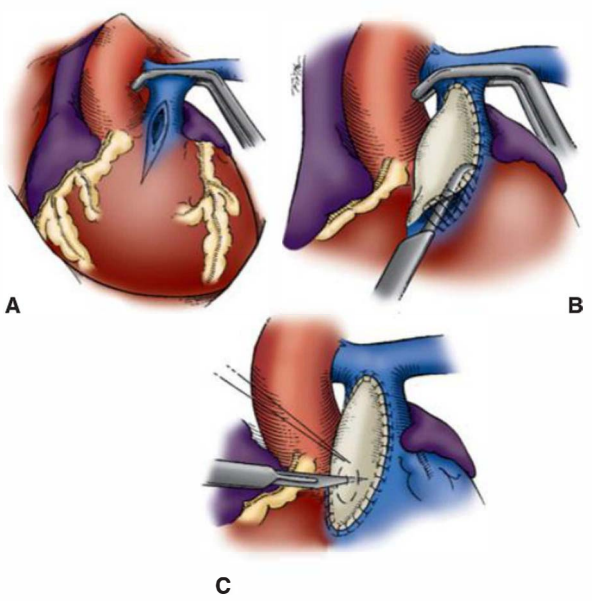

**FIGURE 70-2** Off-pump transannular pulmonary outflow tract pericardial patch. **A.** A cross clamp is placed on the main pulmonary artery as shown. The main pulmonary artery is incised and extended with a partial-thickness incision of the myocardium. **B.** The pericardial patch suture is left loose along the inferior edge until the annulus is divided and the right ventricular myocardium is completely incised into the outflow tract. **C.** Additional opening of the right ventricular outflow tract can be achieved with a No. 11 scalpel through a purse-string suture in the patch.

***Tricuspid Valvotomy.*** Tricuspid valvotomy is considered in patients with severe RV hypoplasia where the possibility of a subsequent biventricular repair is minimal. As mentioned above, preoperative catheterization must determine the absence of sinusoids or RVDCC prior to decompression of the RV. A tricuspid valvotomy can be performed through a median sternotomy using cardiopulmonary bypass and

cardoplegic myocardial arrest. Under direct visualization, the TV can be incised sharply at the commissural sites to allow decompression of the RV with resultant tricuspid valve regurgitation. An enlargement of the ASD can be performed if necessary to improve decompression of the right heart.

A closed technique of TV valvotomy has been described and may be indicated in cases where cardiopulmonary bypass should be avoided.[25] In many patients, decompression of the RV results in regression of the narrow, tortuous type of sinusoid and does not result in myocardial ischemia if the native circulation is intact.

## SURGICAL MANAGEMENT OF OLDER CHILDREN

Infants with PA/IVS are followed closely after their initial palliative procedures. With improving results, an increasing number of patients are presenting for later interventions. A cardiac catheterization is performed at 3 to 6 months of age, depending on the infant's initial morphology and subsequent echocardiographic findings. In patients with severe RV hypoplasia, repeat catheterization at 2 to 3 months is recommended as there may be a high mortality in this group while awaiting repair. The selection of operative procedures is based primarily on RV morphology and on assessment of the TV and RV growth since the previous intervention. In many patients, continued growth of the TV and RV will be comparable and relatively similar, making decisions about definitive repair easier. Disparity of growth between the TV and the RV cavity can lead to difficult decisions about subsequent procedures. Whereas in neonates the size of the TV and the RV usually correlate quite well, in older children there can be a significant discrepancy between these two measurements. Definitive procedures will be determined based on the anatomic findings at catheterization. These patients are again divided into those with mild, moderate, or severe RV hypoplasia (Table 70-2).

The use of an adjustable snare to close the ASD permits control of right-to-left shunting at the atrial level in children where RV volume and compliance may limit forward RV outflow to the pulmonary arteries. The ability to adjust the size of the ASD allows for postoperative control of right-to-left shunting and for the adjustment of forward flow through the RV.[31,32] This can be very helpful in optimizing RV output and avoiding excessive cyanosis.

***Biventricular Repair for Patients with Mild Right Ventricular Hypoplasia.*** In patients with mild RV hypoplasia, later surgical intervention often includes closure of the ASD with an adjustable snare, enlargement of the RV cavity and outflow tract by myocardial resection, and patch augmentation of the RVOT. In order to achieve a competent pulmonary valve, either a pericardial monocusp valve or a bioprosthetic tissue valve is inserted in the RVOT. Use of a homograph pulmonary valved conduit or a Contegra bovine jugular vein valved conduit may also be considered. A successful biventricular repair is achieved in the majority of these patients. Some patients with mild hypoplasia treated by valvotomy may not require subsequent surgery unless the obstruction to the outflow tract has recurred.

**TABLE 70-2: Surgical Management for Definitive Repair of Patients with Pulmonary Atresia with Intact Ventricular Septum**

| Classification of RV Hypoplasia | Treatment Options |
|---|---|
| Mild | Closure of ASD (adjustable snare), enlargement of RV and RVOT, and transannular patch with monocusp valve. Ligation of previous shunt. |
| | Closure of ASD (adjustable snare), enlargement of RV and RVOT, and valved pulmonary homograft. Ligation of previous shunt. |
| Moderate | Closure of ASD (adjustable snare), bidirectional Glenn shunt, enlargement of RV and RVOT, and transannular patch with oversized bioprosthetic valve. Ligation of previous shunt. |
| | Closure of ASD (adjustable snare), bidirectional Glenn shunt, enlargement of RV and RVOT, and valved pulmonary homograft. Ligation of previous shunt. |
| Severe | Staged bidirectional Glenn shunt for later Fontan procedure. |
| | Adjustable ASD. Partial ligation of previous shunt. |
| | Fontan with adjustable ASD. Ligation of previous shunt. |

ASD, atrial septal defect; RV, right ventricle; RVOT, right venticular outflow tract.

***Biventricular and Partial Biventricular Repair for Patients with Moderate Right Ventricular Hypoplasia.*** In the patient with moderate RV and TV hypoplasia, definitive repair is dictated by the previous growth and development of the RV and the TV. If the TV diameter is one-half to two-thirds normal size, repair will then consist of partial closure of the ASD with an adjustable snare, enlargement of the RV cavity by myocardial resection, and insertion of a valved conduit between the RV and the PA. If the TV diameter is one-third to one-half of normal, then repair will consist of partial closure of the ASD with an adjustable snare, enlargement of the RV cavity, creation of a bidirectional Glenn cavopulmonary shunt, and insertion of a valved conduit between the RV and PA. The bidirectional Glenn cavopulmonary shunt reduces the volume load on the small RV and provides an obligatory source of pulmonary blood flow. This allows the channeling of approximately one-third of the systemic venous return from the superior vena cava (SVC) directly to the pulmonary arteries while the inferior vena cava (IVC) (two-thirds of the systemic venous return in small children) continues to pass through the TV and RV. This has been termed the "one-and-one-half ventricle" or "partial biventricular" repair. The ASD

is adjustable to create a gradient between RA and left atrium to encourage forward flow through the RV. This will in turn enhance its development (as well as that of the TV) and increase the likelihood of a subsequent two-ventricle repair. Based on the growth of the RV and the TV, either a two-ventricle repair can be achieved (with takedown of the Glenn shunt) or a single ventricle repair with Fontan completion.

***Staged Fontan Procedure for Patients with Severe Right Ventricular Hypoplasia.*** In patients with PA/IVS and severe RV and TV hypoplasia, a biventricular repair is usually not possible. Most of these patients will have undergone placement of a systemic-to-PA shunt in the neonatal period with or without tricuspid valvotomy, depending on the presence or absence of RVDCC. The bidirectional Glenn cavopulmonary anastomosis is performed in the first 3 to 6 months of life with a plan for a total cavopulmonary connection within the first 3 to 4 years of life. Fenestration of the Fontan circuit may be used as an ASD with an adjustable snare when a lateral tunnel technique is utilized (see Chapter 77). The Fontan may be performed either as a lateral tunnel or as an extracardiac conduit. Both types of Fontan procedures can be constructed with an effective adjustable fenestration to the atrial chamber.

***Surgical Management of Children with PA/IVS with Ebstein's Malformation.*** Ebstein's malformation of the TV is present in 10 percent of patients with PA/IVS. This group of neonates should be considered separately. Most of these patients will have severe TV insufficiency and a normal-sized or enlarged RV. There is also massive dilatation of the RA. The LV function is often compromised in these infants because of the dilated dysfunctional RV and septal shift into the LV cavity. Although an aorta-to-PA shunt may establish adequate pulmonary blood flow, LV output often remains compromised by the dilated RV. Surgical intervention in these patients is associated with greater than 50 percent mortality.[33] Orthotopic heart transplantation should be considered as an initial therapeutic option in these patients.

***Surgical Management of Children with Right Ventricle-Dependent Coronary Circulation.*** A RVDCC is one in which there are sinusoidal connections between the cavity of the RV and the coronary circulation, either with obstruction in the native coronary circulation or with broad sinusoidal connections that would result in runoff from the coronary circulation into the low-pressure RV. Tortuous sinusoidal connections without coronary stenoses do not usually denote a RVDCC. Decompression of the RV at the time of the bidirectional Glenn anastomosis will usually result in closure of these sinusoids as opposed to the broad-based fistulous connections. In some cases, the large fistulous connections can be identified on the surface of the heart and be suture ligated at the time of the bidirectional Glenn shunt, allowing RV decompression at that time.

In infants with RVDCC, systemic RV pressure must be maintained to ensure adequate coronary perfusion to the myocardium.[34] Even in older children, decompression of the RV by augmentation of the outflow tract or tricuspid valvotomy may lead to severe myocardial ischemia and acute cardiac failure. If a RVDCC is identified, a single-ventricle surgical strategy is pursued and a bidirectional Glenn anastomosis performed at 3 to 6 months of age without RV decompression. Any additional source of pulmonary blood flow, such as a previously placed shunt, may be reduced or ligated at the time of the Glenn procedure. At 2 to 4 years of age, the Fontan completion is carried out. In order to bring oxygenated blood to the TV, the atrial septum is excised and the coronary sinus unroofed at the time of Fontan completion.

If there are signs of myocardial ischemia either preoperatively or intraoperatively, the RVDCC may be improved by creating an aortic-to-RV shunt.[35] This shunt theoretically changes the RV systolic pressure to equal the systemic pressure, elevating the diastolic pressure and maintaining coronary perfusion. Flow through such a shunt appears to be bidirectional and biphasic. Experience to date has been limited with this technique, and long-term follow-up is not yet available. If myocardial ischemia results from decompression of an undiagnosed RVDCC, coronary artery bypass grafting using the internal mammary artery may be attempted. Unfortunately, the use of coronary artery bypass grafting in these patients is limited by technical difficulties, conduit options, and limited long-term graft patency.

Finally, in patients with RVDCC and severe RV dysfunction, early shunt placement may be followed by consideration of orthotopic heart transplantation.

## SPECIFIC OPERATIVE PROCEDURES IN OLDER CHILDREN

***Enlargement of the Right Ventricular Cavity and Right Ventricular Outflow Tract.*** The RV cavity is enlarged by using cardiopulmonary bypass with bicaval cannulation and cardioplegic arrest to sharply resect trabecular muscle. The RA is opened longitudinally and the TV inspected; the annulus is measured and compared to normal values and its competence tested with cold saline. An incision is made longitudinally from the main PA through the annulus and across the infundibulum to the main RV cavity. The cavity is enlarged by resection of trabecular muscle under direct vision. Care is taken to work between the papillary muscles, which should be avoided. A glutaraldehyde-treated pericardial outflow patch is then placed on the RV incision. In infants, we generally prefer a pericardial patch with a monocusp valve. In older children, we have used a porcine valve within the RVOT or an RV to PA conduit.

***Adjustable Atrial Septal Defect.*** If the ASD is large, it is closed with a Gore-Tex vascular patch. If the defect is small with firm edges, it may be closed with the purse-string suture of the "adjustable ASD." The adjustable ASD is created by placing a No. 1 polypropylene suture as a purse string around the tissue edges of the existing septal defect, with a pericar-

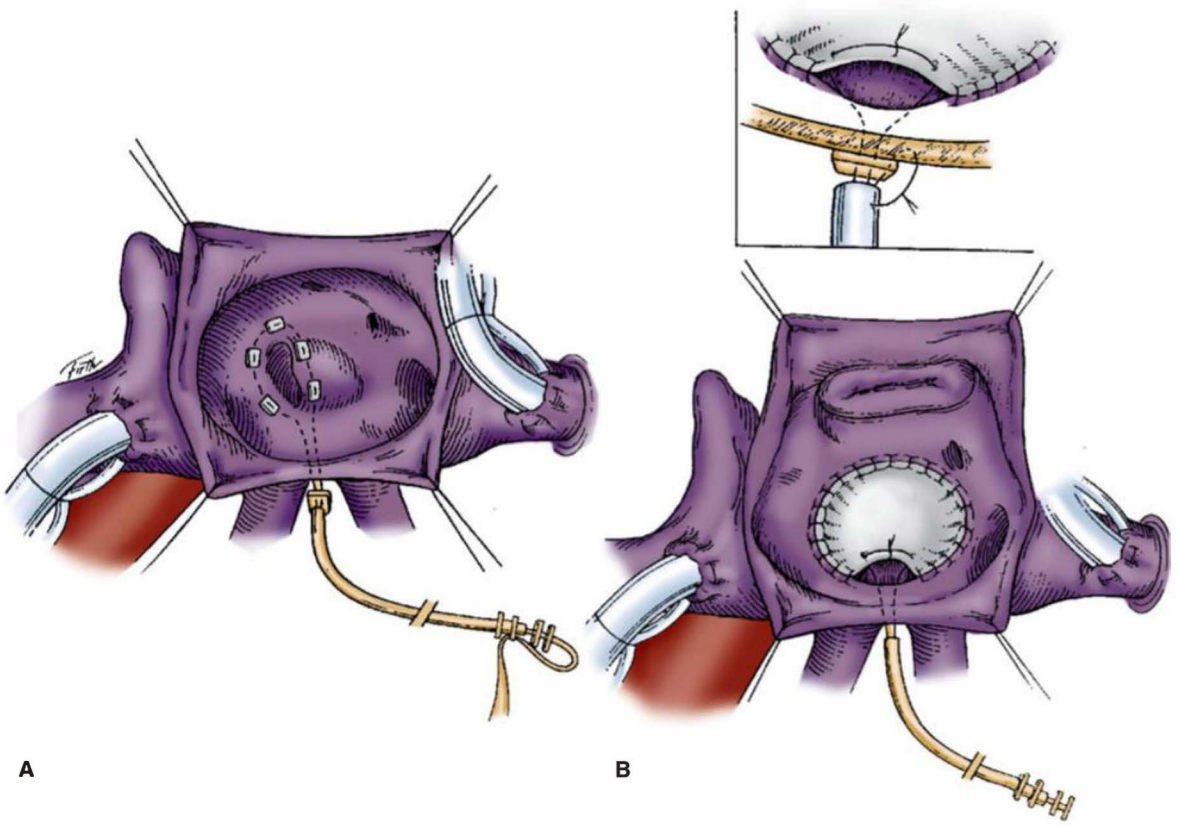

**FIGURE 70-3** Adjustable atrial septal defect with and without patch closure of the native atrial septal defect. **A.** A No. 1 polypropylene purse-string suture is secured around the border of the atrial septal defect using pericardial or felt pledgets. The snare is constructed using 8F polyethylene tubing placed over the No. 1 polypropylene suture and measured to reach the linea alba. **B.** If a large secundum atrial septal defect is present, it is closed with a Gore-Tex or pericardial patch, and a defect is left in the lateral wall. A No. 1 polypropylene suture is brought in through the interatrial groove and placed as a horizontal mattress stitch through the edge of the patch. The No. 1 polypropylene suture is then anchored to the edge of the patch with a 5-0 polypropylene suture.

dial pledget used as a reinforcement. Both ends of the suture are then brought out through the interatrial groove. An 8F polyethylene tube is cut to length to reach the linea alba and passed over the ends of the polypropylene suture to construct the snare. The tubing is sutured to the atrial wall with a single chromic suture (Fig. 70-3A). The snare is adjusted by tightening or loosening the polypropylene suture at the end of the tubing and securing the length with medium clips. The end of the snare is left under the subxiphoid linea alba, where it can be retrieved under local anesthesia postoperatively for subsequent adjustment. The same technique can be used to create an adjustable defect in a Gore-Tex (expanded polytetrafluoroethylene or ePTFE) patch. The defect in the suture line is left on the right side where it is surrounded by a polypropylene suture as described above (Fig. 70-3B). The ASD is left open until the patient is weaned from bypass. The ASD is then slowly closed, using the snare while monitoring the RA pressure and arterial oxygen saturations. A target RA pressure of about 12 to 14 mm Hg with an oxygen saturation of 88 percent or above on 100 percent inspired oxygen is considered optimal.

***Bioprosthetic Valve Insertion with Transannular Patch.*** A transannular incision is made vertically across the pulmonary outflow tract and extended onto the left PA and down into the RV. Any residual membrane in the region of the annulus is resected. The distance between the RVOT and the PA bifurcation is assessed. If it is short, use of a homograft may not be possible, as the proximity of the proximal and distal suture lines will result in bulging of the homograft. For this situation, a larger porcine valve can be placed under a pericardial (autologous or bovine) patch within the RVOT. The porcine valve may be implanted at the level of the native valve annulus (Fig. 70-4A) or in the subvalvular region below the level of the true pulmonary annulus (Fig. 70-4B) to accommodate a larger valve and reduce the amount of

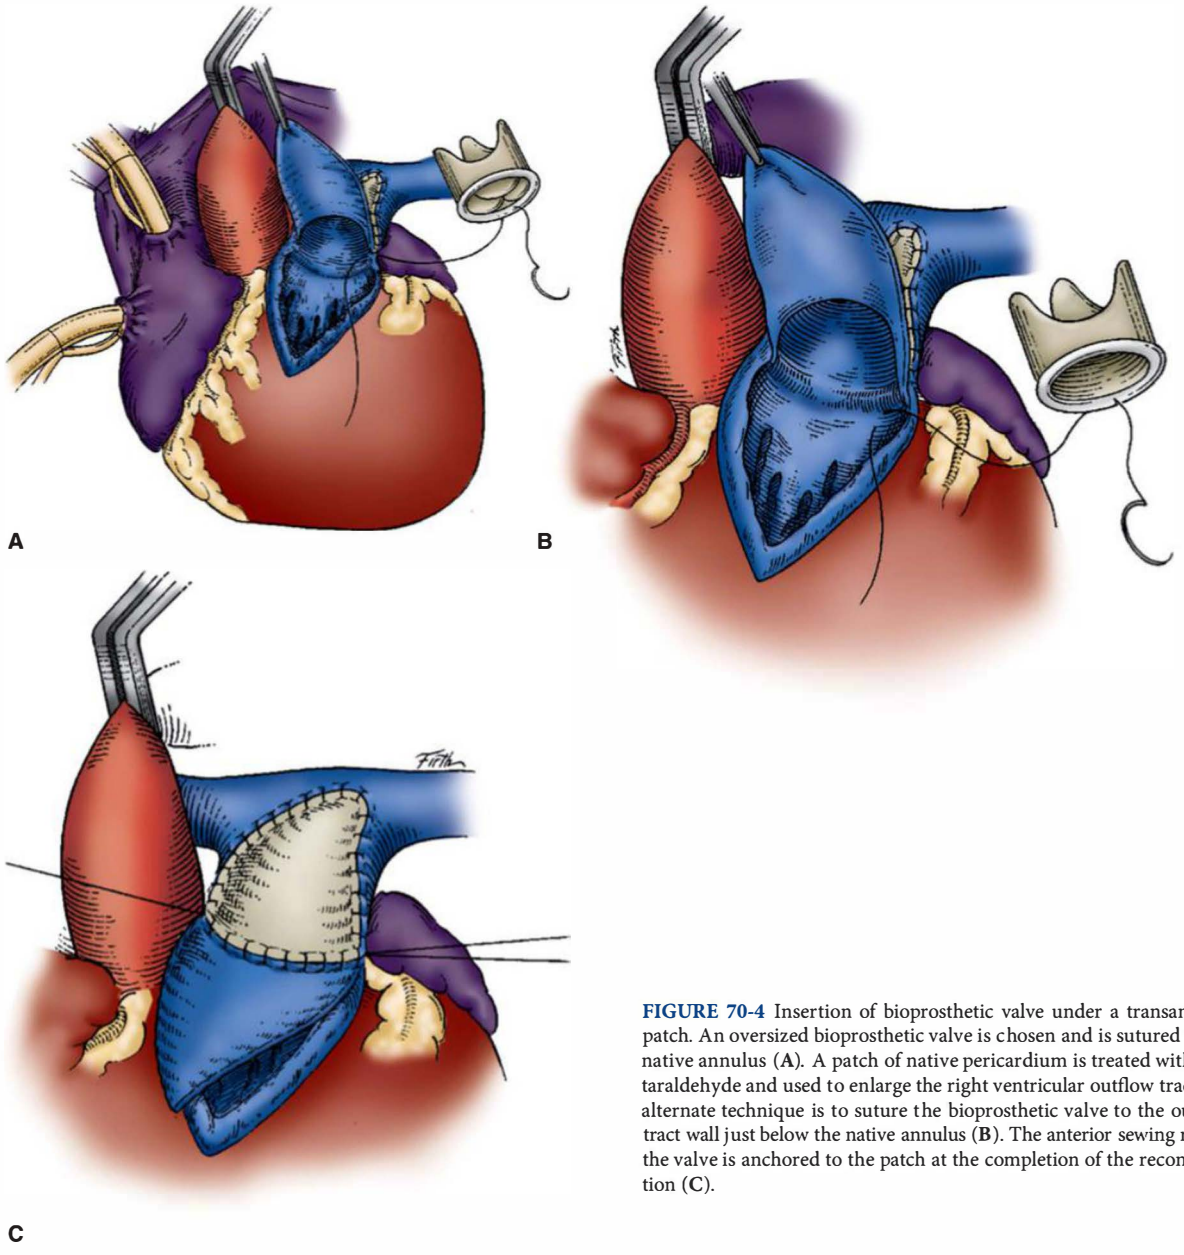

**FIGURE 70-4** Insertion of bioprosthetic valve under a transannular patch. An oversized bioprosthetic valve is chosen and is sutured to the native annulus (**A**). A patch of native pericardium is treated with glutaraldehyde and used to enlarge the right ventricular outflow tract. An alternate technique is to suture the bioprosthetic valve to the outflow tract wall just below the native annulus (**B**). The anterior sewing ring of the valve is anchored to the patch at the completion of the reconstruction (**C**).

compression that may result from closure of the sternum. A running polypropylene suture is used to insert the valve, which is also sutured to the patch anteriorly (Fig. 70-4C).

***Homograft Valve Insertion.*** If the distance between the RVOT and the PA bifurcation is adequate, an appropriate aortic or pulmonary homograft is chosen. A running polypropylene suture is used distally just below the PA bifurcation. Proximally, the homograft is sutured to the RVOT just below the pulmonary valve with a running suture. The proximal anastomosis of the homograft and the RVOT are augmented with a pericardial or synthetic (ePTFE or Dacron) patch.

***Transannular Patch with Pericardial Monocusp Valve.*** This technique is used for neonates and infants but can also be used for small children. It should be used for patients with mild or moderate RV hypoplasia and with acceptable PA size as the valve will remain competent for a shorter period of time than a complete tissue valve. It has the advantage,

however, of rarely causing obstruction even when the valve has become incompetent.

***Bidirectional Glenn Cavopulmonary Shunt.*** A median sternotomy incision is used for a Glenn cavopulmonary anastomosis. The right PA and SVC are dissected free from surrounding tissues and the azygos vein is divided between ligatures. Excessive dissection in this region may disrupt lymphatic tissue and result in postoperative chylothorax. The PA pressure is measured on both sides. A left SVC may be identified anterior to the left PA. The SVC is clamped just above the RA and the proximal pressure is monitored. If the pressure does not rise above a mean of 30 mm Hg, a left SVC should be suspected (as it would be in case of absence of the left innominate vein). If both right and left SVCs are present, cardiopulmonary bypass or a temporary shunt may not be necessary. If the proximal pressure in the clamped SVC is 30 mm Hg or greater, a temporary shunt should be used. A vertical purse-string suture is placed on the SVC at its junction with the innominate vein. A second purse-string suture is placed in the RA appendage. The patient is heparinized and a temporary bypass shunt is created using two venous cannulae and a Y connector with a *chapeau* attachment. The SVC is cannulated with the bevel of the cannula placed toward the right internal jugular vein. The second cannula is placed in the RA appendage. The circuit is connected after air is completely evacuated from the cannulae and the clamps are removed, with visualization of flow. The SVC is then clamped at its junctions with the RA and the innominate vein. The anterior aspect of the SVC and the superior margin of the right PA are marked to ensure proper alignment of the cavopulmonary anastomosis. The SVC is divided at the atrial junction and the open end of the SVC is enlarged by an incision in the posterior wall of the vessel. The anastomosis is performed with a running 6-0 or 7-0 polypropylene suture (Fig. 70-5).

Any previously placed systemic-to-PA shunt is now reduced in size or eliminated to give an estimated $Q_p$:$Q_s$ of 1.3:1 or less. The SVC and PA pressures are measured, as well as the arterial oxygen saturations on 100 percent oxygen.

***Lateral Tunnel Fontan with Adjustable Atrial Septal Defect.*** A Fontan procedure is usually performed as a second- or third-stage operation. A median sternotomy is performed and bicaval venous cannulation between the SVC and IVC is carried out. Systemic hypothermia to 32°C is used in addition to cold blood cardioplegic arrest.

A right atriotomy is performed just anterior to the linea terminalis and the edges are retracted with stay sutures. The coronary sinus is identified and cannulated with a retrograde cardioplegia catheter. Cold blood cardioplegia is delivered intermittently both antegrade and retrograde.

The atrial septum is excised. The SVC orifice is identified from within the RA. It is important that this orifice be widely open and not restrictive. The right PA is incised adjacent to the opening in the SVC stump. The posterior wall of

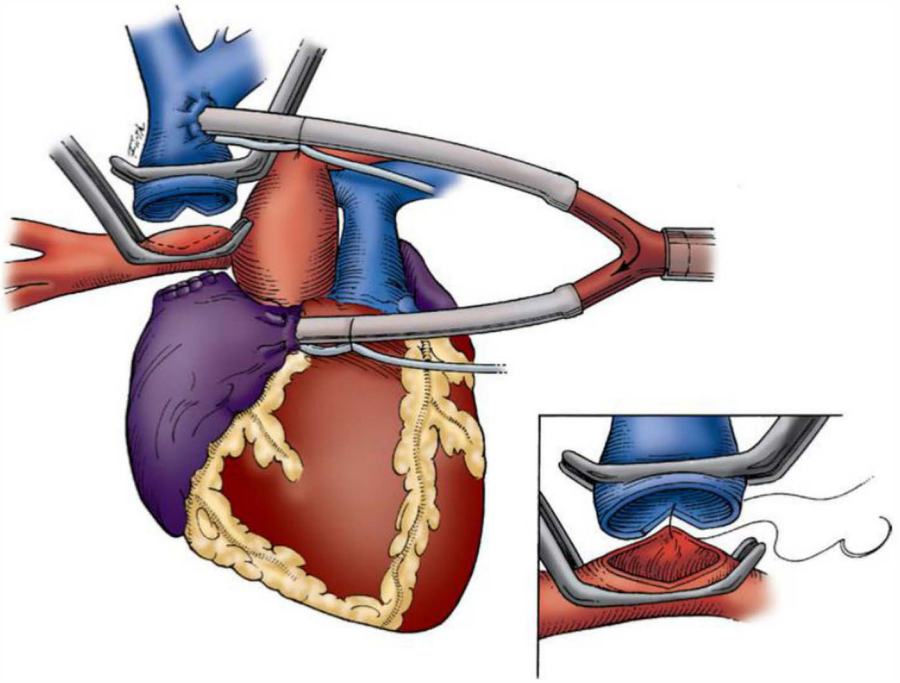

**FIGURE 70-5** Bidirectional Glenn shunt. The Glenn shunt operation is performed using a superior vena cava–to–pulmonary artery shunt. The cannulae are placed in the superior vena cava and the right atrium, allowing continuous flow of venous return to the right atrium during the reconstruction. To avoid stenosis, the anastomosis is tailored as shown in the insert.

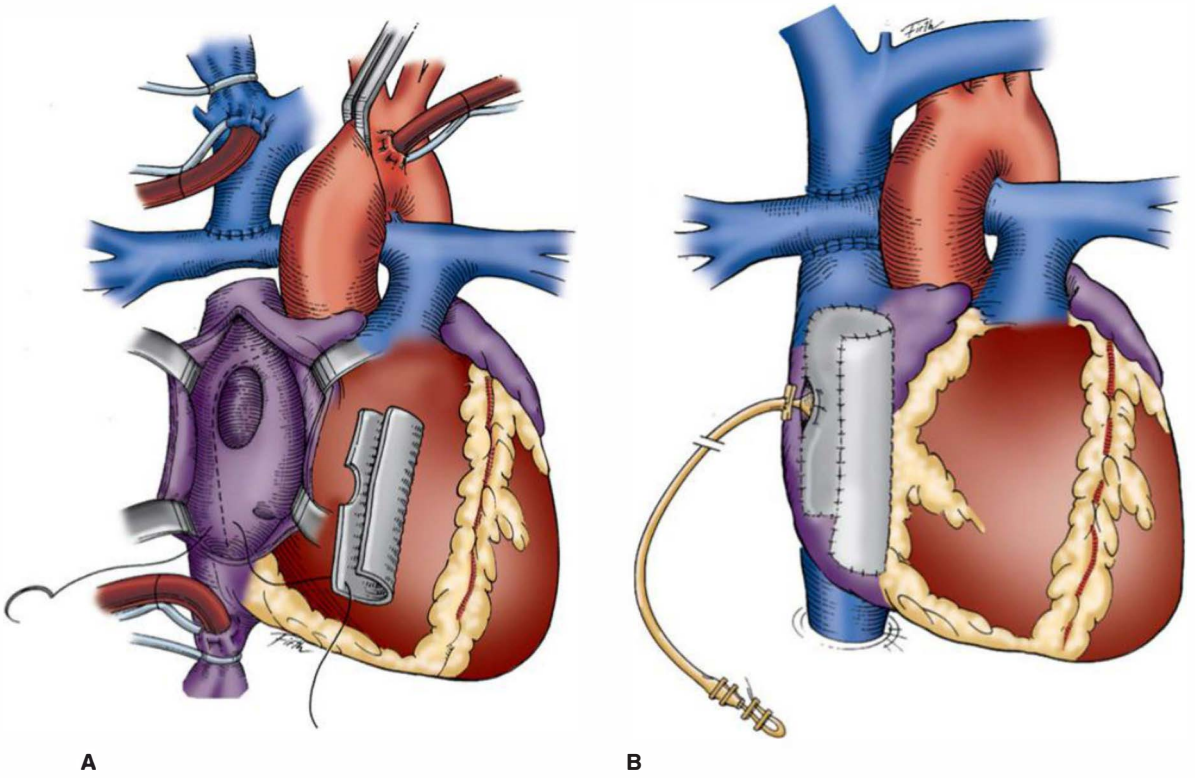

**FIGURE 70-6** Lateral tunnel Fontan with an adjustable atrial septal defect. A tunnel of uniform caliber is constructed by suturing a Gore-Tex vascular patch to the orifice of the inferior vena cava and the superior vena cava and to the lateral atrial wall (**A**). A defect is left in the tunnel and an adjustable atrial septal defect is achieved by passing a No. 1 polypropylene suture through the lateral portion of the interatrial septum and through the edge of the Gore-Tex tunnel. The No. 1 polypropylene suture is then secured to the edge of the Gore-Tex with a 5-0 polypropylene suture. The suture is brought back out the interatrial septum and through a pericardial pledget. The snare is constructed with a No. 8F polyethylene tubing and anchored to the heart through a pledget as shown (**B**). The completed lateral tunnel Fontan reconstruction is shown with the adjustable atrial septal defect left open.

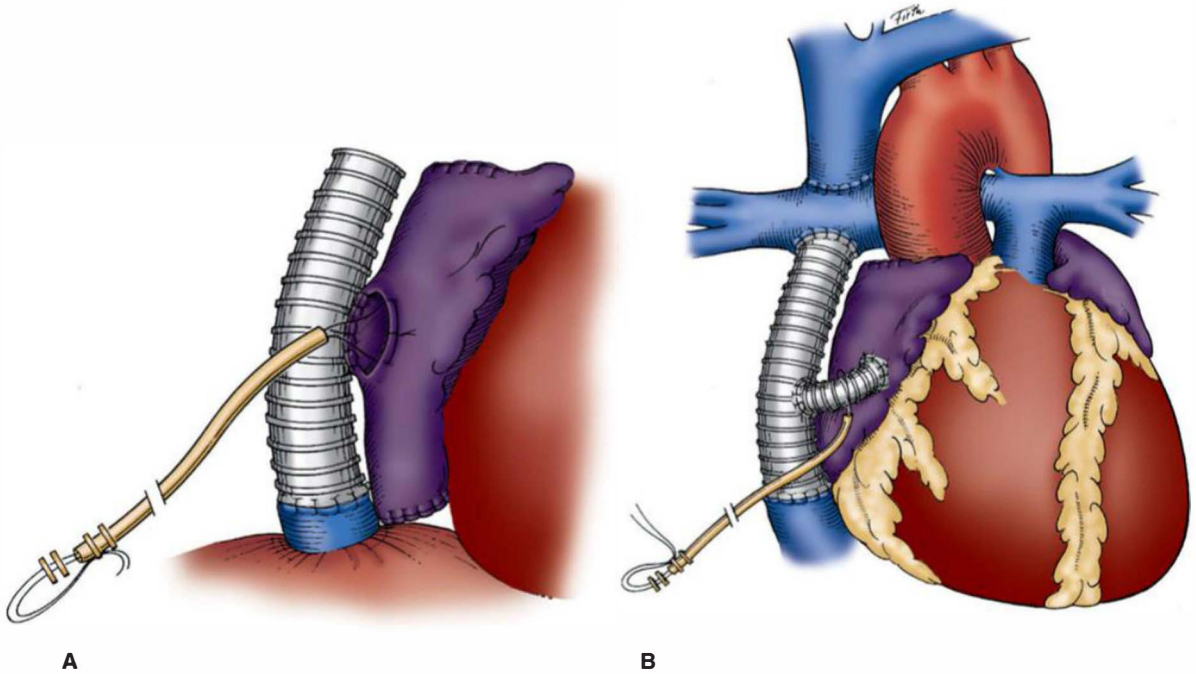
the anastomosis is created by suturing the adjacent PA and RA together with polypropylene suture. Anteriorly, the connection is bridged with a pericardial patch to assure patency without obstruction.

After the RA-to-PA anastomosis has been completed, the lateral tunnel is constructed. A rectangular Gore-Tex patch is cut from 0.8-mm-thick Gore-Tex vascular patch material. The length is carefully measured from the orifice of the IVC to that of the SVC. The width is left about two-thirds of the length to be trimmed after completion of the posterior suture line. A running polypropylene suture is used for the posterior suture line, which is begun at the IVC orifice (Fig. 70-6A). The suture line is carried superiorly to the site of the orifice of the adjustable ASD where it ends. This site is chosen because it comprises a natural recess close to the right superior pulmonary vein at the superior and lateral end of the fossa ovalis. A second polypropylene suture line is begun at the superior end of the ASD defect and carried superiorly around the SVC orifice. The ASD is sized according to the patient's age and made large in diameter so that it may be reduced in size if necessary after the patient comes off bypass. As a rule of thumb, the defect's size is 4 mm for 2-year olds, 6 mm for 4-year olds, and 8 mm for children 6 years old and older. The patch is trimmed appropriately as the suture line advances. Before the anterior suture line is completed, the snare control is placed for the adjustable ASD. A No. 1 polypropylene suture is brought through a pericardial pledget, through the interatrial septum at the lower border of the ASD, and through the edge of the Gore-Tex patch. It is then brought back through the upper edge of the Gore-Tex patch and out through the interatrial septum and through the pericardial pledget. An 8F polyethylene tube is cut to the appropriate length to reach the linea alba and the polypropylene sutures are brought through this snare. The No. 1 polypropylene is sutured to the edge of the Gore-Tex patch with a 5-0 polypropylene suture, the polyethylene tubing is sutured to the lateral wall with 2-0 chromic catgut, and the polypropylene is fixed to the heavy polypropylene with a medium-size clip. These three points of fixation prevent inadvertent closure of the ASD by tugging on the polypropylene. The patch is now trimmed to create a wide-open connection and to reach just anterior to

the linea terminalis. The anterior part of the suture line is completed using full thickness sutures to avoid a suture-line leak. The RA incision is then closed with a polypropylene suture (Fig. 70-6B).

Transthoracic lines are generally placed in the left and right atria. If an internal jugular line is not inserted, the RA line can be inserted to measure the pressure in the pulmonary system via the Fontan tunnel or the Glenn anastomosis. The patient is weaned from cardiopulmonary bypass and the ASD snare is adjusted to achieve arterial saturations of 80 to 85 percent with an $FIO_2$ of 50 percent while attempting to maintain pressure in the Fontan circuit at or below 16 mm Hg.

***Extracardiac Fontan with Adjustable Atrial Septal Defect.*** The extracardiac Fontan is performed through a median sternotomy using cardiopulmonary bypass and bicaval cannulation. The procedure can be completed in most patients without the need for cardioplegic arrest of the heart. A clamp is placed on the IVC near its junction to the RA. The IVC is then divided between the snared venous cannula and the clamp. The atrium is repaired and the clamp is removed.



The open end of the IVC is anastomosed end-to-end to a Gore-Tex conduit (16–20 mm in diameter) using a running Gore-Tex suture. The proximal anastomosis is performed end-to-side between the Gore-Tex conduit and the inferior aspect of the right PA. The clamps are released and flow is established between the IVC and the pulmonary arteries.

To create the adjustable fenestration, a partially occluding vascular C clamp is placed on the Gore-Tex graft. A direct anastomosis is performed between the extracardiac conduit and the RA. A snare is inserted to control the opening and closing of this "ASD" (Fig. 70-7A). An alternate method uses a conduit for the defect. With this technique an 8 mm Gore-Tex graft is anastomosed end-to-side to the middle of the larger conduit. A similar technique is used to create an opening in the RA and the other end of the 8 mm graft is anastomosed to this site. A snare is inserted around the smaller conduit (Fig. 70-7B). A distinct drawback to the extracardiac Fontan is the need for anticoagulation with warfarin postoperatively for up to a year, with subsequent conversion to aspirin therapy.

## COURSE AND PROGNOSIS

### Postoperative Care in Neonates

Neonates may be critically ill in the early postoperative period following operative intervention for PA/IVS. The presence of low cardiac output may require substantial inotropic

A B

**FIGURE 70-7** Extracardiac Fontan with an adjustable fenestration. The extracardiac conduit is implanted and a direct anastomosis is made between the conduit and the atrial wall. The defect is controlled with an adjustable snare (**A**). The extracardiac conduit is implanted and a communication is established between the conduit and the atrium using an 8 mm Gore-Tex graft. The graft diameter is then controlled by an adjustable snare (**B**).

support. In the presence of a systemic-to-PA shunt, balanced pulmonary and systemic blood flow must be achieved. The management of pulmonary and systemic vascular resistance is critical to maintaining adequate oxygenation and cardiac output. Episodes of pulmonary hypertension must be managed quickly and may require the use of inhaled nitric oxide. An excessively large shunt may lead to pulmonary overcirculation and require adjustment or replacement of the shunt. Postoperative ischemia can develop due to unrecognized RVDCC and may be associated with electrocardiographic changes, ventricular dysrhythmias, and segmental wall dyskinesia on echocardiography. In patients with persistent hypoxemia despite adequate medical management, residual RVOT obstruction or severe tricuspid hypoplasia should be excluded.

### Postoperative Care in Older Children

Early management after the Fontan procedure should focus on optimizing cardiac output and reducing systemic venous pressure. Inotropes are routinely used, starting with dopamine and dobutamine. If additional inotropic support is needed, milrinone may be added. If systemic vascular resistance is low and additional inotropic support is required, the use of epinephrine may be indicated. The adjustable ASD is useful because it allows as much as one-third of the systemic venous return to traverse the ASD, thus lowering the systemic venous pressure while increasing LV preload and the cardiac output. With a $Q_P$:$Q_S$ ratio of 1.5:1, the arterial oxygen saturation should be approximately 85 percent. A systemic venous pressure of 12 to 15 mm Hg is optimal. It should be noted that the presence of a patent right-to-left shunt increases the risk of paradoxical emboli from thrombus, which may develop in the RA or the hepatic veins. Therefore, complete closure of the adjustable ASD should be performed when it is hemodynamically tolerated.

If pulmonary vascular resistance is elevated postoperatively following a Glenn or Fontan procedure, it is reduced in our practice with an infusion of nitroglycerin and $PGE_1$. These medications are more effective in lowering pulmonary vascular resistance if delivered directly into a catheter in the Glenn or Fontan circuit. If these medications are not sufficient, nitric oxide is administered through the ventilator. Unlike intravenous medications, nitric oxide does not result in the lowering of systemic vascular resistance.

Extubation within the first 24 h is generally attempted after both Glenn and Fontan procedures. The development of pleural and pericardial effusions is anticipated, and mediastinal and pleural chest tubes are left in place for several days postoperatively until drainage is minimal.

If a jugular vein line has been inserted, it is used for measuring the PA pressure and for the infusion of pulmonary vasodilators if necessary. The line is removed within 12 hours to avoid venous thrombosis.

## OUTCOMES

Historically, the surgical treatment of PA/IVS was associated with very high morbidity and mortality.[5,36] Previous extensive reviews of the clinical and pathologic aspects of this malformation have allowed for a greater understanding of the disease and for the development of surgical therapy.[37] With increasing surgical experience, a more standardized approach has evolved and outcomes from many institutions have steadily improved.[38–44] The role of catheter-based interventions in these patients, including balloon valvotomy and stenting of the RVOT and the ductus arteriosus, is evolving and remains to be defined.[45]

In the CHSS multi-institutional study, 408 neonates with PA/IVS were studied from 33 institutions. Overall survival was 77 percent at 1 month, 70 percent at 6 months, 60 percent at 5 years, and 58 percent at 15 years. Prevalence of end states at 15 years were as follows: two-ventricle repair, 33 percent; Fontan palliation, 20 percent; one-and-a-half ventricle repair, 5 percent; heart transplant, 2 percent; death before reaching definitive repair, 38 percent; and alive without definitive repair, 2 percent. The authors concluded that 85 percent of neonates with PA/IVS are likely to reach a definitive surgical repair or palliation, with a two-ventricle repair achieved in an estimated 50 percent and a Fontan circulation achieved in 35 percent in the current era.[46]

### Future Considerations

Transcatheter therapy in patients with PA/IVS is becoming a more common approach to initial interventions in neonates. These techniques include radiofrequency valvotomy, PDA stenting, RVOT stenting, and device closure of ASD. As experience increases, these techniques are gaining wider acceptance as alternatives to or complements to surgery in treatment options.[47–49] Various hybrid approaches may emerge combining both surgical and catheter-based interventions. In some studies, catheter-based interventions in neonates have rarely avoided surgical interventions.[50,51]

In utero perforation and dilatation of the PV in midgestational fetuses with PA/IVS has been reported in a limited experience.[52] The overall effect of this type of fetal intervention on subsequent growth and development of the RV and its clinical impact on outcomes in patients with PA/IVS remains to be defined.

## PULMONARY STENOSIS AND PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM BOARD REVIEW QUESTIONS (CHAPTER 70)

1. Which is correct regarding pulmonary stenosis?
   A. The valve is typically flat with central leaflet fusion.
   B. The RV is usually smaller than normal.
   C. The pulmonary annulus is either normal or smaller than expected.
   D. If the RV is enlarged, this portends a better prognosis.
   E. Intervention is indicated with a mean gradient above 30 mm Hg.

2. Which is true regarding treatment of pulmonary stenosis?
   A. Permissive systemic hypotension is useful to reduce ductal flow.
   B. Inotropic agents will increase flow across the RVOT.
   C. Open valvotomy should extend to the edge of the annulus.
   D. A partial valvectomy should be avoided.
   E. Dilators can rupture the infundibulum.

3. Which is correct regarding PA with IVS (PA–IVS)?
   A. Surgical approach is primarily based on the degree of RV hypertrophy.
   B. Untreated patients have a mortality approaching 85 percent at 6 months.
   C. RV-to-coronary artery fistulas are more common in patients with a severely enlarged RV and an incompetent tricuspid valve.
   D. Pulmonary blood flow is almost entirely dependent on an ASD.
   E. Ebstein's malformation is not seen in PA–IVS.

4. Which is correct regarding PA–IVS and RV hypoplasia?
   A. Neonates with mild RV hypoplasia are best treated with pulmonary valvotomy and patch augmentation of the RVOT.
   B. Neonates with moderate RV hypoplasia are best treated with pulmonary valvotomy and a systemic-pulmonary shunt.
   C. Pulmonary valvotomy is usually sufficient in relieving RV hypertension in patients with severe RV hypoplasia.
   D. Decompression of the RV does not result in regression of narrow sinusoids.
   E. Broad fistulas to the RV can be directly ligated on the surface of the heart.

5. Which is true regarding outcomes for PS and PA–IVS?
   A. Following surgical correction of PS, there is often a residual gradient.
   B. Ten percent of PS patients will require reintervention within 2 years for residual stenosis.
   C. Overall survival after surgery for PA–IVS is 90 percent at 5 years.
   D. Most patients with PA–IVS will die before reaching definitive repair.
   E. Fontan repair is the most common pathway in the current era.

## ANSWERS

1. **Answer: C.** The pulmonary annulus is either normal or smaller than expected. The valve is typically dome shaped with commissural fusion. The RV is usually of normal size; if enlarged, this is associated with a very poor prognosis. Intervention is indicated with a mean gradient exceeding 50 mm Hg.
2. **Answer: C.** Open valvotomy should extend to the edge of the annulus. Systemic hypotension should be avoided, as this will reduce ductal flow and worsen hypoxemia. Inotropic agents can worsen functional obstruction of the RVOT. Partial valvectomy may be necessary to remove thickened valve tissue or fibrous scar. Dilators are useful to size the annulus and dilate the annular tissue.
3. **Answer: B.** Untreated patients have a mortality approaching 85 percent at 6 months. The surgical approach is primarily based on the degree of RV and TV hypoplasia. RV to coronary artery fistulas are more common in patients with a severely hypoplastic RV and a competent tricuspid valve. Pulmonary blood flow is almost entirely dependent on a PDA. Ebstein's malformation is seen in about 10 percent of patients.
4. **Answer: E.** Broad fistulas to the RV can be directly ligated on the surface of the heart at the time of shunting. Neonates with mild RV hypoplasia are best treated with pulmonary valvotomy and a systemic–pulmonary shunt, whereas patients with moderate RV hypoplasia will require patch augmentation of the RVOT. Pulmonary valvotomy is usually not effective in relieving RV hypertension in patients with severe RV hypoplasia. Decompression of the RV generally results in regression of narrow sinusoids.
5. **Answer: A.** Following surgical correction of PS, there is often a residual gradient across the RVOT. About 25 percent of PS patients will require reintervention within 2 years for residual stenosis. Overall survival after surgery for PA–IVS is 60 percent at 5 years. About 40 percent of PA–IVS patients will die before reaching definitive repair. Two-ventricle repair is the most common pathway, with about 50 percent of patients achieving this result.

# 71 Double Outlet Right Ventricle

*Jess Thompson*
*Joseph A. Dearani*

## KEY CONCEPTS

- Epidemiology
  - Relatively uncommon congenital anomaly seen in 0.09 in 1000 births
- Pathophysiology
  - Considerable variability in pathophysiology is seen with double outlet right ventricle (DORV) and is primarily dependent on the location of the ventricular septal defect (VSD), the relationship of the great arteries and the presence of great vessel stenosis
- Clinical features
  - Patients usually present by age 2 months (range 1 day–4 years). Presentation is variable and is dependent on the type of DORV and associated cardiac anomalies. Heart failure is seen in patients with unrestricted subaortic, doubly-committed or non-committed VSDs without right ventricular outflow tract obstruction (RVOTO). Cyanosis results from RVOTO leading to restriction of pulmonary blood flow or by preferential streaming of blood from the left ventricle (LV) to pulmonary artery (PA) as seen in the Taussig–Bing anomaly.
- Diagnosis
  - Echocardiography defines the relationship of the great arteries to the right ventricle (RV) and to each other, and delineates the size and position of the VSD. MRI may provide complementary information about intracardiac anatomy, size and status of the aortic arch and PAs, and 3-dimensional relationship of chambers and great arteries. Catheterization can be performed to determine hemodynamics, exclude pulmonary vascular disease and assess coronary anatomy.
- Treatment
  - Definitive management includes operation, preferably complete repair during infancy. The surgical repair is tailored to address the variable anatomical abnormalities. In patients with a subaortic or doubly-committed VSD without RVOTO, the repair is performed with an intraventricular tunnel from the VSD to the aorta. If RVOTO exists, right ventricular outflow tract (RVOT) augmentation or conduit placement is performed. The Taussig–Bing anomaly is treated with the arterial switch operation and tunneling of the VSD to the PA. Patients with a remote VSD, other complex valve abnormalities or unbalanced ventricles may require staged palliative single ventricle procedures.
- Outcomes/prognosis
  - Outcomes are determined by the anatomy and the repair performed. Late results may range from those of tetralogy of Fallot to those of complex intraventricular tunnels, with potential use of conduit, who are at subsequent risk for subaortic obstruction, conduit failure, and need for reoperation(s). Patients undergoing the arterial switch operation have excellent late survival but may have a greater incidence of neoaortic valve regurgitation requiring subsequent reoperation. Complex biventricular intracardiac repairs are associated with a higher operative risk and the potential need for reoperations. Fontan procedures for complex anatomy are associated with less operative mortality and lower reoperation rates. Functional benefits of complex biventricular repairs compared to single-ventricle palliation have not been defined.

# INTRODUCTION/BACKGROUND

## Definition

Double outlet right ventricle (DORV) is best defined as an anomaly of cono-truncal development that results in both great arteries arising entirely or predominantly from the right ventricle (RV).[1] Consequently, DORV is not a specific congenital malformation; rather DORV is a descriptive term used to define the relationship of the great arteries to the RV. Most authors agree that the degree of aortic override of the RV has to be at least 50 percent and that the only outlet of blood from the left ventricle (LV) is the ventricular septal defect (VSD).[2]

## Historical Highlights

Although cases of DORV were documented in the mid-19th century,[3,4] the term "double outlet ventricle" was first used by Braun in 1952 to describe the postmortem anatomy of a heart with complete dextroposition of the aorta, subaortic VSD, and pulmonary stenosis.[5] Five years later, another series of postmortem examinations described four cases of what were termed "double outlet right ventricle." The first recognition of DORV on a living patient was made the same year at Mayo Clinic at the time of surgical correction.[6]

During the decades that followed, the complex spectrum of anatomic variations that could be classified as subgroups of DORV became apparent. The importance of distinguishing DORV from simple VSD prior to attempting surgical intervention was emphasized by Engle and Steinberg.[7] Neufeld was the first to suggest clinicopathologic subsets of DORV when he stratified patients into those with or without pulmonary stenosis.[8] In the same original manuscript that distinguished patients without pulmonary stenosis,[8] he described the location of the VSD relative to the aorta and pulmonary artery (PA). This seminal work was carried forward by Lev when he classified the VSD relative to their position to the subarterial outlets: subaortic, subpulmonary, doubly-committed, and non-committed.[1] The importance of the spacial relationship of the great vessels to each other was also highlighted.[9–11] Although the Taussig-Bing heart was physiologically more similar to TGA with VSD,[12] it was Neufeld who recognized that the Taussig-Bing heart was an anatomic subset of DORV.[13] Mayo Clinic surgeons were the first to report surgical correction of the Taussig–Bing heart,[14] and intraventricular tunnel repair of this disorder.[15]

## Embryology

There are two theories that attempt to describe the cono-truncal abnormalities that result in the development of DORV. Lev has proposed that DORV results when there is an abnormal spiraling septation of the aorta from the PA that is more than Fallot's tetralogy but less than transposition.[16] Alternatively, Van Praagh's theory proposed that conal underdevelopment results in the great arteries emerging from the RV in a side-by-side arrangement.[17]

## Classification

Based on the spatial relationship of the VSD to the semilunar valves, DORV can be anatomically classified as subaortic, subpulmonary, doubly-committed, or remote.[1] It should be noted, however, that the pathophysiology and type of surgical repair are influenced not only by the relative location of the VSD to the semilunar valves, but also by the relationship of the great arteries to each other, and any associated abnormalities. Because there is no absolute correlation between the commitment of the VSD to the great arteries and the surgical approach,[18,19] a nomenclature system that defines four types of DORV based on clinical presentation and treatment has been adopted by the STS-EACTS.[2] The four types are: (1) VSD-type, (2) Fallot-type, (3) TGA-type, and (4) DORV with non-committed VSD. This system offers the advantage of uniformity to DORV nomenclature which allows an accurate and reproducible pediatric cardiac surgery database, resulting in reliable and meaningful outcome studies for the variety of surgical procedures available.

## Ventricular Septal Defect

DORV is, for practical purposes, always associated with a VSD. Rarely is DORV not associated with an interventricular communication,[20] and this anatomic rarity most likely represents spontaneous closure of a preexisting VSD. The most well known classification of DORV is based on the relative position of the VSD to the arterial outlets.[1] Most often, the VSD is located between the anterior and posterior limbs of the trabecula septomarginalis (TSM) (Fig. 71-1), and as such can be described as "committed."[21] The attachment of the infundibular septum to either the anterior or posterior limb predicts which great artery is related to the VSD. Sub-aortic VSD is associated with the infundibular septum being attached or aligned with the anterior limb of the TSM. Conversely, posterior limb alignment of the TSM with the infundibular septum results in a subpulmonary VSD. The infundibular septum is absent or markedly attenuated in cases of doubly-committed VSD. The non-committed VSD is away from the semilunar valve(s) and it has been proposed that this distance be greater than the diameter of the aortic valve.[22] The noncommitted VSD is located in the inlet septum (atrioventricular (AV) canal defect or muscular) or the trabecular ventricular septum. The majority of VSDs in DORV are unrestrictive, but restrictive VSDs may be seen in approximately 10 percent of patients. Although restrictive VSDs are diagnosed preoperatively in approximately 1.6 percent, an additional 11 percent of patients require VSD enlargement at the time of repair to prevent subaortic obstruction.[6,19] Multiple VSDs can be seen in 13 percent, and it is extremely rare for no VSD to be present. In the absence

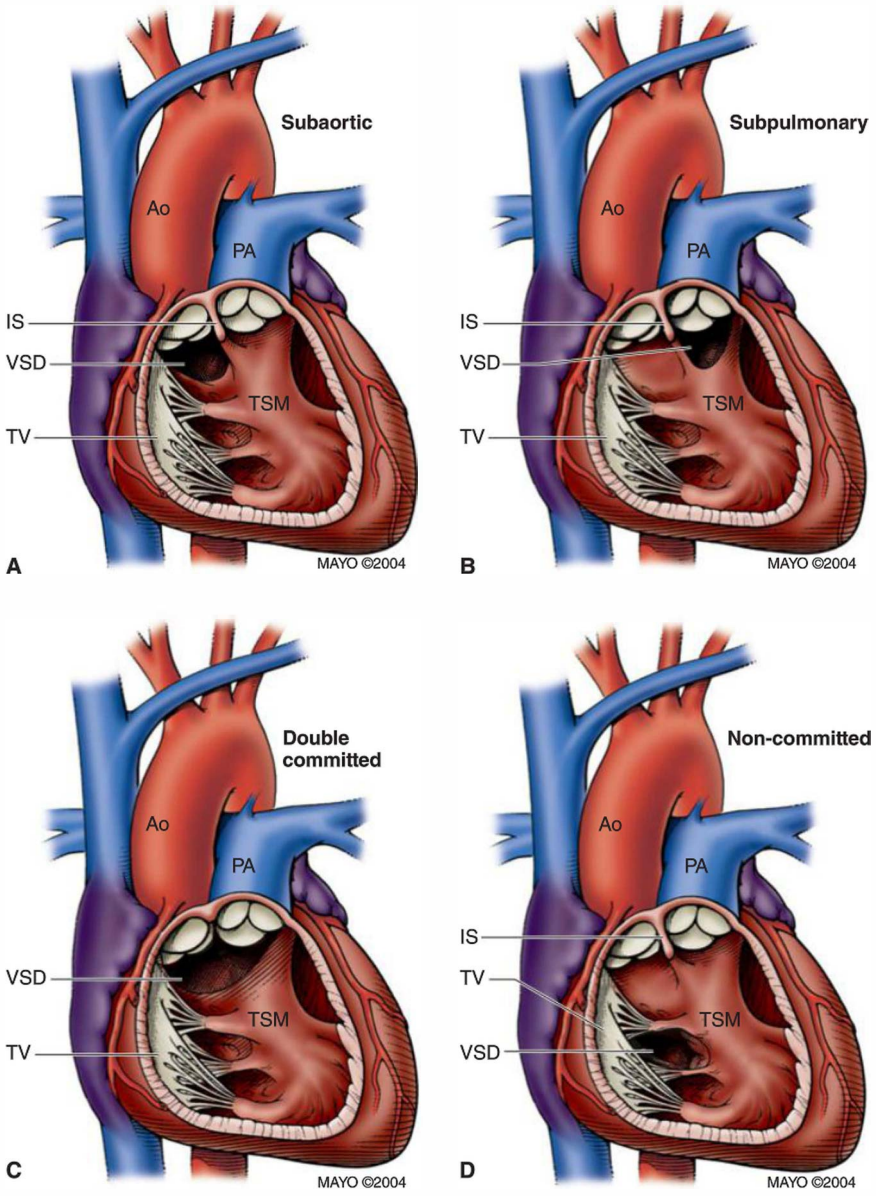

**FIGURE 71-1** **A.** Diagram illustrating double outlet right ventricle (DORV) with subaortic ventricular septal defect (VSD). **B.** Diagram illustrating DORV with subpulmonic VSD. **C.** Diagram illustrating DORV with doubly committed VSD. **D.** Diagram illustrating DORV with noncommitted VSD. All rights reserved.)

of a VSD, there is an ASD, which serves as left-to-right shunt. In this situation, the LV is usually hypoplastic.[2]

## SUBAORTIC VSD

This is the most common type of VSD and occurs in approximately 50 to 55 percent of patients undergoing repair of DORV. The VSD is unrestrictive. Bilateral coni are present in 77 percent of patients and a subpulmonary conus is present in 23 percent (Table 71-1).[22] The length of the conus determines the distance of the VSD from the aortic valve. Due to the relationship of the infundibular septum being aligned with the anterior limb of the TSM, the subaortic VSD is located in a posterior position in the ventricular septum

**TABLE 71-1: Relationship of VSD and Conus Pattern in DORV**

| | Type of Conus | | | |
|---|---|---|---|---|
| **Position of VSD** | **Bilateral (%)** | **Subaortic (%)** | **Subpulmonary (%)** | **Absent (%)** |
| Subaortic | 77 | 0 | 23 | 0 |
| Subpulmonary | 45 | 55 | 0 | 0 |
| Doubly committed | 67 | 0 | 0 | 33 |
| Non-committed | 50 | 50 | 0 | 0 |

Data based from Green Lane Hospital of 42 autopsy specimens and adapted from Kirklin JW, Barratt-Boyes BG. Double outlet right ventricle. In: Kirklin JW, Barratt-Boyes BG (eds). *Cardiac Surgery*, 3rd ed. New York: Churchill Livingston, 2003:1509–1539.

(Fig. 71-1A). In the presence of aortic–mitral fibrous continuity (i.e., absent subaortic conus; the left cusp or the base of the anterior leaflet of the mitral valve forms the posterosuperior margin of the VSD) the VSD is termed juxta-aortic. Individuals with a subaortic VSD have a relatively normal pattern of circulation.

### SUBPULMONIC VSD

This type of VSD is often seen in the Taussig-Bing anomaly. This VSD is located in a more anterior position in the ventricular septum since the posterior limb of the TSM is rotated and aligned with the infundibular septum (Fig. 71-1B). Pulmonary stenosis is usually absent and the VSD is unrestrictive. A subpulmonary VSD is present in approximately 30 percent of patients with DORV undergoing surgical repair.[6,19] As with the subaortic VSD, the length of the pulmonary conus determines the distance of the VSD from the pulmonary valve. In this situation, the conus forms the anterosuperior margin of the VSD. The absence of subpulmonary conus results in pulmonary–mitral and occasionally pulmonary–tricuspid continuity. This results in the VSD being juxtapulmonary. Individuals with a subpulmonary VSD have a transposition-like circulation because the LV blood is directed to the PA.

### DOUBLY-COMMITTED VSD

This type of VSD is seen in 3 to 10 percent of surgical series.[23] The VSD is usually large due to attenuated or absent infundibular septum. The semilunar valves form the superior border while the limbs of the TSM form the anterior, inferior and posterior margins (Fig. 71-1C).

### NONCOMMITTED VSD

This type of VSD is remote from the semilunar valves and is seen in 3 to 20 percent of surgical series.[22] Most are associated with DORV and complete AV septal defects. Straddling of the AV valve may be present with this type of VSD (Fig. 71-1D).

## Relationship of the Great Arteries

The relationship of the great arteries at the level of the semilunar valves in DORV can be grouped into two broad categories: (1) spiraling and (2) parallel. Spiraling great arteries is the normal anatomic relationship with the aortic trunk positioned posterior and to the right of the pulmonary trunk; this is the most common great vessel relationship in DORV.[2] When the great arteries are parallel, the aortic trunk is in a more anterior position relative to the pulmonary trunk. There are multiple degrees of variability in the anteroposterior relationship between aortic trunk and pulmonary trunks. In general, however, this relationship can be broken down into the following: (1) aorta located to the right and side-by-side with the PA (Taussig–Bing), (2) aorta located to the right and anterior to the PA (D-TGA), and (3) aorta located anterior and to the left of the PA (L-malposition).

It must be noted that the relationship of the great arteries and the type of VSD present are independent of each other. In general terms, however, spiraling and L-malposition of the great arteries are most commonly associated with a subaortic VSD. Side-by-side (parallel) great arteries are most often associated with a subpulmonic VSD.[2]

## Other Cardiac Anomalies

Associated cardiac anomalies are common with DORV, and almost any type of congenital cardiac anomaly can be present. At the Mayo Clinic, 179 patients with a diagnosis of DORV were operated on between 1972 and 1992, and 87 (48.6 percent) had concomitant congenital anomalies. Table 71-2 shows the concomitant anomalies present in this series. ASD was the most common associated anomaly, followed by persistent left SVC and coronary artery anomalies. Multiple VSDs were seen in approximately 12 percent of patients and are a risk factor for early mortality.[24] Coarctation of the aorta is a commonly associated anomaly in approximately 50 percent of patients with the Taussig–Bing form of DORV.[25]

Overriding and/or straddling of the AV valve apparatus may be present in DORV, making biventricular repair difficult. Straddling of the right AV valve may permit a biventricular

**TABLE 71-2: Concomitant Congenital Cardiac Anomalies in 179 Patients Undergoing Repair for DORV (Exclusive of Pulmonary Stenosis) at the Mayo Clinic From 1972 to 1992**

| | Number | Frequency (%) |
|---|---|---|
| ASD | 99 | 55 |
| Persistent L SVC | 34 | 19 |
| Coronary anomalies | 28 | 16 |

Adapted from unpublished data.

repair.[26] Significant overriding of the right AV valve may result in a small inlet portion of the RV after VSD closure and a concomitant bidirectional cavopulmonary shunt may be necessary.[27] Left AV (mitral) valve anomalies include mitral atresia, parachute valve, straddling, and supravalvular stenosing ring.

Pulmonary stenosis occurs commonly in DORV, particularly in those cases with subaortic and doubly-committed VSDs. The stenosis is most often at the level of the infundibulum.

## Coronary Artery Anatomy

The coronary artery anatomy in DORV is predominantly the normal pattern.[28] However, anomalous coronary patterns can be seen in up to 16 percent of patients undergoing operation. The most common abnormality is anomalous origin of the left anterior descending artery from the right coronary artery. This pattern is typically seen in the subgroup of DORV with subaortic VSD and right ventricular outflow tract obstruction (RVOTO).[29] Coronary arterial patterns that are seen with transposition of the great arteries are also present in patients with DORV.

## Conduction Tissue

The AV node and His bundles follow pathways that are specific for the type of AV connections. In AV concordance, the VSD is usually perimembranous (conoventricular) and the conduction tissue is along the posterior-inferior border of the defect. In the presence of AV discordance, the conduction pathways are anterior and adjacent to the PA.

# CLINICAL FEATURES

## Epidemiology

DORV is a rare congenital cardiac anomaly. Its frequency is approximately 0.09 per 1000 births. There is no racial or gender predominance.[30,31]

## Pathophysiology and Clinical Manifestation

### SUBAORTIC VSD

The position of the infundibular septum and the presence of RVOTO determine the clinical presentation. Anterior deviation of the infundibular septum producing RVOTO presents with cyanosis, similar to tetralogy of Fallot. Concomitant pulmonary stenosis may be present. Other findings that can be seen as a result of RVOTO include failure to thrive, dyspnea on exertion, squatting and polycythemia.

Management is similar to that of tetralogy of Fallot. In the absence of RVOTO, the clinical presentation is like that of a large VSD with heart failure being the presenting symptom.

### SUBPULMONARY VSD

Clinical presentation is usually cyanosis due to unfavorable streaming of deoxygenated blood into the aorta and oxygenated blood into the PA via the subpulmonary VSD. This presentation is very similar to that of patients with D-TGA. Subaortic stenosis may be present in up to 35 percent of patients with Taussig–Bing anomaly.[25] Concomitant coarctation or arch hypoplasia may occur in up to 50 percent of infants with DORV and subpulmonary VSD. Patients are seen in early infancy with cyanosis, heart failure, failure to thrive and frequent respiratory infections. High pulmonary blood flow in this subgroup of DORV results in pulmonary vascular obstructive disease at an early age if surgical correction is not undertaken.

### DOUBLY-COMMITTED VSD

This lesion is uncommon and presentation depends on the presence of favorable or unfavorable streaming. Pulmonary stenosis may also be present.

### REMOTE VSD

Clinical presentation is similar to patients with single ventricle. Oxygen saturations are usually that of complete mixing due to the remoteness of the VSD from the great arteries. Pulmonary blood flow may be balanced, increased or decreased.

# PHYSICAL EXAMINATION

There are no specific findings on physical exam that are pathognomonic of DORV. Patients in heart failure can present with tachypnea and failure to thrive, while cyanosis is seen in patients with inadequate pulmonary blood flow.

## DIAGNOSTIC STUDIES

### Electrocardiography

There are no electrocardiography (ECG) findings that are pathognomonic for DORV. There are, however, certain ECG abnormalities that can be seen in DORV (Fig. 71-2). The most common abnormality seen is RV hypertrophy and right axis deviation. This is a result of high RV pressures. LV hypertrophy can be seen in the presence of a restrictive VSD or from volume overloading in the presence of high pulmonary blood flow as can be seen in DORV with subpulmonic VSD (Taussig–Bing anomaly). Right atrial enlargement is commonly seen with pulmonary stenosis. In contrast, left atrial enlargement is seen in the absence of pulmonary stenosis or when functional mitral stenosis is present. Other ECG abnormalities include first-degree AV block and left axis deviation due to posterior displacement of the conduction tissue.

### Chest X-Ray

Variable chest x-ray findings can be associated with DORV. Patients with pulmonary stenosis will have diminished pulmonary vascular markings. In contrast, patients with high pulmonary blood will show increased pulmonary markings. Patients presenting late with pulmonary vascular obstructive disease usually have diminished pulmonary vascular markings and prominent central pulmonary arteries. Cardiomegaly can be present. DORV with RVOTO (i.e., TOF physiology) may have RV hypertrophy and an upwardly turned apex of the cardiac silhouette. LV hypertrophy and enlargement, which may be seen in the presence of an unrestrictive VSD may have a downwardly turned and displaced apex below the diaphragm.

### Echocardiography

Transthoracic echocardiography is the imaging technique that is most commonly used for making the diagnosis of DORV. Transesophageal echocardiography is utilized for more complex abnormalities of the AV valves (i.e., overriding and straddling). Diagnosis is established by demonstrating both great arteries predominately arising from the anterior RV, and VSD as the sole outlet of the LV. Echocardiography can also delineate aortic–mitral fibrous discontinuity. Concomitant cardiac anomalies (i.e.,

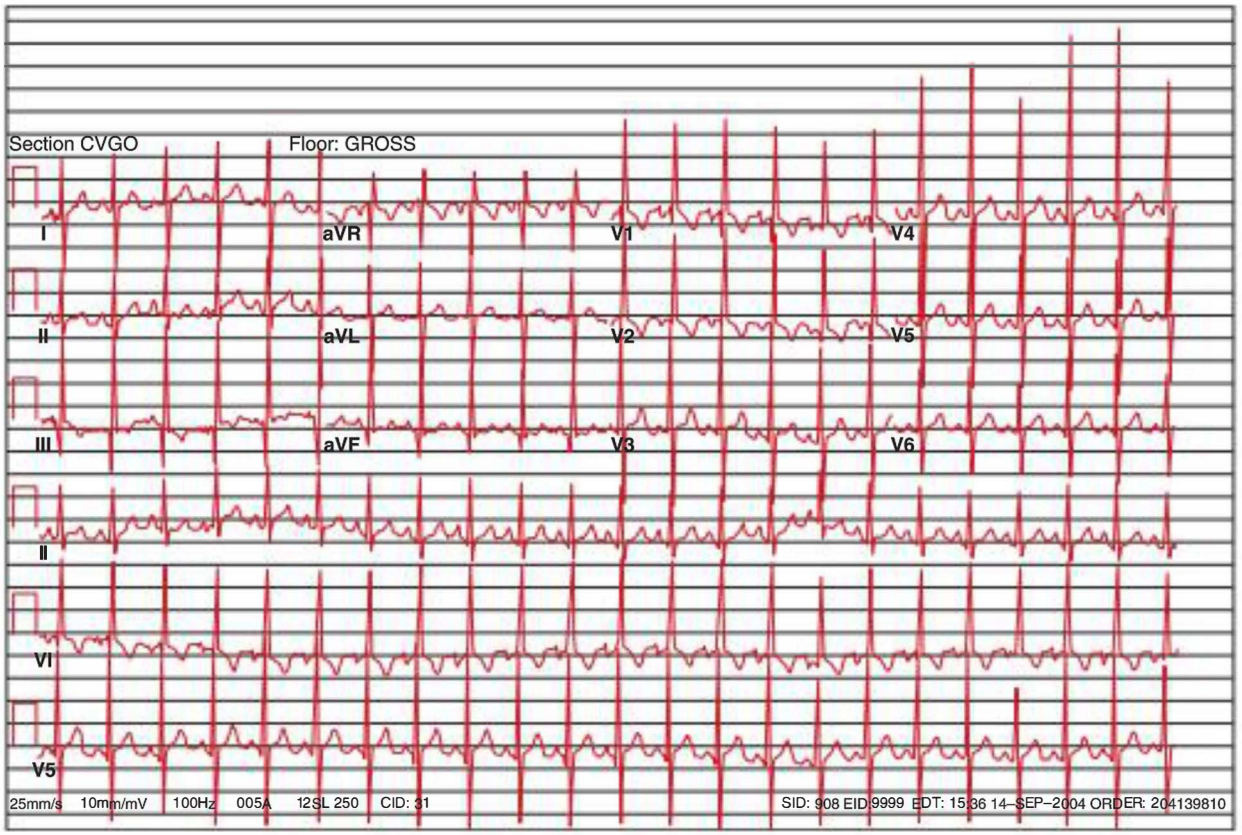

**FIGURE 71-2** Electrocardiograph of 6-month-old patient with DORV and subaortic VSD, exhibiting some of the features that can be seen with this anomaly: normal sinus rhythm with biatrial enlargement, right ventricular hypertrophy and right axis deviation.

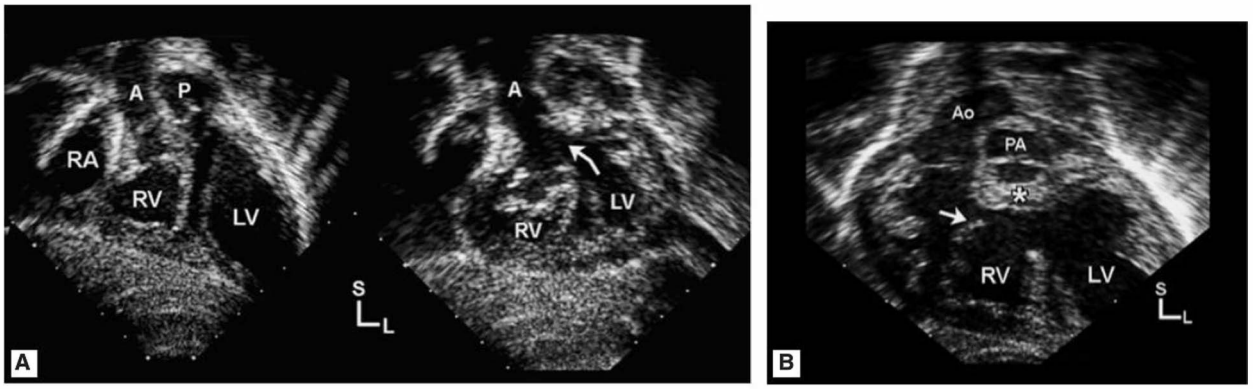

**FIGURE 71-3** **A.** Transthoracic echocardiogram (ECHO) in patient with double outlet right ventricle with subaortic VSD. Left image: Subcostal four-chamber view with anterior angulation demonstrates both great arteries arising from the right ventricular outflow tract (RVOT) with aorta (A) to the right and pulmonary artery (P) to the left. Right image: Slight posterior angulation of the scan plane reveals that the ventricular septal defect (VSD) (arrow) is closely related to the aorta. There is infundibular muscle interposed between the VSD and the pulmonary the pulmonary valve. There is no pulmonary or subpulmonary stenosis and no important structures or valve attachments lying between the VSD and the aortic valve. Repair in this situation requires placement of an intraventricular tunnel to direct left ventricular outflow across the VSD toward the aorta and allowing the right ventricle to eject anteriorly to the patch directly into the pulmonary artery. **B.** Transthoracic echocardiogram illustrating double outlet right ventricle with remote VSD. Subcostal four chamber view with anterior angulation demonstrates both great arteries arising from the RVOT. Note, however, that the semilunar valves are relatively further away as compared to the ECHO shown in A. The pulmonary valve is to the left and is separated from the VSD by a thick wall of malposed infundibular septum (asterisk). The tricuspid valve has an outlet attachment that is positioned between the VSD and the aortic valve (arrow). Simple septation in this case is not possible. The three options for complete repair here would be to: (1) perform a complex intraventricular tunnel (multiple patch technique) and tricuspid valve replacement; (2) arterial switch operation with resection of the leftward portion of the malpositioned infundibular septum; and (3) treat this complex anatomical DORV variant as a functionally univentricular heart and channel the patient down a Fontan palliation strategy.

coronary artery patterns, coarctation, etc.) are usually readily noted by echocardiography. Usually echocardiography is the only diagnostic modality required in an infant for establishing the appropriate plan of management. Figure 71-3 illustrates some of the characteristic views by echocardiography in making the diagnosis of DORV. Additional diagnostic techniques are usually required in older children and adults.

## Cardiac Catheterization

Cardiac catheterization may be required to determine hemodynamics for suitability of repair, exclude pulmonary vascular obstructive disease and to determine coronary artery anatomy.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides complementary information about associated intracardiac defects and the relationship of the aorta and PAs. In addition, MRI can provide a 3-dimensional relationship of the cardiac chambers and arrangement of the great vessels and coronary arteries, as well as an accurate assessment of left and RV size and function. MRI may be helpful in predicting feasibility of biventricular repair in DORV hearts with non-committed VSDs.[32]

# SURGICAL THERAPY

In 1957, Kirklin performed the first repair of DORV in a child at the Mayo Clinic. This technique involved an intraventricular tunnel to establish LV–aortic continuity via a subaortic VSD.[6] Since that time, many surgical procedures have been developed to repair some of the more complex anatomical variations seen with DORV.[33–37] The optimal surgical approach is tailored to the specific anatomy. Complete anatomical repair is the goal when feasible. This includes establishing continuity of the LV with the systemic circulation, the RV to the pulmonary circulation and VSD closure.

A palliative operation prior to complete repair may be required, and is undertaken in 42 to 75 percent of patients with DORV.[24,33,34] Furthermore, approximately 25 percent will undergo more than one palliative operation, thus illustrating the complexity of this anomaly. Palliative operations have included systemic to PA shunts, PA banding, and repair of other anomalies such as coarctation. Anatomical anomalies precluding complete repair include ventricular hypoplasia, straddling or overriding of the atrioventricular valves, multiple VSDs, pulmonary obstructive vascular disease and other associated complex cardiac anomalies.

It is helpful to the surgeon to categorize DORV into four groups, which helps in guiding the appropriate surgical management:

1. Subaortic or doubly-committed VSD and RVOTO—TOF-type
2. Subpulmonary VSD—TGA-type

3. Subaortic or doubly committed VSD without RVOTO—VSD-type
4. Noncommitted VSD with or without RVOTO

## Subaortic or Doubly Committed VSD Without RVOTO (VSD Type)

The VSD is usually exposed through a longitudinal right ventriculotomy with care taken to avoid injury to large conal branches or the left anterior descending artery. A right atrial approach can also be performed. However, it is difficult to assess proper alignment of the intraventricular tunnel from the VSD to the aorta with this approach. After the right ventriculotomy is made, the size and location of the VSD is established, particularly noting whether the VSD abuts the tricuspid valve or has a rim of muscle along its posterior border. The diameter of the VSD must be at least the diameter of the aortic annulus to prevent outflow tract obstruction to the aorta. If the VSD is restrictive, it is enlarged by resecting a wedge of muscle in an antero-superior direction. Obstructing muscle bundles of the RV and a small portion of the infundibular septum are often excised for proper alignment of the patch, which is shaped like a tunnel. RVOTO is a potential complication of this procedure. This problem is avoided by establishing that the distance between the tricuspid annulus and the pulmonary annulus is at least the diameter of the aortic annulus. This can be assessed preoperatively by subxiphoid views on echocardiography and by intraoperative assessment. The VSD patch material used is often a Sauvage Dacron patch (USCI Sauvage filamentous Dacron fabric, C.R. Bard, Inc, Bellerica, MA.), Gore-Tex (W.L. Gore and Assoc., Inc, Flagstaff, AZ.), or a tailored Dacron tube graft. The patch is sewn to channel the flow of blood from the LV across the VSD to the aortic annulus. It is important to note that the patch is not flat, but rather an opened tube or tunnel, thus providing an unobstructive channel between the VSD and the aorta. Superiorly, the patch is sewn to the aortic annulus. Posteroinferiorly, the suture line is deviated away from the edge of the VSD to avoid injury to the conduction tissue. Posteriorly, the patch is sewn to the base of the septal leaflet of the tricuspid valve. If muscle interposes the tricuspid annulus and VSD then the VSD repair sutures can be placed in this muscle without damaging the conduction tissue (Fig. 71-4). The right ventriculotomy is closed with a patch to avoid RVOTO created by the intraventricular tunnel.

Complete intraventricular tunnel repair is performed within the first 6 months of life because of the increased risk of developing pulmonary vascular obstructive disease. In previous years, initial palliation with a PA band followed by an intraventricular tunnel and debanding in early childhood was performed.

## Subaortic VSD and RVOTO (TOF Type)

The repair of this anomaly is similar to repairs described ifor TOF (see Chapter 68). Exposure is usually accomplished via a right ventriculotomy; however, exposure of the VSD can be

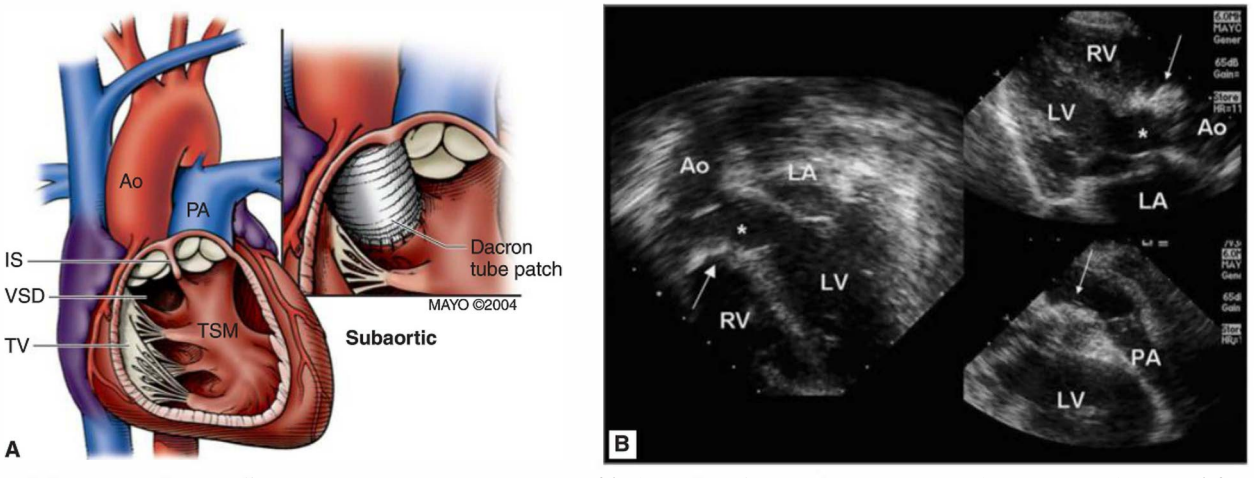

**FIGURE 71-4** **A.** Diagram illustrating intraventricular tunnel repair of double outlet right ventricle (DORV) with subaortic ventricular septal defect (VSD). Left ventricular ejection is directed via the VSD to the aorta. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.) **B.** Postoperative transthoracic echocardiogram illustrating repair in a patient with DORV and subaortic VSD with no postoperative left ventricular outflow tract and right ventricular outflow tract obstruction. The left panel is an anteriorly angulated apical view illustrating deviation of the VSD patch (subaortic VSD) in order to channel flow from the VSD to the aorta. The arrow points to the right ventricular (RV) surface of the VSD patch. The asterisk indicates the pathway from the left ventricular (LV) to the aortic valve created by the patch. The upper right panel is a parasternal long-axis image in the same patient. Again, the arrow points to the RV surface of the patch and asterisk indicates the pathway from the LV to the aortic valve created by the patch. The lower right panel is a modified parasternal view focused on the long axis of the main pulmonary artery. The RV outflow has been deviated anterior to the patch (arrow), but remains widely patent.

obtained via the transatrial approach. The os of the infundibulum is resected to enlarge the right ventricular outflow tract (RVOT). The VSD is closed using the tunnel technique described above. The right ventriculotomy is closed with a patch to prevent RVOTO. An anomalous coronary artery crossing the RVOT can limit the ventriculotomy, resulting in inadequate relief of RVOTO. In this situation, a valved extracardiac conduit from the RV to PA can be used. In the current era, most centers would perform complete repair in the first year of life. Alternatively, palliation with a shunt can be performed if surgical treatment is required in the first 2 to 3 months of life.

## Subpulmonary VSD (Taussig–Bing Type)

The operation of choice for DORV with subpulmonary VSD and no RVOTO (i.e., Taussig–Bing anomaly) is the arterial switch operation and patch closure of the VSD, directing blood flow from the LV to the pulmonary (neoaortic) valve (Fig. 71-5). Details of the arterial switch operation are described in Chapter 74. Closure of the VSD can be performed via the right atrium, RV or the aortic root (neopulmonary artery) depending on the location of the VSD.

Results of the arterial switch operation for this anomaly has been excellent, and the operative mortality for this form of DORV has significantly decreased in recent years.[37]

Intraventricular tunnel repair techniques such as the Kawashima operation are performed less commonly for patients with Taussig-Bing anomaly.[38] Increasing expertise with the arterial switch operation has made the Kawashima repair less appealing.

Concomitant aortic arch hypoplasia can be present with Taussig–Bing hearts and should be addressed as a single-stage complete repair. In the presence of arch hypoplasia, there is a high likelihood of hypoplasia of the RVOT leading to clinically important infundibular obstruction. As such, RVOT obstruction should always be evaluated in the presence of arch hypoplasia.

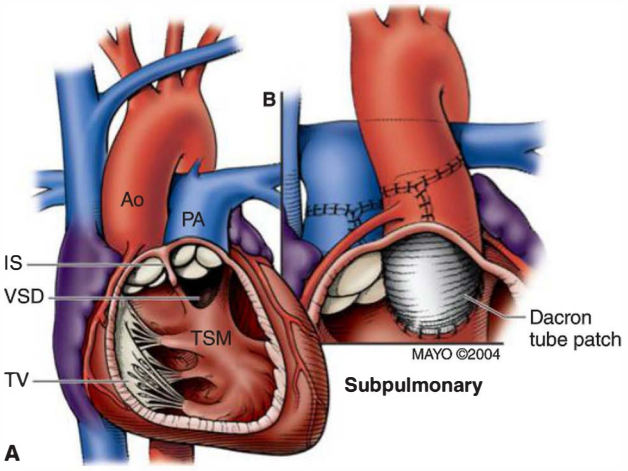

**FIGURE 71-5** Diagram illustrating arterial switch operation and tunneling of LV flow through the VSD to the neoaorta for Taussig–Bing anomaly. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

The REV operation (*réparation à l'etage ventriculaire*) introduced by Lecompte is yet another intraventricular repair designed for patients in whom an arterial switch and simple intraventricular tunnel repair of the VSD are not feasible. This situation arises when there is coexisting LV outflow tract obstruction, that is, pulmonary stenosis. In this operation the LV outflow is directed to the aorta and the pulmonary trunk is transected with the distal segment directly anastomosed to the RV.[39,40]

## Doubly-Committed VSD

This anatomy is uncommon. When present, repair is usually accomplished in the first 6 months of life. Closure of the superior aspect of the VSD may be challenging because of the absence of the infundibular septum. Enlargement of the VSD is performed as needed and as described above. If the VSD is more closely related to the PA, then arterial switch operation as described for the Taussig–Bing anomaly is preferred.

## Non-committed VSD

Surgical repair in this group is complex and challenging. Despite the challenges faced with the long-term results of the Fontan operation,[41] many groups continue to pursue univentricular palliation.[42] Typically, this strategy involves placement of a PA band during the neonatal period. A bidirectional cavopulmonary shunt is performed at 4 to 6 months of age. The Fontan procedure is then performed between 18 months and 4 years of age.

The Fontan procedure has undergone many modifications and, presently, medium-to-late term results are quite favorable.[24] As a result, some have advocated that the more complex anatomical variants of DORV be channeled toward a single ventricle physiological track.[35] Brown et al. in their 20-year experience in treating DORV performed modified Fontan operations in 26.6 percent of patients with DORV. In addition to remote VSD, indications for Fontan type operations have included complex anomalies such as straddling AV valves, AV septal defects or hypoplastic LV, or a combination of AV septal defects and hypoplastic ventricle, atrial isomerism, multiple VSDs, and major PA anomalies including atresia, slings, and discontinuous branch pulmonary arteries. Early morality when Fontan-type operations are performed has been shown to be approximately 5 percent in this complex group of patients.[33]

Although a biventricular repair is desirable in the presence of two normally functioning ventricles and AV valves, the complexity of the intracardiac repair and tunnel can be associated with high early mortality.[6] The distance between the noncommitted VSD and the aorta necessitates a long

prosthetic intracardiac baffle. This can result in impaired function of either the tricuspid or pulmonary valves or the creation of an akinetic portion of the LV. Another obstacle to the two-ventricle repair is the subaortic obstruction caused by the baffle as a result of somatic growth. Others have reported a multiple patch technique to create the tunnel between the VSD and aorta.[43] One possible solution is tunneling the VSD to the pulmonary infundibulum followed by an arterial switch.[36]

There are few data describing the results of intracardiac repair of non-committed VSD type DORV. Of 10 patients undergoing rerouting of the VSD to the PA followed by arterial switch, there was only 1 postoperative death. At 20 months, the remaining nine survivors were in NYHA class I, in sinus rhythm, and had no subaortic gradient greater than 15 mm Hg.[36] Of 7 patients with tunneling of the VSD to the aorta,[44] 70 percent of these patients required VSD enlargement and 60 percent required a subaortic resection of the conal septum.[45] Two patients with VSD enlargement required a pacemaker. There was one postoperative death in a patient who developed mediastinitis. There was one late reoperation in a patient with non-committed VSD-type DORV who underwent VSD–PA baffle and an arterial switch operation.

## PALLIATIVE OPERATIONS

Palliative operations are less frequently performed in the current era due to lower mortality rates demonstrated with complete repair in neonates and infants. Furthermore, recent series have shown that patient age and weight do not adversely impact mortality.[33,34] However, these studies were undertaken in centers that perform a large number of operations in neonates and infants. Many reported surgical series continue to demonstrate between 42 and 75 percent of patients having had an initial palliative operation, most being a modified Blalock-Taussig shunt.[6,22] This may reflect, in part, that many patients were operated on in an earlier era. This percentage will continue to decrease as results of complete repair during infancy continue to improve.

## OUTCOME/PROGNOSIS

Results of complete repair for DORV have been reported in large contemporary series[24,33,36,46] and early mortality has been shown to range from 2.6 to 9 percent. In general, late outcome is determined by anatomy and postrepair physiology.

Patients with DORV similar to tetralogy of Fallot, have results similar to tetralogy of Fallot. When repair requires the use of an RV-to-PA conduit, repeat operation(s) for conduit replacement are required. The REV procedure (PA directly attached to the RV) may lessen the need for reoperation,[47] but may occur at the expense of RV dilatation and subsequent RV failure.

Patients undergoing arterial switch operation have excellent late survival. In contrast to simple transposition, the incidence of neoaortic valve regurgitation is more common and may require the need for reoperation for valve repair or replacement.[48]

Subaortic obstruction is a complication that can be seen both early and late in patients who have undergone complete repair for DORV. This complication is a result of intracardiac tunneling of the VSD to the aorta. Late development of subaortic obstruction results from protrusion of the inferior rim of the tunnel into the LVOT or from fibrous tissue growth below the aortic valve.[49] The risk of this complication can range from 5 to 50 percent depending on the individual anatomy. Treatment of subaortic obstruction is surgical and involves an extended septoplasty (Fig. 71-6) and subaortic resection of fibrous tissue.

Brown et al. reported a 20-year experience in 124 patients. Survival at 15 years was 96 percent for simple intracardiac repairs, 90 percent for subpulmonary VSD, and 90 percent for straddling AV valves or hypoplastic ventricles. Freedom

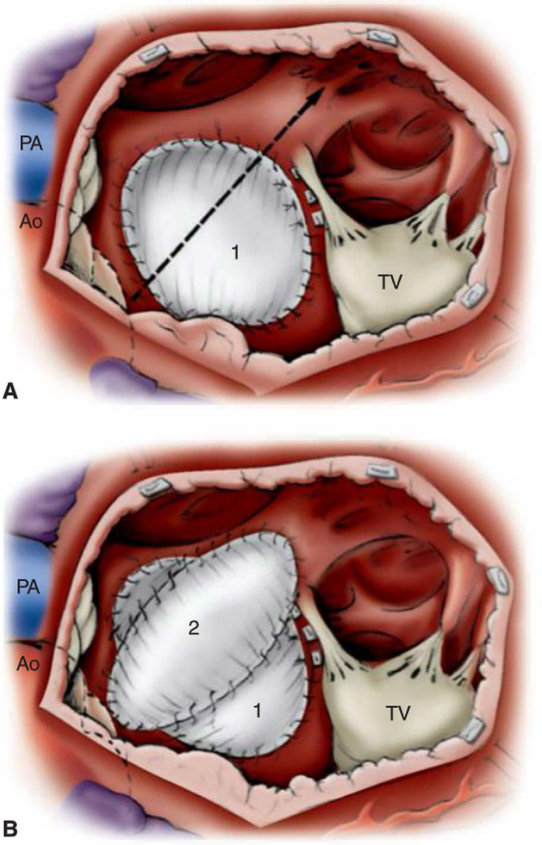

**FIGURE 71-6** Extended septoplasty for management of late subaortic obstruction following complete repair for DORV. **A.** Right ventriculotomy approach. The arrow illustrates the septal incision made through the patch and toward the apex (leftward). **B.** Following septal incision, a second patch is placed resulting in augmentation of the LVOT. (Reprinted with permission from Belli et al., *J Thorac Cardiovasc Surg* 1996;112:1570.)

from reoperation at 15 years was 87 percent for simple intracardiac repairs, 72 percent for subpulmonary VSD, and 100 percent for those with more complex intracardiac anatomy who underwent an arterial switch operation and VSD closure, thus avoiding a complex intracardiac tunnel repair.

Risk factors for early mortality have been variable and include aortic arch obstruction, AV septal defects, mitral stenosis/regurgitation, multiple VSDs and age less than 1 month.[24,33,34]

## CONCLUSIONS

In summary, DORV is a type of ventriculo–arterial connection whereby both great arteries arise from the RV. It is a form of complex congenital heart disease that can be associated with many other cardiac anomalies. The physiology and clinical presentation ranges from VSD-like physiology, to tetralogy of Fallot, to transposition, to single ventricle physiology. Understanding the physiology allows the proper surgical management strategy. Late results are favorable for most patients, although the potential need for reoperation remains.

## DOUBLE OUTLET RIGHT VENTRICLE BOARD REVIEW QUESTIONS (CHAPTER 71)

1. Which is not a recognized type of DORV?
   A. VSD type
   B. Fallot type
   C. Mitral atresia type
   D. TGA type
   E. Noncommitted VSD type

2. Which is correct regarding the VSD in DORV?
   A. Subaortic VSD is the least common type.
   B. Bilateral coni are present in over 75 percent of patients with a subaortic VSD.
   C. A doubly committed VSD is associated with the Taussig–Bing heart.
   D. A subpulmonic VSD is associated with pulmonary stenosis and is restrictive.
   E. Noncommitted VSDs are associated with DORV and partial AV canal defects.

3. Which is true regarding clinical features of DORV?
   A. Anterior deviation of the infundibular septum and a subaortic VSD presents with cyanosis.
   B. Clinical presentation of a subpulmonary VSD is usually congestive heart failure.
   C. Subpulmonary VSDs are associated with arch hypoplasia in less than 10 percent of patients.
   D. A doubly committed VSD almost always presents with cyanosis.
   E. A remote VSD presents with cyanosis due to the distance from the PA.

4. Which of the following is correct regarding surgical repair of DORV?
   A. Complete intraventricular tunnel repair is performed after 1 year of palliation for subaortic or doubly committed VSD without RVOTO.
   B. Most centers will perform complete repair of subaortic VSD with RVOTO within the first year of life.
   C. The operation of choice for subpulmonary VSD without RVOTO is the atrial switch operation.
   D. Concomitant arch hypoplasia and Taussig–Bing heart is best treated with a two-stage repair.
   E. Noncommitted VSD is treated with simple patch closure of the VSD.

5. Which is true regarding outcomes after repair of DORV?
   A. Early mortality is 10 to 15 percent.
   B. The REV procedure reduces RV size over time.
   C. The incidence of neoaortic valve regurgitation after arterial switch for DORV is higher than after repair for simple transposition.
   D. AV septal defects are not a risk factor for early mortality.
   E. Subaortic obstruction occurs in less than 10 percent.

## ANSWERS

1. **Answer: C.** There is no mitral atresia type of DORV. The four types adopted by the STS and EACTS are VSD, Fallot, TGA, and noncommitted VSD.
2. **Answer: B.** Bilateral coni are present in over 75 percent of patients with a subaortic VSD. Subaoartic VSD is the most common type. Taussig–Bing anomaly is associated with a subpulmonic VSD. This form of VSD is typically unrestrictive and there is no pulmonary stenosis. Noncommitted VSDs are associated with DORV and complete AV canal defects.
3. **Answer: A.** Anterior deviation of the infundibular septum and a subaortic VSD presents with cyanosis due to RVOT obstruction. Clinical presentation of a subpulmonary VSD is usually also cyanosis. Subpulmonary VSDs are associated with coarctation or arch hypoplasia in up to 50 percent of patients. A doubly committed VSD has variable presentation due to streaming patterns. A remote VSD also has variable presentation due to the complete intracardiac mixing.
4. **Answer: B.** Most centers will perform complete repair of subaortic VSD with RVOTO within the first year of life. Complete intraventricular tunnel repair is performed

within the first 6 months for subaortic or doubly committed VSD without RVOTO. The operation of choice for the Taussig–Bing heart is arterial switch with patch VSD closure. Concomitant arch hypoplasia and Taussig–Bing anomaly is best treated with a single repair strategy. Noncommitted VSD is a complex anomaly and best individualized.

5. **Answer: C.** The incidence of neoaortic valve regurgitation after arterial switch for DORV is higher than after arterial switch for simple transposition. Early mortality rates range from 3 to 9 percent. The REV procedure can result in RV dilation and failure. AV septal defects are a risk factor for early mortality. Subaortic obstruction occurs in up to 50 percent of patients.

# Truncus Arteriosus

*Tara Karamlou*
*D. Michael McMullan*
*Gordon A. Cohen*

**KEY CONCEPTS**

- Epidemiology
  - Truncus arteriosus is a rare cyanotic cardiac malformation with an incidence of 0.07 per 1000 live births (1.1 percent of all cardiac anomalies), with 40 percent of patients disclosing 22q11 deletion on genetic testing. There is also a variable phenotypic association with DiGeorge syndrome and craniofacial defects.
- Morphology
  - A single truncal valve usually overrides a large ventricular septal defect. The different classification schemes are based on the origin of the pulmonary arteries (PAs) (from truncus, ductus arteriosus, or descending aorta), the association of aortic arch interruption, and ventricular septal defects.
- Pathophysiology
  - Typically, there is intracardiac mixing (atrial and/or ventricular septal defect) with pulmonary over-circulation and, if interrupted aortic arch (IAA) is present, features of duct-dependent distal aortic perfusion. If untreated, chronic pulmonary vascular changes ensue, leading to fixed pulmonary hypertension.
- Clinical features
  - Presentation is in the neonatal period with pulmonary over-circulation and worsening symptoms as pulmonary vascular resistance falls. Hemodynamic collapse, acidosis, and lower body malperfusion are seen in patients with associated IAA and closure of the patent ductus arteriosus.
- Diagnosis
  - Echocardiography is usually all that is needed to proceed to surgical correction. Truncal anatomy, truncal valve morphology and function, location of the ventricular septal defect, and coronary anatomy are usually well defined echocardiographically. Additional diagnostic modalities include cardiac catheterization, computed tomography, and magnetic resonance imaging with three-dimensional reconstruction.
- Treatment
  - Complete repair in the neonatal period is standard treatment, following resuscitation and prostaglandin ($PGE_1$) infusion in newborns with IAA and ductal closure. Repair entails closure of the ventricular septal defect, truncal septation with reestablishment of continuity from the right ventricle (RV) to the PA with a valved conduit, and, if required, IAA and truncal valve repair. PA banding is currently very rarely performed in neonates and infants, in whom complete correction is contraindicated.
- Outcomes
  - In contemporary series, operative mortality ranges between 4 and 7 percent and is correlated to the reactivity of the pulmonary vascular bed and operative weight below 3 kg. Long-term prognosis is dependent on need for reintervention for truncal valve repair/replacement and structural failure of the RV-PA conduit.

## HISTORY AND EPIDEMIOLOGY

Truncus arteriosus (also termed common arterial trunk) is an unusual[1-4] developmental anomaly, characterized by incomplete conotruncal septation, leading to a common aortopulmonary trunk and ventricular septal defect. The disorder was first described by Wilson in 1798.[5] Initial surgical management consisted of palliative pulmonary artery (PA) banding; however, long-term survival associated with this treatment was poor. The first surgical repair was performed in 1962, when Behrendt and colleagues closed the ventricular septal defect and used a valveless conduit to

establish continuity between the right ventricle (RV) and the PA.[6] Complete repair of truncus arteriosus with a valved conduit was first reported by McGoon in 1967[7] and remains the procedure of choice for the majority of patients.

A recent prospective population-based study estimated the prevalence of truncus arteriosus to be approximately 0.07 per 1000 live births, representing 1.09 percent of all congenital cardiac malformations.[3,8] The incidence may be more than 3-fold higher in infants of diabetic mothers.[9] Twenty years ago, the 1-year mortality rate for corrected truncus arteriosus was estimated at 2.6 per 100,000 live births, representing 3.7 percent of all deaths due to congenital heart disease during that period.[10] Median 1-month mortality was 23 percent. With contemporary advancements in surgical technique and perioperative management, survival is likely higher. Without surgical correction, approximately 70 percent of infants die within the first 3 months of life,[11] whereas some individuals who are diagnosed later in life may survive for years without surgical intervention.[12–15] This subset likely represents those individuals with relatively balanced pulmonary-systemic circulations during infancy, and in whom severe pulmonary vascular obstructive disease inevitably develops.

## EMBRYOLOGIC DEVELOPMENT

The heart and great vessels develop from primitive mesoderm and neural crest cells. At approximately 20 days' gestation, blood islands of the cardiogenic plate coalesce to form the left and right endocardial tubes within the intraembryonic coelom (early pericardial cavity). The endocardial tubes fuse to become the bulbus cordis at approximately 23 days. The most cephalad portions of the bulbus cordis become the truncus arteriosus and conus cordis. During this period, the bulboventricular structures begin to rotate anteriorly and to the right to form the heart loop. At approximately 29 days, cono-truncal swellings begin to develop into distinct ridges. As these ridges grow, they fuse to form the truncal septum, which divides the aorta from the PA and the conal septum, becoming the supraventricular crest and the subpulmonic infundibulum. Spiral rotation along an axis similar to the heart loop separates the posterolateral aortic root from the more antero-medial PA root at approximately 37 days. Fusion of the conal septum with the endocardial cushions during this period establishes ventricular separation, with resultant left ventricle–aorta and RV–PA concordance.

Persistent truncus arteriosus results from incomplete or altered septation and rotation of components of the bulbus cordis. Morphogenetic patterning of the conotruncus, and eventual septation into a PA and aorta, involves initial migration of the dorsal and ventral neural crest cells followed by differentiation of these cells into vascular smooth muscle cells, in response to poorly characterized developmental cues.[16–18] Experimental ablation of these regions of the neural crest is associated with hypoplasia or aplasia of the thymus, thyroid, and parathyroid glands and persistent truncus arteriosus. Although the mechanisms by which neural crest cells regulate cono-truncal development have not been clearly elucidated, it is believed that alterations in neural crest cell migration may explain the association between cono-truncal malformations and cranio-facial defects such as those observed in patients with the DiGeorge syndrome. Recent experimental studies have implicated abnormalities in the family of GATA zinc-finger transcription factors, particularly GATA-6, which play critical roles in regulating morphogenetic patterning of the cardiac outflow tract and aortic arch during development.[19,20]

## GENETIC FACTORS

The genetic basis for persistent truncus arteriosus is likely multifactorial. An association between persistent truncus arteriosus and chromosome 22q11 deletion is well established. Chromosome 22q11 deletion affects approximately 700 infants annually in the United States and is present in 1.5 percent of patients with congenital heart defects[21] and in up to 40 percent of patients with truncus arteriosus.[22,23] Moreover, truncus arteriosus is present in approximately 10 percent of patients with chromosome 22q11 deletion.[24] In addition to cardiovascular malformations, chromosome 22q11 deletion has also been clearly linked to aplasia and hypoplasia of the thymus.[21,25,26] It is now recognized that 22q11 deletion syndrome encompasses the phenotypes previously described as DiGeorge syndrome and velocardiofacial syndrome. Because of these strong associations, genetic testing for chromosome 22q11 deletion in patients diagnosed with truncus arteriosus or thymic aplasia or hypoplasia is warranted. Recent evidence suggests that conditional inactivation of GATA-6 within neural crest cell derived smooth muscle cells results in cono-truncal defects including truncus arteriosus, interrupted aortic arch (IAA), and double-outlet RV.[19,27] Additional potential etiologic genetic alterations linked to truncus arteriosus include chromosomal duplication of 8p and 8q[28,29] and mutations in transcription factors NKX2.5[30] and Pitx2.[31] Evidence supporting rare autosomal recessive inheritance of truncus arteriosus in the absence of 22q11.2 deletion has been reported.[32]

## MORPHOLOGY

Truncus arteriosus is characterized by a single aortopulmonary trunk arising from the base of the heart, which gives rise to the coronary, systemic, and pulmonary arteries. An obligatory ventricular septal defect is present. The origin of the PAs varies considerably and forms the basis of the two major classification systems. Collett and Edwards[14] proposed the first widely accepted classification scheme in 1949. In their system, the spectrum of truncal variations is divided into four general categories based on the origin of the PAs. In type I truncus arteriosus, the left and right branch PAs arise from a single short main pulmonary trunk. The main pulmonary trunk commonly arises from the posterior aspect

of the truncus, just above the truncal valve. In type II truncus arteriosus, the origins of the left and right PAs are in close proximity to one another along the posterior aspect of the truncus. In type III truncus arteriosus, the origins of the left and right PAs arise more laterally and separate from one another. In type IV truncus arteriosus, the PAs arise from the descending aorta rather than the truncus (extrapericardial origin of the branch PAs). Although this configuration has historically been referred to as "pseudotruncus," it is now generally believed to represent a form of pulmonary atresia with aortopulmonary collateral vessels and should not be classified as a variation of truncus arteriosus.

An additional classification system was developed by Van Praagh and Van Praagh in 1965.[33] Like the Collett and Edwards classification systems, this system also divides truncus arteriosus into four categories. Type A1 is characterized by a main PA segment arising from the truncus due to a partially formed aorticopulmonary septum. Type A2 is characterized by the presence of left and right PAs arising independently from the truncus, irrespective of the proximity of their origins. Type A3 is characterized by the presence of a single PA arising from the truncus. In this form, often referred to as "hemitruncus," the contralateral lung is supplied by a pulmonary collateral vessel arising from either the distal aorta or the ductus arteriosus. Type A4 is characterized by a hypoplastic or IAA with PAs arising from a large ductus arteriosus. In this classification scheme the designation of type B indicates absence of a ventricular septal defect. However, because the presence of a true truncus arteriosus in these patients is questionable, the Van Praagh B classification is seldom used. These classification schemes share overlapping features and are schematically represented in Figure 72-1. Collett and Edwards type I and Van Praagh type A1 are essentially the same. Van Praagh type A2 encompasses the Collett and Edwards types II and III.

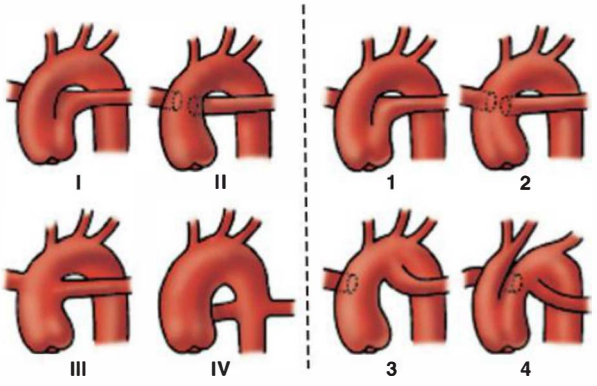

**FIGURE 72-1** Morphologic classifications of truncus arteriosus. The Collet–Edwards classification describes truncus types I to IV according to the origin of the branch pulmonary arteries, whereas Van Praagh's types 1 to 4 are subdivided according to presence (subtype A) or absence (subtype B) of associated ventricular septal defects (details in text). (From Vricella LA, Tsang VT. Truncus arteriosus. In: Yang SC, Cameron DE (eds). *Current Therapy in Thoracic and Cardiovascular Surgery*. Philadelphia: Mosby, 2004:751. With permission.)

In 2000, a new classification system was developed by the STS Congenital Heart Surgery Database Committee and representatives of the European Association for Cardiothoracic Surgery.[34] This system, based on the Van Praagh scheme, divides truncus arteriosus into three main categories: truncus arteriosus with confluent or near confluent PAs, truncus arteriosus with absence of one PA, and truncus arteriosus with IAA or coarctation. In this system, modifiers are used to denote the number of truncal valve leaflets, the presence and degree of truncal valve stenosis or insufficiency and the presence of ventricular hypoplasia, coronary artery anomaly, overriding truncal valve, transposition, or thymic aplasia. A similar nomenclature scheme to describe various methods of repairing or palliating truncus arteriosus has also been proposed. Although these classification systems may be very useful for risk-stratification analysis, the Van Praagh and Collett and Edward's classification systems continue to be widely used.

The truncal valve is most commonly tricuspid (about 50 percent), quadricuspid (about 30 percent), or bicuspid (about 5 percent). More than four cusps and, rarely, a single cusp may also be seen. Valve leaflets may be thickened and dysplastic, contributing to valvular insufficiency or stenosis. Despite these functional and morphologic variations, fibrous continuity between the truncal valve and the mitral valve is preserved. The tricuspid valve may be in fibrous continuity or may be separated from the truncal valve by a thin muscular band. The truncal valve typically overrides the interventricular septum and the subarterial ventricular septal defect in a balanced manner or may be more committed to the RV. Less frequently, the truncus arises predominantly from the left ventricle. The ventricular septal defect is normally located in the subarterial portion of the infundibular septum. The ventriculoinfundibular fold typically forms the posterior margin of the defect and separates it from the anterior leaflet of the tricuspid valve. Less commonly, the ventricular septal defect may extend posteriorly to the tricuspid valve annulus in the perimembranous outlet portion of the septum. The inferior margin of the ventricular septal defect is made up by the trabecula septomarginalis, and the superior margin typically extends to the truncal valve.

Coronary artery anatomy in truncus arteriosus may exhibit significant variability.[35] Two coronary ostia are generally present. The left coronary artery typically originates from the left portion of the truncus. It may originate high in the sinus of Valsalva or above the sinus in proximity to the takeoff of the PA. The right coronary artery typically originates from the right anterior portion of the truncus. However, an anterior descending coronary artery may originate from the right coronary artery and cross the RV near the infundibulum. In up to 18 percent of cases, a single coronary ostium originating from either the left or right is present. Additional coronary anomalies that have been reported include the circumflex artery originating from the right coronary artery, ostial stenosis due to structural deformation related to the

adjacent commissure, right coronary artery originating from the anterior descending coronary artery, and major coronary branches of the right coronary artery crossing the RV outflow tract to supply antero-basal surfaces of both ventricles and the upper portion of the interventricular septum.[36] Abnormal coronary anatomy must be carefully considered in planning surgical correction, because failure to recognize variations in coronary anatomy may cause or contribute to perioperative morbidity or mortality.[37]

Truncus arteriosus is generally associated with a left aortic arch, but a right aortic arch is present in approximately 30 percent of cases. Association with double aortic arch[38] and persistent embryonic fifth aortic arch[39,40] has also been reported. In approximately 15 percent of cases, the aortic arch is either interrupted or severely hypoplastic.[41] The interruption usually occurs distal to the origin of the left common carotid artery (type B aortic arch interruption; see Chapter 76) and is accompanied by ductal continuity with the descending thoracic aorta. In this morphologic variant, the PAs arise from the ductus arteriosus. Other associated abnormalities of the great vessels include IAA with postductal origin of all brachiocephalic vessels[42] and the absence of one PA.[43] Absence of one PA occurs most frequently on the same side as the aortic arch. Truncus arteriosus is also commonly associated with patent foramen ovale/secundum atrial septal defect and tricuspid insufficiency or stenosis.[44]

## PATHOPHYSIOLOGY

The physiologic features of truncus arteriosus are typical of those seen in other forms of cyanotic congenital heart disease with increased pulmonary blood flow. The single aortopulmonary trunk results in parallel pulmonary–systemic circulations, making intracardiac mixing of systemic and pulmonary blood at the level of the ventricular septum obligatory to maintain adequate systemic oxygenation. Additional mixing occurs at the level of the atrial septal defect when present (Fig. 72-2). During fetal development pulmonary blood flow represents less than 10 percent of the cardiac output due to increased pulmonary vascular resistance. At birth, the combined cardiac output traverses the truncal valve and the amount of pulmonary blood flow is determined by the change in pulmonary vascular resistance and the presence of any PA narrowing. Because the pulmonary vascular resistance initially falls below the systemic vascular resistance, severe hypoxia rarely occurs. When it does, proximal or distal PA narrowing must be suspected. As the pulmonary vascular resistance continues to fall during early postnatal life, pulmonary blood flow increases. Increased pulmonary venous return leads to volume overload of the RV, cardiopulmonary inefficiency, and congestive heart failure. Any degree of truncal valve incompetence can further increase the volume load on the ventricle, as well as compromise coronary perfusion due to diastolic flow reversal in the common trunk. The large, nonrestrictive ventricular septal defect enables pressure equilibration between the LV and RV, which leads to RV hypertrophy. Increased pulmonary blood flow, combined with systemic level arterial pressures within the pulmonary circulation, ultimately brings about pulmonary vascular changes that, in turn, increase pulmonary vascular resistance. Because the PAs originate above the truncal valve, the pulmonary circulation is exposed to systemic-level pressures during both systole and diastole. It is believed that this accelerates the abnormal pulmonary vascular changes leading to increased pulmonary vascular resistance and pulmonary hypertension. Although increased pulmonary vascular resistance and pressure generally occur several months later in life, there is evidence that early

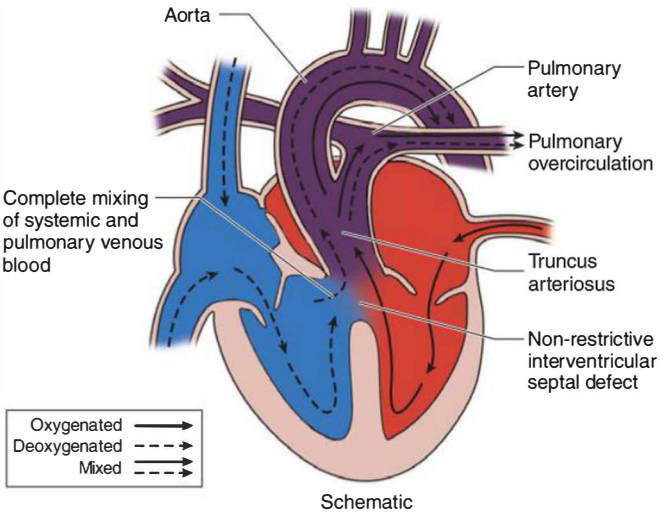

**FIGURE 72-2** Diagram illustrating the pathophysiology of truncus arteriosus. (From Reitz BA, Yuh DD (eds). *Congenital Cardiac Surgery*. New York: McGraw-Hill, 2002:153. With permission.)

molecular and cellular changes occur within a few weeks in the presence of increased pulmonary blood flow[45] and that observed vascular changes are related to alterations in nitric oxide and endothelin activity.[46] These findings may explain the improved outcomes associated with early surgical repair.

## CLINICAL FINDINGS

The clinical findings associated with truncus arteriosus depend on the degree of truncal valve competence, pulmonary vascular resistance, and coexisting cardiac defects. Shortly after birth, infants will generally exhibit mild cyanosis, tachycardia, tachypnea, costo-sternal retractions, and diaphoresis, which may worsen during feeding. The second heart sound is single and a harsh systolic ejection murmur may be audible at the left lower sternal border. A precordial thrill may be present. Pulmonary runoff produces a low diastolic pressure and widened pulse pressure. Truncal valve stenosis and insufficiency may produce a more pronounced ejection murmur or a diastolic decrescendo murmur, respectively. Cyanosis may improve as pulmonary vascular resistance continues to fall over the first few weeks. Increasing pulmonary overcirculation leads to progressive worsening symptoms of congestive heart failure, including pulmonary edema, hepatomegaly, and failure to thrive. These findings may develop at an accelerated rate or may be more pronounced in the setting of truncal valve insufficiency. Neonates not undergoing repair may exhibit improvement in heart failure symptoms but worsening of cyanosis as maladaptive pulmonary vascular changes progress and pulmonary blood flow decreases. Infants with Van Praagh type A4 truncus arteriosus (IAA, ductal origin of PAs) may exhibit symptoms of systemic hypoperfusion and ischemia as well as hypoxia as the ductus arteriosus begins to close shortly after birth. Features such as micrognathia, choanal atresia, and cleft palate may be found in patients with coexisting chromosome 22q11 deletion syndromes (Fig. 72-3).

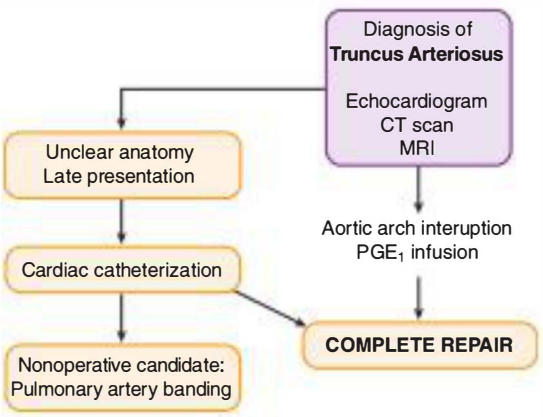

**FIGURE 72-3** Decision-making flowchart. Clinical decision-making algorithm for neonates with truncus arteriosus.

## Diagnostic Studies

Truncus arteriosus is most commonly diagnosed shortly after birth; however, prenatal diagnosis is becoming increasingly common as prenatal care becomes more accessible. All cyanotic infants should undergo careful diagnostic testing, including blood gas analysis, pulse oximetry, electrocardiography, chest radiography, and transthoracic or transesophageal echocardiography. Early pulse oximetric screening may detect evidence of truncus arteriosus before symptoms develop.[47] Biventricular hypertrophy is generally evident on the electrocardiogram and may become more pronounced over time. Although initial chest radiographs may appear normal, subsequent studies typically demonstrate cardiomegaly and increased pulmonary vascular markings. Absence of the thymic shadow may be observed in patients with coexisting neural crest disorders such as DiGeorge syndrome. A right-sided aortic arch may be apparent in approximately 30 percent of cases. Two-dimensional and Doppler echocardiography accurately detect truncus arteriosus and characterize important anatomic and hemodynamic features, including type of truncus, truncal valve morphology and function, presence of PA stenosis, size and location of the ventricular septal defect, location of coronary ostia, pulmonary blood flow and resistance, and presence of associated lesions.[48] Although the echocardiographic distinction between different conotruncal abnormalities is challenging in the fetus, truncus arteriosus may be accurately diagnosed by fetal echocardiography.[49] Accurate in utero diagnostic studies are invaluable in counseling parents. Cardiac catheterization and coronary angiography are useful for accurate anatomic and physiologic assessment of the PAs and to determine the precise orientation and course of the coronary arteries. This is especially important in older infants who may exhibit pulmonary vascular hypertrophic changes and in infants with echocardiographic evidence of coronary artery abnormalities. Computed tomography and resonance magnetic imaging with three-dimensional reconstruction are gaining wide acceptance as additional diagnostic tools.

## CLINICAL MANAGEMENT

The initial medical management of these patients should focus on the treatment of congestive heart failure and ensuring adequate oxygen delivery. Initial hypoxia may necessitate endotracheal intubation and mechanical ventilation. As pulmonary vascular resistance falls, decreased diastolic coronary perfusion may lead to worsening of heart failure symptoms, especially during feeding and crying. Diuretics, digoxin, and occasionally more powerful inotropic agents are useful in managing heart failure. Hypocalcemia must be corrected in patients with coexisting syndromes involving the deletion of chromosome 22q11. The findings of progressive tachycardia, hypotension, acidosis, and hypoxemia during early postnatal life suggest truncus arteriosus

with IAA (Van Praagh type A4). Intravenous prostaglandin therapy must be initiated to arrest closure of the ductus arteriosus. Genetic screening for chromosome 22q11 deletion should be undertaken in all patients with truncus arteriosus. Patients presenting later in life with evidence of advanced pulmonary vascular obstructive disease and pulmonary hypertension, may benefit from inhaled nitric oxide therapy. However, the prognosis for these children remains poor.

## Surgical Therapy

Initial surgical management of truncus arteriosus was limited to palliative PA banding, which resulted in survival rates similar to those observed in untreated patients. The first reported surgical repair utilizing a nonvalved Teflon conduit was performed in 1962.[6] Following this, McGoon and colleagues performed the first successful repair with a valved conduit in an older child in 1967.[7] Reports of successful repair and improved outcomes in younger infants[50] subsequently led to earlier repair and avoidance of maladaptive pulmonary vascular changes. Currently, banding of the PAs should be considered only when coexisting conditions such as sepsis, shock, or intracranial hemorrhage prevent surgical repair. Rarely, in cases where truncus arteriosus coexists with IAA, banding may be considered as initial palliation.[51]

The timing of surgical intervention in these patients has received considerable attention. Overall, the trend has been toward earlier repair in infants and neonates. Repair of truncus arteriosus during the first few weeks of life may be safely accomplished in the majority of patients[52] and appears to improve survival.[53] Early repair ameliorates congestive heart failure and failure to thrive and prevents irreversible pulmonary vascular disease. However, the overall operative mortality associated with neonatal correction of truncus arteriosus, estimated at 15.4 percent based on a recent large multi-institutional sample, remains relatively high compared with repair of other forms of complex congenital cardiac disease.[54–56] The reason for this discrepancy is unclear. A review of the strategy for management of truncus arteriosus by Brizard and colleagues[57] found that weight less than 3 kg is an independent risk factor for early perioperative mortality and that deferring surgery until 2 to 3 months of age decreases surgical risks. Although such a policy results in surgical intervention on infants of greater body weight and the use of larger valved conduits with associated longer freedom from reoperation, improved results may represent exclusion of neonates with otherwise unfavorable characteristics or risk factors. We prefer initial complete correction in infancy, except in unusual circumstances (extremely low-birth weight or prematurity, severe truncal valve dysfunction, arch anomalies), where we have used an initial palliative approach consisting of removal of the PAs from the truncus and subsequent connection to a 6-mm RV-to-PA (Sano-type) shunt. This procedure is then followed by complete intracardiac repair at a more favorable time.

## Operative Technique

We routinely employ intraoperative transesophageal echocardiography to evaluate valve function, intracardiac shunting, and wall motion before and after repair. Repair of a type 1 truncus arteriosus is depicted in Figure 72-4. Following median sternotomy, a generous portion of pericardium is harvested and treated with glutaraldehyde. The origin and course of the coronary arteries are carefully evaluated. The common arterial trunk, complete aortic arch, and great vessels are extensively mobilized. The PAs are mobilized well into the hilum and snares are placed. When a ductus arteriosus is present, care must be taken to avoid injuring it. In the presence of an IAA, snares are also placed around the great vessels. Arterial cannulation should be performed in the most distal ascending aorta or the transverse arch. Bicaval cannulae and a left ventricular vent are used to adequately decompress the heart. Snares are tightened to occlude the PAs upon initiation of cardiopulmonary bypass. If a ductus arteriosus is present, it is ligated. After distal aortic cross-clamping, cold blood cardioplegia is administered via an ascending aortic cannula and readministered intermittently throughout the procedure. In the setting of significant

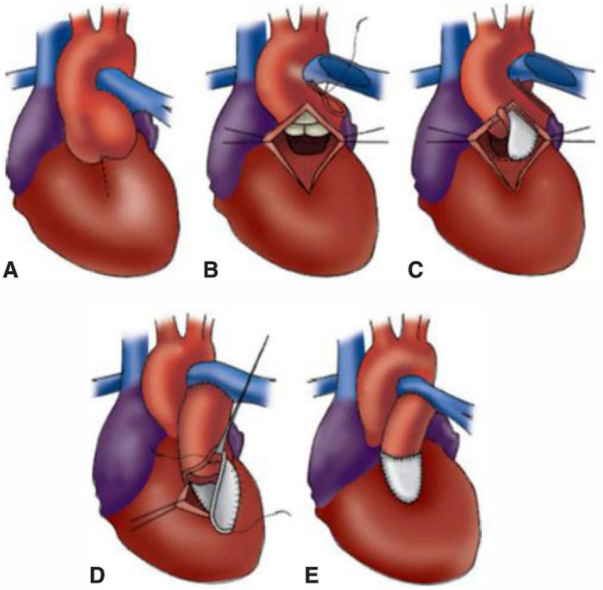

**FIGURE 72-4** Schematic rendition of complete repair of truncus arteriosus, Collet–Edwards, type I. The procedure entails septation of the truncus and a right ventriculotomy to perform ventricular septal defect (VSD) closure [dotted lines (**A**)]. Following septation of the truncus, the large VSD is exposed through a right ventriculotomy (**B**). The VSD is closed with a patch (**C**). Continuity between right ventricle and pulmonary arterial confluence is reestablished with a valved conduit and a proximal hood (**D**). Completed procedure (**E**). (From Vricella LA, Tsang VT. Truncus arteriosus. In: Yang SC, Cameron DE (eds). *Current Therapy in Thoracic and Cardiovascular Surgery*. Philadelphia: Mosby, 2004:753. With permission.)

truncal valve insufficiency, retrograde cardioplegia may be delivered via the coronary sinus. Alternatively, the common trunk may be opened just distal to the origin of the PAs and cardioplegia given directly into the coronary ostia. Topical iced slush is applied and the patient is cooled to 32°C.

In the presence of a clearly defined common PA, it is transected close to the common arterial trunk and the resultant truncal defect is closed with a Dacron patch and a running polypropylene suture. When the PAs arise separately, the common arterial trunk should be opened in a transverse fashion just distal to the origin of the PAs, which are divided proximally. This approach often enables primary closure of the aorta without distortion of the coronary ostia. When insufficiency is detected by echocardiography, complete transection of the common arterial trunk facilitates thorough evaluation of the truncal valve.

A longitudinal incision, originating at the base of the common arterial trunk, is performed in the anterior surface of the RV outflow tract. This incision must be modified if a significant coronary artery crosses this area.[36,37] The edges of the ventriculotomy are trimmed to create a smooth oval opening. When a sub-arterial ventricular septal defect is present, it is easily visualized and repaired though this incision. The septal defect is closed with a Dacron sauvage patch and either running or interrupted 6-0 polypropylene suture. Subarterial ventricular septal defects are commonly surrounded by a clearly defined circumferential rim of muscle. The superior aspect of the patch is sewn to the subvalvular aspect of the ventriculotomy by passing pledget-supported interrupted sutures through the anterior wall of the RV outflow tract. Injury to the conduction system is unlikely, as the system is separated from the septal defect by the posterior muscle tissue of the ventriculoinfundibular fold. In contrast, the conduction system is at risk in the setting of a perimembranous inlet type of ventricular septal defect, in which the defect extends to the tricuspid annulus. In this setting, we have found that approaching the defect through the right atrium provides the best exposure and facilitates suture placement through the base of the septal leaflet of the tricuspid valve. Sutures should be placed well away from the edge of posteroinferior margin of the defect so as to avoid injury to the conduction system. A patent foramen ovale or secundum atrial septal defect is typically present. Rather than completing closure of the defect, we prefer to leave in place some interatrial communication to allow right-to-left shunting in the early postoperative phase. This may be accomplished by partial closure or by closing the defect with a fenestrated autologous pericardial patch. The 2- to 4-mm fenestration may easily be closed at a later time using percutaneous techniques. With this approach, cardiac output can be safely maintained in the setting of postoperative pulmonary hypertensive crises.

A valved conduit is most commonly used to establish RV-to-PA continuity. Several types of conduit have been used successfully for this purpose, including aortic and pulmonary homografts,[58–61] composite bioprosthetic conduits,[62–64] pulmonary xenografts,[65,66] aortic xenografts,[67] autologous pericardial valved conduits,[68,69] and valved venous xenografts.[70–73] Choice of conduit is generally based on availability of homograft tissue and surgeon's experience and preference. Generally, pulmonary homograft tissue is preferred because it may offer improved valve longevity and is technically easier to sew than composite (Dacron) valved conduits.[59,74,75] Aortic homografts develop conduit stenosis at an accelerated rate in infants and children. The reported longevity of homograft conduits varies widely, with reported freedom from homograft replacement ranging from approximately 50 percent at 3 years[59] to approximately 75 percent at 10 years.[58] Aortic homografts develop conduit stenosis at an accelerated rate in infants and children compared to pulmonary homografts and other conduit types.[76] Conduit stenosis is the most common reason for reintervention (i.e., conduit replacement).[77] A recent prospective multi-institutional study by the Congenital Heart Surgeons' Society of conduit survival in children less than 2 years of age found that 40 percent will require a conduit-related intervention within 2 years of initial implant.[76] Multivariable risk factors for accelerated conduit failure included younger age at initial implant, presence of PA arborization abnormalities, and an initial conduit *Z*-score less than +1. Limited availability of small homografts is a significant limitation to the use of homograft conduits. Large adult homografts have been successfully downsized by longitudinal wall excision and conversion to bicuspid conduits.[78]

In general, composite xenograft conduits are more prone to calcification and early failure than homografts. Significant obstruction of the RV outflow tract occurs in up to 77 percent of patients within 12 months of surgery.[79] Actuarial freedom from reintervention following implantation ranges from 48 percent at 18 months[62] to 64 percent at 4 years,[80] depending on the type of conduit used. Small conduit size has also been identified as a risk factor for conduit failure in composite xenograft conduits.[80] Initial reports describing the use of stentless xenograft root conduits in these patients also describe limited conduit durability.[66,67]

The Contegra (Medtronic Inc., Minneapolis, MN) bovine jugular vein graft has more recently become popular for use as an RV-to-PA conduit. The graft is derived from a segment of bovine jugular vein that contains a naturally integrated tricuspid valve with associated sinuses. This graft offers several advantages, including superior tissue-handling characteristics, the availability of several sizes (12–22 mm), obviation of the need for proximal extension 'hoods' for infundibular shaping, and the ability to position the valve near the distal anastomosis. Data suggest that the Contegra conduit has improved durability compared to homografts especially in young children, though long-term data are lacking.[76,81] Widespread enthusiasm for the Contegra has been somewhat tempered by anecdotal reports of aneurysmal dilation,[82] thrombus formation,[83] and fibrotic membrane formation leading to distal conduit stenosis.[84]

Several methods have been devised to establish RV-to-PA continuity without the use of homografts or xenografts. Fresh autologous pericardial valved conduits have been

constructed and used in patients with truncus arteriosus.[69] Although preliminary follow-up indicates 66 percent freedom from reoperation at approximately 7 years, the mean age of these patients at initial operation was 6 months. Performed in younger patients, this technique has been associated with excellent freedom from reoperation but increased in-hospital mortality.[85] Direct RV-to-PA anastomosis has also been employed to reconstruct the RV outflow tract in patients with favorable PA anatomy.[86] Following direct posterior approximation, an anterior patch, with or without a pericardial monocusp, is fashioned from pericardium or Dacron. This repair is also associated with increased early mortality but improved freedom from reoperation at 8 to 10 years.[87,88] Although debatable, significant pulmonary insufficiency may be detrimental during the early postoperative period. The potential benefit of conduit growth must be weighed against pulmonary regurgitation in considering each of these repair techniques.

The distal conduit-to-PA anastomosis is completed first. In cases where the branch PAs arise from a single common pulmonary trunk, the common orifice may have to be enlarged to accommodate an appropriately sized conduit. This is especially true when a PA band has been placed previously. Enlargement of the PA orifice may be accomplished by incising the common pulmonary trunk laterally along the course of the one or both proximal branch PAs. The extent of lateral incision must be modified when there is a significant discrepancy in the size of the branch PAs. The incisions may have to be extended into the hilum in cases of severe branch stenosis or hypoplasia. The distal conduit is trimmed accordingly and anastomosed to the common pulmonary orifice using 6-0 polypropylene suture. In the setting of type I truncus with a relatively long common arterial segment, the pulmonary orifice may be sewn directly to the right ventriculotomy. Advantages of this method include capacity for growth and relative freedom from conduit stenosis.

The aortic cross clamp may be removed prior to construction of the proximal RV-to-conduit anastomosis. However, we find that the proximal anastomosis may be performed efficiently and most accurately on an arrested heart during a period of active rewarming. When an aortic homograft is used, it should be oriented so that the anterior leaflet of the mitral valve can be used as a hood to close the right ventriculotomy without distorting the homograft valve. Alternatively, a segment of Gore-Tex, bovine pericardium, Dacron, or homograft tissue may be used as an extension to close the remaining ventriculotomy. The valved portion of the homograft may be advanced toward the distal anastomosis to reduce the possibility of valve distortion caused by sternal compression. In this technique, the homograft is divided and the distal segment utilized for the proximal anastomosis. Irrespective of the technique used, narrowing of the ventriculotomy opening and distortion of the homograft valve must be avoided. After air has been carefully evacuated from the heart via an aortic root vent, the aortic cross clamp is removed. Once cardiac activity has been reestablished, the patient is weaned from cardiopulmonary bypass support. Transesophageal echocardiography provides important information regarding truncal and neopulmonic valve function and the presence of retained intracardiac air. Greater than mild truncal valve insufficiency should be addressed immediately by reinstituting full cardiopulmonary bypass, cooling, cardioplegic arrest, to achieve satisfactory valve repair. Consideration should be given to temporary left atrial and PA catheters. The additional hemodynamic information may be very helpful during the early postoperative period.

## Specific Technical Considerations

### DISCONTINUOUS PULMONARY ARTERIES

In cases where the left and right PAs arise from the common trunk in a noncontiguous manner, direct primary anastomosis of a common PA orifice to the right ventriculotomy is not possible. The left PA, which generally arises from the ductus arteriosus, is first mobilized and separated from ductal tissue at its origin. The right PA is then detached and the common trunk defect closed as described above. An aortic homograft is prepared for use as a conduit by removing the two proximal brachiocephalic vessels at their origin and ligating the left subclavian stump at its takeoff. The homograft is then anastomosed end to end to the shorter of the two PAs. The remaining PA is anastomosed end to side to the homograft at the site of the excised brachiocephalic vessels. The proximal anastomosis is performed as described above. Alternatively, a pulmonary homograft may be used if the branches are of sufficient length. A composite bioprosthetic conduit may be utilized in the absence of an appropriate homograft; however, the conduit's inherent stiffness may lead to distortion of the branch PAs.

### TRUNCUS ARTERIOSUS WITH INTERRUPTED AORTIC ARCH

Correction of truncus arteriosus with IAA is generally performed under hypothermic circulatory arrest. The ascending aorta, brachiocephalic vessels, and PAs are widely dissected to facilitate extensive mobilization of these structures. The origins of the first two to three intercostal arteries are divided to enable adequate mobilization of the descending aorta and permit a tension-free aortic reconstruction. We prefer to conduct cardiopulmonary bypass using bicaval and aortic/selective right subclavian artery cannulation. This approach provides excellent exposure for aortic reconstruction and permits low-flow antegrade cerebral perfusion during lower body circulatory arrest. The branch PAs are occluded with snares on initiation of cardiopulmonary bypass. A left ventricular vent is used to keep the heart adequately decompressed. The patient is cooled to 18°C and cerebral cooling packs are applied. Snares are used to occlude the innominate, left common carotid, and left subclavian arteries, and a clamp is used to occlude the descending aorta distal to the isthmus. Lower body circulatory arrest is accompanied by

low-flow antegrade cerebral perfusion. Care must be taken to avoid injury to the coronary arteries in separating the proximal main PA from the aorta. After carefully inspecting the truncal valve through this defect, the latter is closed using a patch, as described above. When an anomalous right subclavian artery arises from the descending aorta, it may be simply divided and ligated. After all ductal tissue has been resected, the lateral aspect of the aorta is incised at the origin of the left common carotid artery and the descending aorta is anastomosed end to side using 6-0 polypropylene suture. After the cannula has been removed from the descending aorta and air from the aorta, the brachiocephalic snares are removed and rewarming is initiated. RV-to-PA continuity is established as described above and the patient is weaned from cardiopulmonary bypass.

Critical compression of the left mainstem bronchus may occur following repair of truncus arteriosus with interrupted aortic arch. This can be avoided by adequate mobilization of structures during surgical correction and high vascular anastomosis at the level of the origin of the left common carotid artery to prevent direct airway compression by the reconstructed aorta. Critical bronchial compression must be considered in the setting of postoperative air trapping in the left lung, pneumonia, or failure to wean from ventilator support. Radiographic confirmation of bronchial compression warrants immediate revision of the aortic reconstruction. A 10-mm Gore-Tex interposition graft placed distal to the left subclavian artery may be used to lengthen the aortic arch and relieve tension on the bronchus by the "Gothic" reconstructed aortic arch. Replacement of this segment with a larger Dacron interposition graft can be performed safely through a left thoracotomy later in life.

The combination of truncus arteriosus and IAA carries high early mortality, and results from early neonatal repair remain poor. The largest series of 50 neonates from the Congenital Heart Surgeons Society reported overall survival from admission of 44 percent at 6 months.[41] Suboptimal outcomes with complete early correction have led to alternative strategies including bilateral branch PA banding with concomitant aortic arch repair initially, followed by delayed intracardiac repair.[51] Primary transplantation had also been advocated in this complex group, especially in the presence of sever truncal valve dysfunction.[41]

### TRUNCAL VALVE DYSFUNCTION

Morphologic and functional dysfunction of the truncal valve must be carefully evaluated using preoperative and postoperative transesophageal echocardiography and direct inspection during surgical correction. Preoperative insufficiency or stenosis may be caused by structural valve abnormalities, altered ventricular loading conditions, abnormal flow characteristics related to systemic-to-pulmonary runoff, or a combination of the two. Therefore, the degree of dysfunction noted during preoperative echocardiography may not accurately predict truncal valve function following surgical partition of the truncus arteriosus and complete intracardiac repair. We believe that any truncal valve dysfunction should be addressed during the initial corrective procedure. Every effort should be made to repair a dysfunctional truncal valve rather than replace it. Some degree of truncal valve insufficiency is present in more than one-third of patients.[89,90] Using a methodical approach to valve insufficiency, numerous repair techniques have been successfully employed.[89–95] The surgeon should be familiar with several repair methods because of the variability of underlying structural defects (See Chapter 81). Prolapsing cusps may be resuspended from the annulus using a pledget-reinforced 6-0 polypropylene mattress suture through the adjacent commissure. Careful resection of thickened cusp edges may improve leaflet apposition. Cusp augmentation, using autologous pericardium, has also been used in the setting of scarred and retracted leaflets.[96] Insufficiency associated with four or more leaflets may improve following suture approximation of incomplete commissures in partially fused leaflets to create a functionally bicuspid or tricuspid valve. Alternatively, leaflet excision and reduction annuloplasty with or without coronary reimplantation may be required in the setting of annular enlargement. Irrespective of the technique utilized, the fundamental goal of repair is to correct truncal insufficiency without narrowing the valve orifice.

Truncal valve stenosis is less common.[53] Stenosis due to leaflet abnormalities may also be amenable to valvuloplastic techniques, such as commissurotomy and debulking of myxomatous zones of coaptation. Resection of a subvalvular fibromuscular membrane should be undertaken when it contributes to stenosis. However, stenosis due to a critically small annulus or continued regurgitation following valve repair generally necessitates valve replacement with an aortic valve homograft (Fig. 72-5).[96,97] The truncus is transected just distal to the origin of the PAs and a right ventriculotomy is created, extending from the free wall of the RV outflow tract to the annulus of the truncal valve. The truncal root and leaflets are excised and coronary ostia buttons preserved. The aortic homograft is then sewn into place using 6-0 polypropylene suture. The homograft should be oriented so that the anterior leaflet of its mitral valve is used to close the ventricular septal defect. Alternatively, the mitral leaflet may be removed and the defect closed with a Dacron patch. The site for attachment of each coronary button is carefully planned to ensure a tension-free, unobstructed anastomosis. Windows are cut into the homograft and the ostia are sewn into place using 8-0 polypropylene sutures. After completion of the distal aortic anastomosis with 6-0 polypropylene, a second homograft (aortic or pulmonic) is used to construct a RV-to-PA conduit as described above.

## POSTOPERATIVE MANAGEMENT

During the early postoperative period, the patient must be vigilantly observed for evidence of RV dysfunction. Pulmonary hypertensive crises may occur in these patients, especially if surgical repair is undertaken after the neonatal

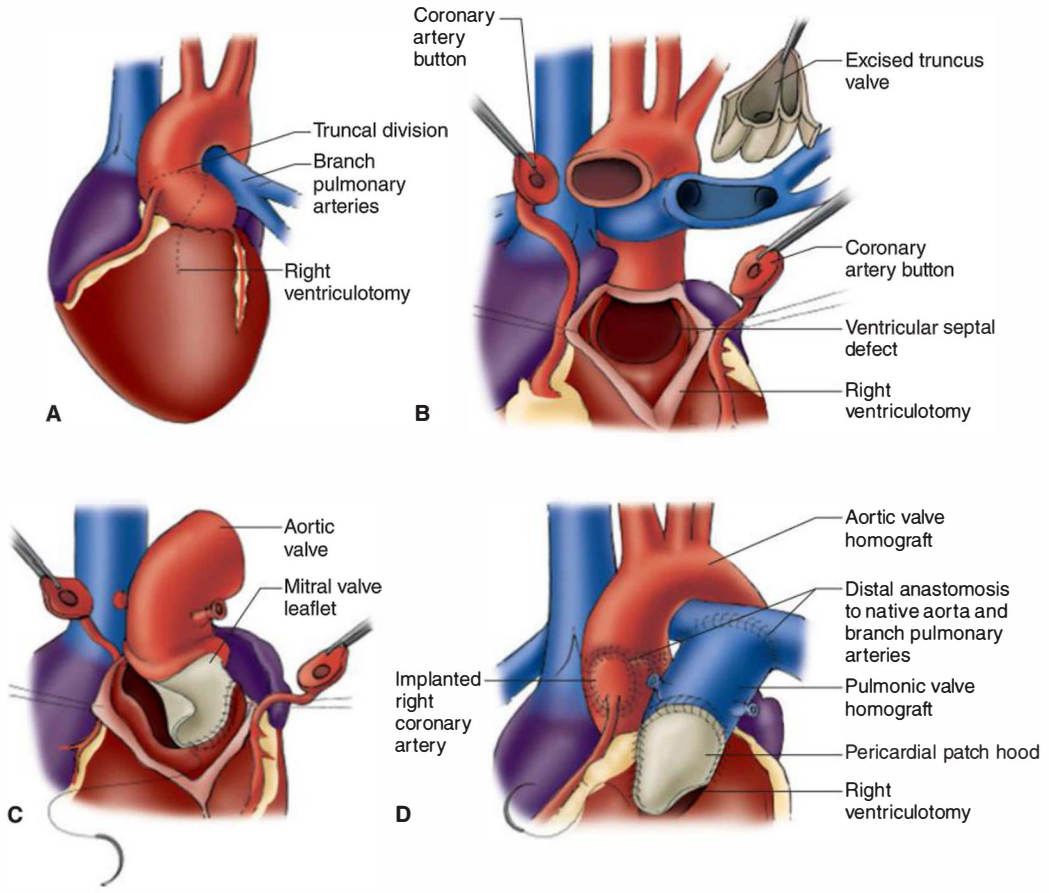

**FIGURE 72-5** Repair of truncus arteriosus, including truncal root replacement. The truncus is septated and the root excised (**A** and **B**). The VSD is closed with the anterior mitral valve leaflet attached to an aortic root homograft (**C**). The coronary buttons are reimplanted and a homograft is utilized to restore RV–PA continuity (**D**). (From Reitz BA, Yuh DD (eds). *Congenital Cardiac Surgery*. New York: McGraw-Hill, 2002:155. With permission.)

period. Early extubation and appropriate use of analgesic and anxiolytic agents are recommended to decrease the risk of pulmonary hypertensive episodes. A hemodynamically significant rise in PA pressure should prompt expeditious initiation of measures to reduce pulmonary vascular resistance, including increasing mechanical minute ventilation and fraction of inspired oxygen, administration of analgesics/anxiolytics, and inhaled nitric oxide. Echocardiographic evidence of acute truncal valve insufficiency, regional wall motion abnormalities, or RV-to-PA conduit obstruction or insufficiency warrant immediate surgical reintervention.

RV systolic and diastolic compliance may be poor because of prior exposure to systemic blood pressure. Accordingly, increased filling pressure may be required to optimize ventricular function. Important right-to-left shunting through the fenestrated atrial septum is not uncommon but generally decreases as RV compliance improves. Significant shunting may lead to cyanosis and suggests critical pulmonary hypertension. Postoperative dysrhythmia can contribute to significant myocardial dysfunction and decreased cardiac output. However, junctional ectopic tachycardia appears to occur less commonly following surgical intervention for truncus arteriosus than for other congenital cardiac anomalies.[98] Because truncus arteriosus is associated with an increased risk of developing necrotizing enterocolitis,[99] postoperative abdominal distention and feeding intolerance should be carefully evaluated.

## OUTCOMES

Outcomes for patients with truncus arteriosus have changed greatly since the introduction of surgical correction in the neonatal period. Increasing numbers of patients undergo nonpalliative, corrective surgery at an earlier age.[76,77,100,101] The trend of improved short- and long-term survival appears to be strongly related to earlier surgical intervention.[53] Surgical repair during the early neonatal period may prevent the development of detrimental pulmonary vascular changes and reduce the risk of postoperative death.[102]

Factors associated with increased mortality in these patients include other coexisting cardiac anomalies,[51,103] truncal valve insufficiency prior to repair,[104] and truncal valve replacement.[105] Early postoperative mortality is approximately 4 to 7 percent at 30 days.[91,106,107] The recent trend toward earlier surgical intervention complicates accurate determination of current long-term survival data; however, recent series have reported long-term survival rates up to 92 percent at 1 year,[106] 90 percent at 5 years,[105] 71 to 85 percent at 10 years,[105,108,109] 83 percent at 15 years,[105] and 60 percent at 20 years.[109] A significant number of late deaths may be related to reoperations.[105,107] The status of the truncal valve is an important predictor of subsequent reoperation. Approximately two-thirds of patients require truncal valve replacement within 10 years if truncal insufficiency is present at initial repair, whereas up to 95 percent of patients without truncal insufficiency at time repair do not require truncal valve replacement at 10 years.[105] Freedom from RV–PA conduit replacement varies according to several factors, including conduit size, type, PA architecture, and age at operation.[76] Cumulative freedom from conduit failure has been reported as approximately 80 percent at 1 year,[107] 50 percent at 10 years,[108,109] and 33 percent at 15 years.[109] Both surgical and nonsurgical methods may be employed to address the recurring problem of conduit failure in these patients. Conduit stenosis has been successfully managed using a percutaneous self-expanding stent.[76,110] The introduction of percutaneous pulmonary valve implantation will likely become another viable alternative to surgical intervention for conduit failure. Such nonsurgical methods may improve long-term outcomes by postponing higher-risk surgical interventions, or allowing implantation of larger conduits or in situ pulmonary valves. Trends toward improved short- and long-term survival indicate that increasing numbers of these patients will be cared for by members of the emerging field of adult congenital cardiac surgery.[111]

## TRUNCUS ARTERIOSUS BOARD REVIEW QUESTIONS (CHAPTER 72)

1. Which genetic factor is not associated with truncus arteriosus?
   A. Transcription factor NKX2.5
   B. Chromosome 22q11 deletion
   C. Inactivation of GATA-6
   D. Microdeletion of chromosome 15q
   E. Duplication of chromosome 8p

2. Which is correct regarding classification of truncus arteriosus according to the Collett and Edwards system?
   A. Left- and right-branch PAs from single, short pulmonary trunk = type II
   B. Origins of left- and right PAs along posterior aspect = type III
   C. Origins of left- and right PAs more lateral and separate = type IC
   D. PAs arise from descending aorta = type IV
   E. "Pseudotruncus" = type III

3. Which is correct regarding coronary artery anatomy in truncus arteriosus?
   A. In up to 50 percent of cases, a single coronary artery is present.
   B. The left coronary artery typically originates from the left portion of the truncus.
   C. The right coronary artery typically originates from the right posterior portion of the truncus.
   D. The anterior descending coronary artery can arise from the right coronary artery.
   E. Three coronary ostia are usually present.

4. Which is correct regarding surgical technique for repair of truncus arteriosus?
   A. A composite bioprosthesis is the preferred conduit for discontinuous PAs.
   B. An anomalous right subclavian artery from the descending thoracic aorta can be ligated and divided in the setting of interrupted aortic arch.
   C. Compression of the left mainstem bronchus can be avoided by limiting the amount of mobilization and perform a low vascular anastomosis.
   D. The fundamental goal of repair is to correct truncal insufficiency by narrowing the common valve orifice.
   E. Postrepair stenosis is best treated by balloon valvuloplasty.

5. Which is true regarding outcomes after surgery for truncus arteriosus?
   A. Early mortality is 10 to 15 percent.
   B. Truncal valve stenosis prior to repair is associated with increased mortality.
   C. Long-term survival is 60 percent at 20 years.
   D. Late deaths are not related to reoperation.
   E. About 50 percent of patients without truncal insufficiency at initial repair will require truncal valve replacement at 10 years.

## ANSWERS

1. **Answer: D.** Microdeletion of chromosome 15q is not associated with truncus arteriosus. Mutations in transcription factor NKX2.5, 22q11 deletion, inactivation of GATA-6 within neural crest cell-derived smooth muscle cells, and duplications of chromosomes 8p and 8q have all been associated with truncus arteriosus.
2. **Answer: D.** Type IV is the classification when the PAs arise from the descending thoracic aorta. When the left- and right branch PAs from single, short pulmonary trunk, this is known as type I. Type II occurs when the origins of the left and right PAs is along the posterior aspect of the ascending aorta. Type III occurs when the origins of the PAs arise more laterally and separate from one another. "Pseudotruncus" was another historical term for type IV truncus arteriosus.
3. **Answer: B.** The left coronary artery typically originates from the left portion of the truncus, and the right coronary artery typically originates from the right anterior portion of the truncus. In nearly 20 percent of cases, there is a single coronary ostium; three coronary ostia are unusual. The right coronary artery can arise from the anterior descending artery.
4. **Answer: B.** In the setting of truncus arteriosus and IAA, an anomalous right subclavian artery from the descending thoracic aorta can be ligated and divided. Either a homograft or composite bioprosthesis can be used for discontinuous PAs; the composite graft, however, may lead to distortion due to inherent stiffness. Compression of the left mainstem bronchus is avoided by adequate mobilization and a high anastomosis. The fundamental goal of repair is to avoid narrowing the valve orifice. Postrepair stenosis generally requires valve replacement with a homograft.
5. **Answer: C.** Long-term survival is 60 percent at 20 years. Early mortality is approximately 4 to 7 percent. Truncal valve insufficiency prior to repair is associated with increased mortality. A significant number of late deaths can be attributed to reoperation. Up to 95 percent of patients without truncal insufficiency at initial repair will be free from truncal valve replacement.

# Total Anomalous Pulmonary Venous Connection

*Ergin Kocyildirim*
*Victor O. Morell*

**KEY CONCEPTS**

- Epidemiology
  - Total anomalous pulmonary venous connection (TAPVC) accounts for 1 to 3 percent of all cases of congenital heart defects. Obstructed TAPVC is one of the few true emergencies in neonatal surgery.
  - TAPVC is either an isolated lesion or associated with complex atrial isomerism.
- Morphology
  - All the pulmonary veins drain into one or several systemic veins instead of the left atrium (LA).
  - The presence of an inter-atrial communication is crucial to sustain life and an atrial septal defect (ASD) or a patent foramen ovale (PFO) is considered as a part of TAPVC complex.
  - Four anatomic subtypes of TAPVC are recognized based on the location of the anomalous pulmonary venous drainage: supracardiac (40–50 percent), cardiac (20–25 percent), infracardiac (10–15 percent), and miscellaneous or mixed (10 percent).
- Pathophysiology
  - TAPVC is a mixing lesion in which pulmonary venous blood completely mixes with systemic venous blood and returns to the right atrium through a systemic vein, with consequent left-to-right shunt.
  - In neonates and small infants with obstructed pulmonary venous return, pulmonary hypertension and pulmonary edema are always present.
- Clinical features
  - Infants with obstructed TAPVC present with cyanosis, respiratory distress soon after birth. Infants with unobstructed TAPVC present later than infants with obstruction.
- Diagnosis
  - Echocardiography is diagnostic. Angiography is not indicated. Magnetic resonance imaging (MRI) may be useful as a supplement to echocardiography.
- Treatment
  - Surgical repair involves creation of a connection between the pulmonary venous confluence and the LA. Stabilization with preoperative extracorporeal membrane oxygenation (ECMO) is an option for desperately ill neonates.
- Outcomes
  - The long-term outcome for patients with repaired TAPVC is very good, with an operative mortality of 10 percent. Pulmonary venous stenosis is a relatively uncommon complication but, when it occurs, the impact on prognosis is profound.

## INTRODUCTION

Total anomalous pulmonary venous connection (TAPVC) is a rare and heterogeneous anomaly that accounts for only 2 percent of congenital heart defects.[1] TAPVC is a condition in which all the pulmonary veins drain into one or several systemic veins instead of the left atrium (LA). Presence or absence of pulmonary venous obstruction is important for the immediate postnatal stability of newborns. Obstructed TAPVC is one of the few true emergencies in congenital heart surgery.

The first attempt at surgical repair was performed by Muller in 1951 by performing an anastomosis between the pulmonary vein and the LA.[2] In 1956 Lewis successfully corrected TAPVC by using hypothermia and inflow occlusion.[3]

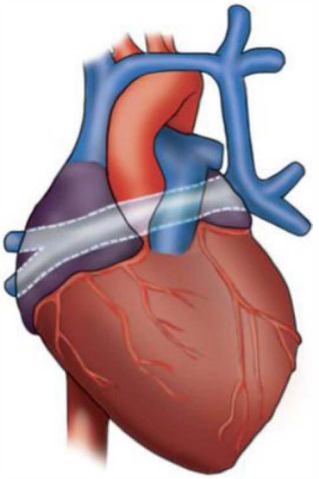

FIGURE 73-1 Supracardiac-type TAPVC. The vertical vein drains the pulmonary vein confluence into the innominate vein.

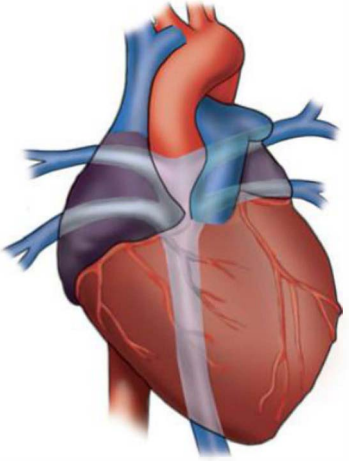

FIGURE 73-3 Infracardiac-type TAPVC. The descending vertical vein drains into the portal vein.

The first successful repair with cardiopulmonary bypass was performed by Burroughs and Kirklin in 1956.[4]

## ANATOMIC CLASSIFICATION

Four anatomic subtypes of TAPVC are recognized based on the location of the anomalous pulmonary venous drainage: supracardiac (40–50 percent), cardiac (20–25 percent), infracardiac (10–15 percent), and miscellaneous or mixed (10 percent). In supracardiac TAPVC, the four pulmonary veins join at a venous confluence (remnant of the common pulmonary vein) behind the LA and typically drain superiorly and to the left of the midline as the vertical vein (Fig. 73-1). This vertical vein will typically connect to the left innominate (brachiocephalic) vein. It may also connect directly with the superior vena cava (SVC) or, rarely, with one of the tributaries of the SVC. In the cardiac form of TAPVC, all four pulmonary veins drain into the common pulmonary vein, which in turn drains into the coronary sinus (Fig. 73-2). In infracardiac TAPVC, there is a common pulmonary vein behind the heart, which passes through the diaphragm and connects to either the portal vein, the ductus venous, or, rarely, directly to the inferior vena cava (IVC) (Fig. 73-3). Miscellaneous or mixed-type TAPVC is a combination of one or more of the other three types.

The etiology of TAPVC is unknown. TAPVC is most often an isolated lesion. Polysplenia, asplenia, and cat's eye syndrome can be seen associated with TAPVC. The presence of interatrial communication [atrial septal defect (ASD)] is necessary to sustain life. A patent foramen ovale (PFO) or patent ductus arteriosus (PDA) may also be present.

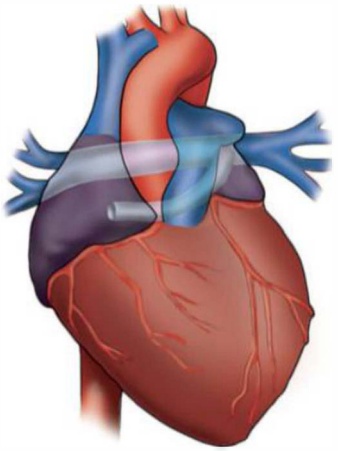

FIGURE 73-2 Cardiac-type TAPVC. The pulmonary vein confluence drains into the coronary sinus.

## PATHOPHYSIOLOGY

TAPVC is a mixing lesion in which pulmonary venous blood completely mixes with systemic venous blood and returns to the right atrium through a systemic vein with the presence of a left-to-right shunt. An unrestrictive right-to-left shunt (usually through an ASD or PFO) is necessary for left ventricular filling. Identical oxygen saturation in all chambers of the heart is very typical. Pulmonary venous obstruction is the most important determining factor for the severity of symptoms and emergency of the clinical presentation.

## CLINICAL FEATURES

Severe congestive heart failure is common in many patients in the early days of life, and is usually associated with cyanosis. Failure to thrive and slowly developing heart failure

can be seen within the first couple of months of life in the presence of unobstructed TAPVC. Infants with obstructed TAPVC are usually in critical condition.

## DIAGNOSTIC MODALITIES

Neonates with obstructed TAPVC will typically disclose normal heart size with gross pulmonary edema on chest x-ray. In neonates and small infants, the differential diagnosis should include surfactant deficiency, severe pneumonia and lymphangiectasia. Right ventricular hypertrophy is present on electrocardiogram (ECG). Prenatal echocardiography is suboptimal for the detection of TAPVC. Postnatal echocardiography will usually show large right-sided and small left-sided cardiac structures, and identify the anatomic subtype of TAPVC with accuracy. The features of supracardiac TAPVC can be defined by imaging left SVC flow. A large coronary sinus is usually present in the cardiac-type TAPVC. In the infradiaphragmatic-type TAPVC, the common pulmonary vein can usually be reliably defined as it courses through the diaphragm. Cardiac catheterization is no longer used in diagnosis. Although echocardiography is usually adequate for diagnosis, magnetic resonance imaging (MRI) with three-dimensional reconstruction may be valuable and used as a supplement (Fig. 73-4).

Infants with unobstructed TAPVC are not severely ill but will often have a history of failure to thrive and present with symptoms later than patients with obstructed TAPVC. Increased pulmonary flow can be seen on chest x-ray, and the so-called "snowman heart" with ground-glass appearance of the lung fields is a very characteristic sign.[5] Except for the presence of obstruction, echocardiographic findings are similar to the ones in obstructed TAPVC. Subdiaphragmatic drainage is a very unusual finding in infants with unobstructed TAPVC.

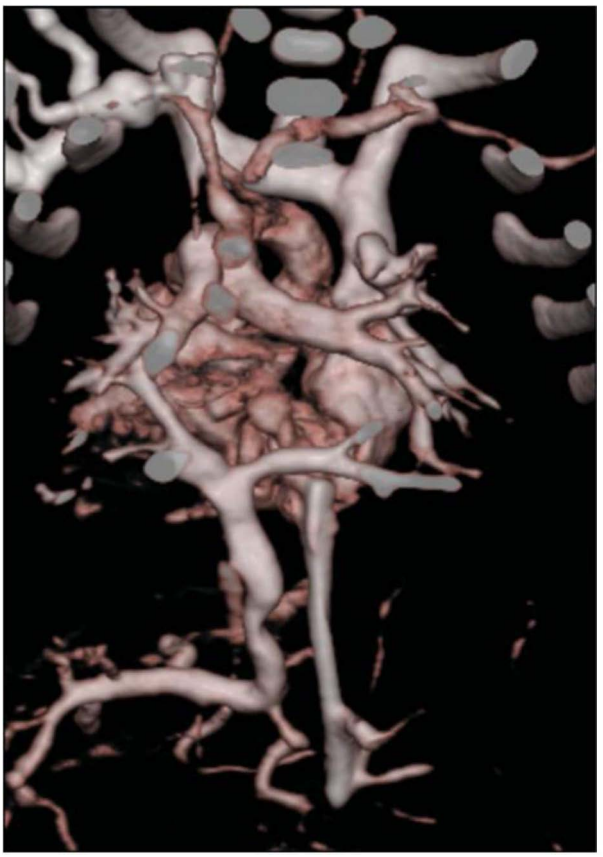

**FIGURE 73-4** Three-dimensional cardiac magnetic resonance imaging reconstruction in a neonate with mixed-type TAPVC (posterior view). On the right side, the upper and middle lobe pulmonary veins drain into the posterior aspect of the SVC. Both lower lobes drain along an infracardiac route. The left upper lobe vein is not well seen, but the vertical vein appears obstructed. (Image courtesy of Dr. Philip Spevak, Johns Hopkins Pediatric Cardiology)

## MEDICAL THERAPY

Preoperative medical therapy in the stable, unobstructed patient will usually consist of diuretic therapy. The management of severely ill infants with obstructed TAPVC can be, on the contrary, very challenging. The goal should be to quickly improve oxygenation and cardiac output, and to avert end-organ damage in anticipation of emergent TAPVC repair. Occasionally, due to intractable hypoxemia and acidosis, this is unachievable without resorting to preoperative extracorporeal membrane oxygenation (ECMO). Such infants are stabilized for 1 to 2 days and then taken to the operating room for repair.

## SURGICAL THERAPY

TAPVC requires surgical correction and remains, as mentioned above, one of the true surgical emergencies in neonatal cardiac surgery. The surgical management of patients with supracardiac and infracardiac TAPVC is similar. After identifying the anatomy precisely, repair requires an anastomosis between the pulmonary vein confluence and the LA. The ASD is routinely closed through a right or left atriotomy. It is our practice to always ligate the vertical or decompressing vein in order to prevent a postoperative left-to-right shunt at this level (Fig. 73-5).

Repair of TAPVC starts with the initiation of cardiopulmonary bypass. The PDA is routinely ligated. At 18 °C, cardiac arrest is provided with a single dose of antegrade cardioplegia and the patient's blood volume is drained into the reservoir. A period of profound hypothermic circulatory arrest (PHCA) is started. There are several advantages associated with PHCA: operating in an asanguinous field, the utilization of single venous cannulation, and the ability to retract the heart extensively with exposure of the retrocardiac structures. In a patient with levocardia, the heart is retracted

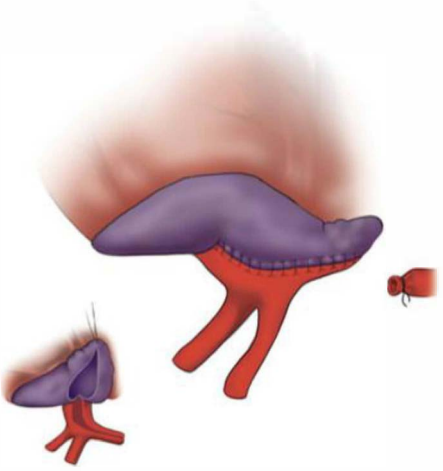

FIGURE 73-5 Supracardiac TAPVC repair with the apex of the heart elevated and retracted rightward, the left atrium and the pulmonary vein confluence are opened and the anastomosis is performed. The vertical vein is ligated and divided.

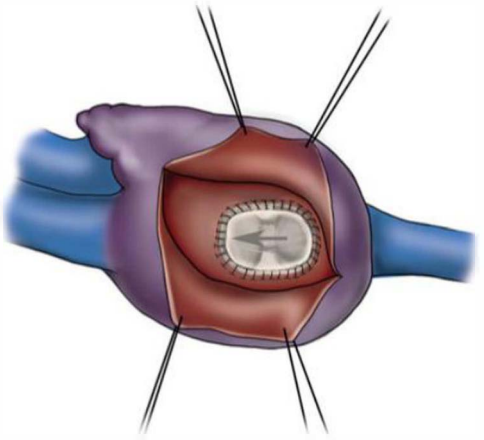

FIGURE 73-6 Cardiac TAPVC repair. **A.** Through a right atriotomy anatomy is visualized. **B.** The coronary sinus is unroofed into the left atrium. **C.** The coronary sinus and the atrial septal defect are closed with a single patch, effectively creating a new venous channel by which blood from the coronary sinus is routed into the left atrium.

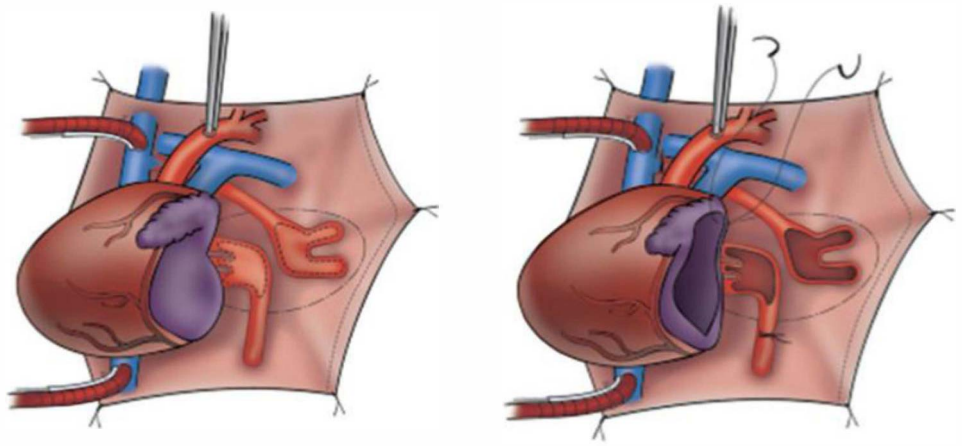

superiorly and to the right, and the pulmonary venous confluence is exposed. The typical retraction of the heart necessary to perform the anastomosis was first described by Williams et al. in 1964.[6] The pulmonary veins and their connections are posterior to the pericardium and can be occasionally difficult to dissect. As mentioned earlier, the ascending or descending vertical vein is then ligated. When the ascending vein drains to the left innominate vein, care should be taken to avoid left phrenic nerve injury. With the apex of the heart elevated and retracted rightward, corresponding incisions are performed and an anastomosis between the pulmonary venous confluence and the LA is performed in continuous fashion with a 7-0 polypropylene suture. If at all possible, the suture line should not involve the ostia of the pulmonary veins to avert the possibility of stenosis. The ASD is then closed by direct suture techniques or with a patch. Cardiopulmonary bypass is re-established and de-airing of the heart is performed before unclamping the aorta. Then the patient is rewarmed slowly. Weaning from cardiopulmonary bypass is undertaken at 36°C. The surgical repair is then checked by echocardiography, although some prefer to avoid transesophageal echocardiography (TEE) altogether in these patients because of the possibility of pulmonary venous compression by the rigid TEE probe. Hawkins described another commonly used technique that involves a right atrial approach with excision of the interatrial septum in order to access the LA.[7] This technique requires opening the posterior wall of the LA and performing the anastomosis to the common pulmonary venous confluence from within the atrium, as opposed to an extracardiac anastomosis such as the one described above. The interatrial septum is then closed with a patch, so as to effectively augment the size of the LA. Several modifications of this technique have also been reported.[8,9]

In the cardiac type TAPVC, the veins drain into the right atrium either directly or via the coronary sinus (Fig. 73-6). Cardiopulmonary bypass with bicaval cannulation and mild hypothermia to 34°C is initiated. After induction of cardioplegic cardiac arrest, the right atrium is opened. If the vein is draining into the right atrium directly, the repair consists of funnelling the pulmonary venous return into the LA through the ASD. The ASD usually needs enlargement, and a piece of pericardium is used to create the pulmonary venous channel. If the veins are draining via the coronary sinus, unroofing of the coronary sinus into the LA and patch augmentation of the pathway (effectively ASD Closure) are required. Extra care should be taken to avoid injury to the AV node.

The mixed-type TAPVC requires the combination of the previous two techniques and/or direct reimplantation in the LA appendage for left-sided lesions. On occasion, a single anomalous pulmonary vein can be left uncorrected without major hemodynamic consequence from a minor left-to-right shunt.

## RESULTS

The long-term outlook for TAPVC patients is very good, with an operative mortality of 10 percent and long-term survival rate approaching 85 percent.[10] Predictors of poor outcome are residual or de novo postoperative pulmonary venous obstruction and the presence of associated cardiac anomalies.[11–13] Recurrent pulmonary venous obstruction typically develops in the first few months after the repair, but could also present later. This postoperative complication is seen more frequently in the infradiaphragmatic and mixed types. Both Lacour-Gayet et al. and Najm et al. described a

A B

**FIGURE 73-7** Primary "sutureless" technique for repair of difficult or mixed venous drainage patterns in TAPVC. The heart is retracted and the pulmonary veins are exposed (mixed type, **A**). The pulmonary veins are incised and the pericardium surrounding them is sutured to the edges of the left atriotomy (**B**).

"sutureless" technique with in situ pericardium for relief of postoperative pulmonary venous stenosis.[14,15] This ingenious technique involves creation of a baffle with autologous pericardium. The veins are opened and allowed to drain into a pouch that funnels the blood into the LA (Fig. 73-7).[16] This technique can also be used as a primary form of drainage for small veins and the mixed type, in which a direct anastomosis between LA and veins would be difficult.

A simple excision of pulmonary venous obstruction after the repair of TAPVC has also been described by other surgeons.[17] For patients who survive surgery and do not develop early recurrent pulmonary venous obstruction, the long-term outlook is fair.[10]

## TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION BOARD REVIEW QUESTIONS (CHAPTER 73)

1. Which is true regarding anatomic classification of total anomalous pulmonary venous connection (TAPVC)?
   A. Supracardiac form occurs in 10 to 15 percent.
   B. Cardiac form occurs in 40 to 50 percent.
   C. Infracardiac form occurs in 20 to 25 percent.
   D. Mixed form occurs in 10 percent.
   E. An interatrial septal defect is not necessary to sustain life.

2. Which is correct regarding clinical presentation and diagnosis of TAPVC?
   A. Severe congestive heart failure is common and is not associated with cyanosis.
   B. If the TAPVC is unobstructed, presentation may be delayed.
   C. A large coronary sinus is usually present in the supracardiac form.
   D. Subdiaphragmatic drainage is a common finding in unobstructed TAPVC.
   E. Echocardiography typically shows small right-sided structures and large left-sided structures.

3. Which is correct regarding surgical repair of TAPVC?
   A. The Hawkins technique involves a right atrial approach.
   B. Unroofing of the coronary sinus into the right atrium is required if the TAPVC drains into the coronary sinus.
   C. The ductus arteriosus is routinely incorporated into the repair.
   D. The vertical vein is left patent in order to decompress the heart.
   E. Hypothermic circulatory arrest is necessary for repair of the cardiac form.

4. Which is correct regarding outcomes after surgery for TAPVC?
   A. Operative mortality is less than 5 percent.
   B. Associated cardiac anomalies are not a risk factor.
   C. Recurrent pulmonary venous obstruction typically develops after the first few months after repair.
   D. Recurrent pulmonary venous obstruction is seen more frequently in the supracardiac form.
   E. The sutureless technique can be used as a primary repair in the mixed form.

## ANSWERS

1. **Answer: D.** The mixed form occurs in 10 percent. The supracardiac form occurs in 40 to 50 percent, the cardiac form occurs in 20 to 25 percent, and the infracardiac form occurs in 20 to 25 percent. An interatrial septal defect is required to sustain life.
2. **Answer: B.** If the TAPVC is unobstructed, the presentation may be delayed for the first few months of life. Severe congestive heart failure with cyanosis is the usual presentation. A large coronary sinus is usually present in the cardiac form. Subdiaphragmatic drainage is very unusual if the TAPVC is unobstructed. Echocardiography typically shows large right-sided- and small left-sided structures.
3. **Answer: A.** The Hawkins technique uses a right atrial approach to access the LA after excising the interatrial septum. If the TAPVC drains into the coronary sinus, this is unroofed into the left atrium. The ductus arteriosus and vertical veins are usually ligated to prevent postoperative left-to-right shunting. Hypothermic circulatory arrest is not required to repair the cardiac form of TAPVC.
4. **Answer: E.** The sutureless technique is useful in patients with small veins and the mixed form. Operative mortality is about 10 percent, and associated cardiac anomalies are a risk factor. Recurrent pulmonary venous obstruction typically develops within the first few months after repair and is seen more frequently in the infracardiac and mixed forms.

# Transposition of the Great Arteries

*Richard G. Ohye*
*Ming-Sing Si*
*Jennifer C. Hirsch-Romano*
*Zuhab A. Qamar*
*Edward L. Bove*

## KEY CONCEPTS

- Epidemiology
  - Transposition of the great arteries (TGA) is the most common cyanotic cardiac anomaly, accounting for approximately 10 percent of congenital cardiac malformations.
- Morphology
  - The aorta arises from the right ventricle (RV) and the pulmonary artery (PA) from the left ventricle (LV). More than 50 percent of patients have an intact ventricular septum (IVS), while the remainder is split between a ventricular septal defect (VSD) with and without pulmonary stenosis (PS). The coronary artery pattern is variable; the most common one involves the left circumflex and left anterior descending (LAD) coronary arteries arising from the leftward and the right coronary artery (RCA) from the rightward sinus, respectively.
- Pathophysiology
  - Systemic and pulmonary circuits are in parallel, with the degree of cyanosis depending on mixing at the atrial septal defect (ASD), patent ductus arteriosus (PDA), or VSD level, as well as with the degree of coexisting PS.
- Clinical features
  - In the absence of PS, pulmonary overcirculation ensues, with variable cyanosis determined by the adequacy of mixing. Cases of TGA with adequate PS and VSD can remain asymptomatic for a prolonged period. Infants with late presentation exhibit LV deconditioning from prolonged exposure of the LV to low pulmonary pressures.
- Diagnosis
  - Electrocardiography (ECG) and chest x-ray (CXR) suggest the diagnosis in the cyanotic newborn. Echocardiography defines the relationship between the great vessels, associated ASD/VSD/PDA/coronary patterns and estimates LV pressures. Cardiac catheterization is rarely required in the current era.
- Treatment
  - In patients with an IVS, severe cyanosis can be improved with percutaneous intervention (balloon or blade atrial septostomy). The arterial switch operation (ASO) with or without VSD closure is the operation of choice, performed after LV training with PA banding in patients with a deconditioned LV. In patients with significant PS and cyanosis, temporary palliation with a modified Blalock–Taussig shunt can be performed before repair with a Rastelli or Nikaidoh operation.
- Outcomes
  - Excellent outcomes are reported, with an operative mortality of less than 5 percent; long-term complications are represented by supravalvar PS, neoaortic regurgitation or stenosis, and coronary insufficiency.

## INTRODUCTION AND MORPHOLOGY

Transposition of the great arteries (TGA) is a common congenital cardiovascular malformation characterized by ventriculoarterial discordance. This discordant anatomy is defined by the fact that the aorta arises from the morphologic right ventricle (RV) and the pulmonary artery (PA) from the morphologic left ventricle (LV). The anatomy of TGA is best understood in the context of Van Praagh's segmental anatomy, a three-letter nomenclature system in which the atria, the cardiac looping, and the position of the great vessels are used to describe cardiac malformations (see Chapter 59). The first letter (S, I, or A) describes atrial *situs* (*solitus, inversus, or ambiguus*). The second letter (D or L) refers to the *dextro* or *levo* looping of the primitive cardiac tube during fetal development, which determines in turn whether atria and ventricles are concordant [D-looping, right atrium (RA) attaches to RV and left atrium (LA) attaches to LV] or discordant. The third letter describes the relative position of the great vessels. The letter S signifies normally related great vessels, and I denotes normally related but inverted great vessels. D or L describes the rightward or leftward position of the aorta relative to the PA in the setting of transposition. Hence in a normal heart, there is atrial *situs solitus*, *dextro* looping, and normally related great vessels, or (S, D, S).

In general, TGA is subclassified in *dextro* (or D-TGA) and *levo* (or L-TGA) transposition, referring to the position of the aorta relative to the PA (the last letter of the segmental anatomy classification scheme described above). In TGA, there is generally *situs solitus* of the atria. D-TGA is invariably associated with D-looping, resulting in a segmental anatomy of (S, D, D). L-TGA is characterized by atrioventricular and ventriculoarterial discordance (RA attaches to LV and LA to RV), and is alternatively termed *congenitally corrected TGA*. This association of L-looping with L-TGA results in an anatomy coded as (S, L, L). Other extremely rare forms of TGA, including (S, D, L), have been described but are beyond the scope of this chapter. However, the treatment options are generally similar. From a strictly morphologic standpoint, there should only be two forms of transposition: D-TGA, properly termed *transposition of the great arteries,* and L-TGA, which should be referred to as *congenitally corrected transposition.*

These are distinct clinical entities, each with several subtypes requiring a number of diverse reconstructive approaches; they are dealt with in separate sections of this textbook. With all forms of D-TGA, there is the need to maintain adequate mixing of oxygenated and deoxygenated blood between the right and left sides of the heart. The circulation in D-TGA is one of two separate circuits, pulmonary and systemic, in parallel (Fig. 74-1). Without communication between the two sides of the heart, deoxygenated blood does not reach the lungs and oxygenated blood does not reach the systemic circulation.

Although TGA was first described by Baillie in 1797,[1] the term *transposition* is credited to Farre, who used "transposition of the aorta and PA" to describe the malformation in 1814.[2] The term was further refined by Van Praagh[3] in 1971 to define *transposition* as ventriculoarterial discordance; the term *malposition* was reserved to positional anomalies of the great arteries observed in other lesions.

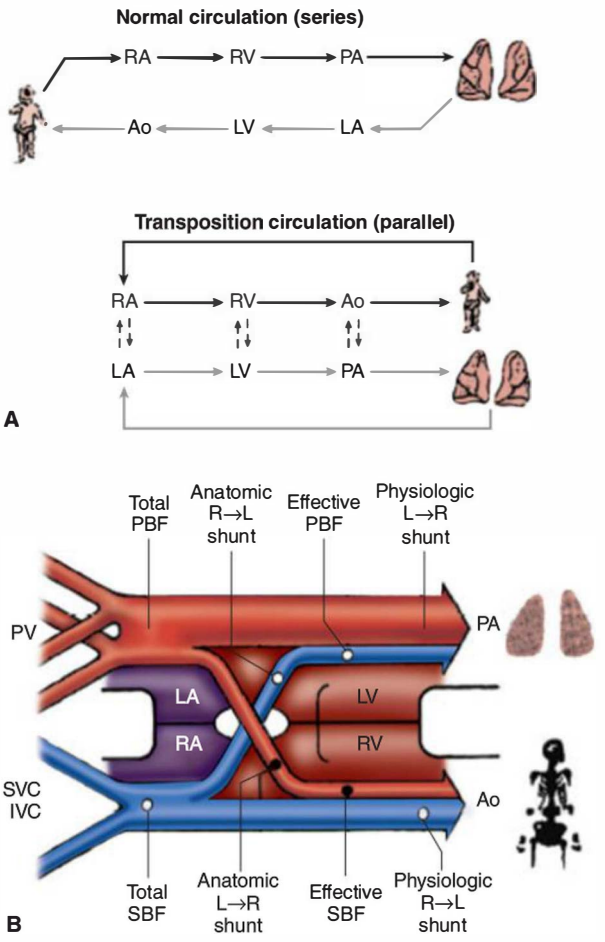

**FIGURE 74-1** Pathophysiology of D-transposition of great arteries (D-TGA). **A.** Systemic and pulmonary circuits in series with normally related great vessels and in parallel with D-TGA. **B.** Flows and shunts in D-TGA with intact ventricular septum. Solid arrows, deoxygenated blood; stippled arrows, oxygenated blood; dashed arrows, intercirculatory shunts; Ao, aorta; IVC, inferior vena cava; L, left; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PBF, pulmonary blood flow; PV, pulmonary veins; R, right; RA, right atrium; RV, right ventricle; SBF, systemic blood flow; SVC, superior vena cava. (From Wernovsky G. Transposition of the great arteries. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ (eds). *Moss and Adams' Heart Disease in Infants, Children and Adolescents,* 6th ed. Philadelphia: Lippincott, Williams & Wilkins, 2001:1038. With permission.)

Initial surgical therapies for TGA were palliative, aimed at increasing intracardiac mixing and improving systemic oxygen saturation. In 1950, Blalock and Hanlon described a technique for performing an atrial septectomy without cardiopulmonary bypass (CPB) to improve mixing at the atrial level.[4] Edwards, Bargeron, and Lyons later reported a modification of the Blalock-Hanlon atrial septectomy in which

the atrial septum was repositioned posterior to the right pulmonary veins, baffling them to the RA.[5] Other partial atrial-level switch procedures were devised by Lillihei and Varco,[6] who anastomosed the right pulmonary veins to the RA and the inferior vena cava (IVC) to the LA, and by Baffes, who performed a similar procedure with an allograft conduit from the IVC to LA.[7]

The first attempts at anatomic correction were directed at switching the two great vessels. Throughout the 1950s, a number of techniques for arterial-level switch operations were described, some including the transfer of one or both coronaries, but most leaving them in the pulmonary circuit. Although they were universally unsuccessful, these pioneering procedures laid the groundwork for the understanding of critical concepts for future procedures, including coronary anatomy and the importance of an LV prepared to handle system workloads. The first successful repairs were once again directed at the atrial level. In 1959, Senning accomplished the first successful atrial-level switch with a series of complex intraatrial baffles of native atrial tissue.[8] This technique was simplified in 1963 by Mustard with the use of prosthetic material.[9] The "Mustard procedure" became quickly the treatment of choice for D-TGA and remained such until Jatene reported the first successful arterial switch operation (ASO) in 1975.[10] Jatene and other authors demonstrated the long-term benefits of a true anatomic repair, which could be achieved with acceptable operative mortality. Although the Mustard and Senning operations are no longer used as primary therapy for D-TGA, they remain important for the treatment of L-TGA, which is discussed in greater detail in Chapter 75.

Several theories have been put forth regarding the embryology of D-TGA. Some authors support the theory that the normal spiral septation of the conotruncus does not occur, and that development of a straight septum results in transposition.[11–13] Van Praagh and Van Praagh have postulated that the etiology is persistence of the subaortic conus and reabsorption of the subpulmonary conus, leading to pulmonary-mitral continuity and, ultimately, TGA.[14] Other theories also propose a similar abnormal development of pulmonary-mitral continuity or of the area below the semilunar valves, or an abnormality of hemodynamics and blood flow as the etiology.[15]

D-TGA can be subdivided into D-TGA with intact ventricular septum (IVS) (55–60 percent), and D-TGA with ventricular septal defect (VSD) (40–45 percent). In D-TGA/VSD, one-third of the ventricular defects are hemodynamically insignificant. The VSDs are most commonly of the perimembranous or outlet morphologic types. Pulmonic stenosis (PS), causing significant left ventricular outflow tract obstruction (LVOTO), occurs rarely with an IVS. It is not uncommon to measure a preoperative gradient across the left ventricular outflow tract (LVOT) due to shifting of the septum from the high-pressure RV outflow tract (RVOT) to the lower-pressure LVOT in D-TGA/IVS. However, the gradient will resolve with anatomic correction and shift of the septum rightward. Hemodynamically significant PS occurs in approximately 10 percent of D-TGA/VSD and may affect operative decision making.[16]

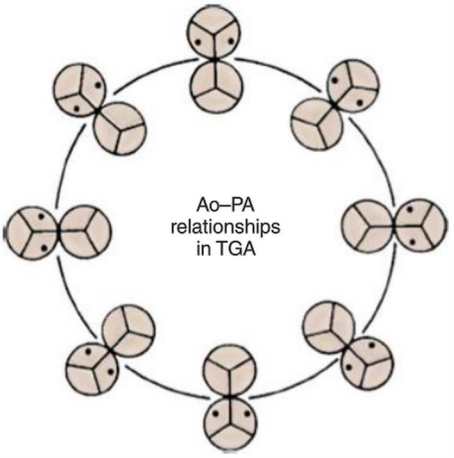

**FIGURE 74-2** The range of the relative positions of the aorta and PA in transposition of the great arteries. AO, aorta; PA, pulmonary artery; TGA, transposition of the great arteries. (From Mavroudis C, Backer CL. Transposition of the great arteries. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery,* 3rd ed. Philadelphia: Mosby, 2003:442. With permission.)

The relative positions of the aorta and PA are variable in TGA (Fig. 74-2). Fortunately, the sinuses of Valsalva of the aorta and PA tend to be arranged in a mirror-image alignment. This arrangement facilitates coronary transfer during the ASO. Similarly, the coronary artery arrangement can be variable. In the current era, most of these coronary artery patterns do not represent an obstacle to surgical correction (as discussed below). To standardize the definition of the coronary anatomy, the sinuses are conventionally numbered 1 and 2. If one imagines oneself standing in the nonfacing aortic sinus looking at the pulmonary root (Fig. 74-3),

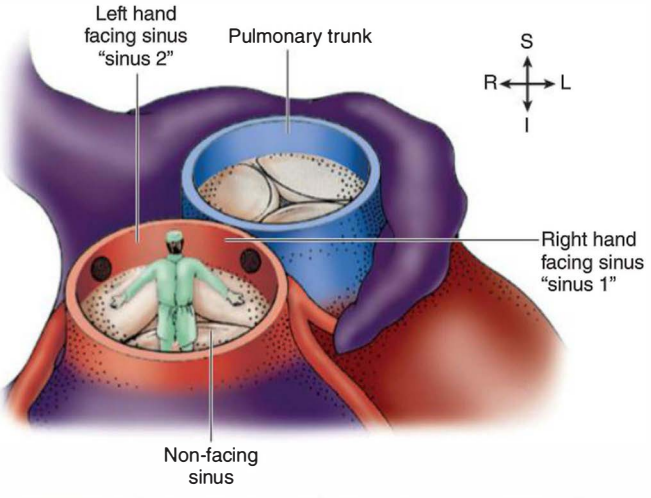

**FIGURE 74-3** Conventional numbering (Leiden convention) of the aortic sinuses for defining the coronary patterns. The illustration shows the typical coronary arrangement in D-TGA. (From Lesions in abnormally connected hearts. In: Wilcox BR, Andreson RH (eds). *Surgical Anatomy of the Heart,* 2nd ed. London: Gower, 1992. With permission.)

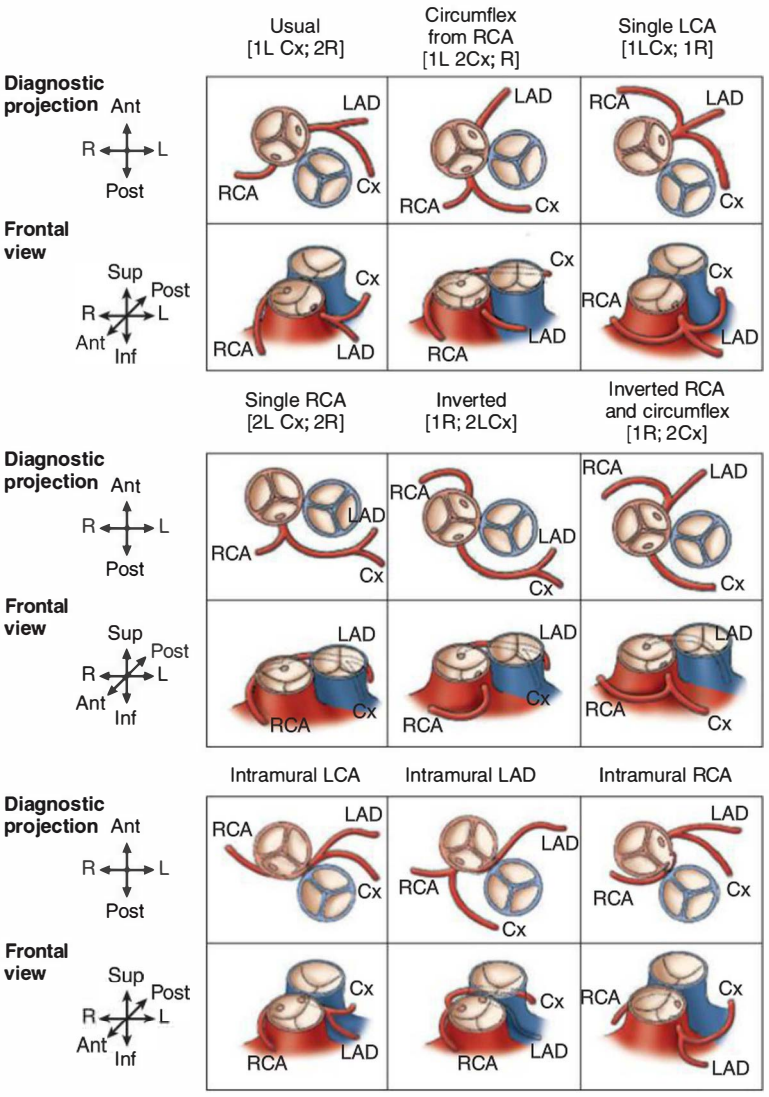

**FIGURE 74-4** Coronary artery patterns in TGA. Upper panel: Two-dimensional echocardiographic view. Lower panel: "surgeon's view." Ant, anterior; Cx, circumflex; Inf, inferior; L, left; R, right; LAD, left anterior descending; Post, posterior; RCA, right coronary artery; Sup, superior. (Modified from Wernovsky G, Sanders SP. Coronary artery anatomy and transposition of the great arteries. *Coron Artery Dis* 1993;4(2):148–157.)

the right-hand sinus is numbered as 1 and the left-hand sinus as 2. Using this convention (also known as the "Leiden" convention), the coronary anatomy is then described based on the sinuses of origin of the various coronary artery branches. For example, in the most common arrangement, the left anterior descending and circumflex coronary arteries arise from sinus 1 and the right coronary artery (RCA) from sinus 2. This pattern, as seen in Figure 74-3, is described as 1LCx2R. The common coronary arrangements are summarized in Figures 74-4 and 74-5.

## PATHOPHYSIOLOGY

As mentioned above, the circulation in D-TGA consists of two circuits in parallel (Fig. 74-1A). Deoxygenated blood is ejected to the body from the RV into the aorta, returning via the venae cavae to the RA and back to the RV. The oxygenated blood cycles from the LV to the PA and through the lungs to return once again to the LA and LV. Thus, intercirculatory shunting is required for mixing to occur. As reflected in Figure 74-1B, the *effective* pulmonary blood flow (the amount of deoxygenated blood reaching the lungs) is

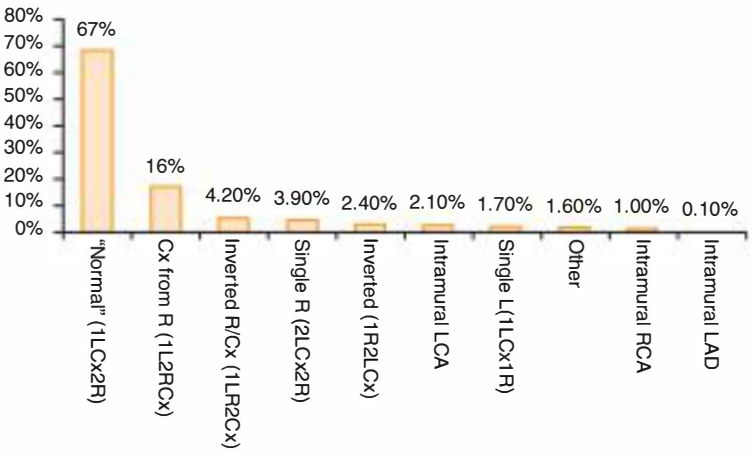

**FIGURE 74-5** Distribution of coronary patterns. (Data from Wernovsky G. Transposition of the great arteries. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ (eds). *Moss and Adams' Heart Disease in Infants, Children and Adolescents,* 6th ed. Philadelphia: Lippincott, Williams & Wilkins, 2001:1033. With permission.)

composed of only the anatomic right-to-left shunted blood. Similarly, the *effective* systemic blood flow (the amount of oxygenated blood reaching the body) is equal to the amount of anatomic left-to-right shunting. There are several potential levels of mixing, including an atrial septal defect (ASD), a VSD, and a patent ductus arteriosus (PDA). In D-TGA/IVS, this is achieved by maintaining a PDA with prostaglandin $E_1$ ($PGE_1$) infusion and ensuring an effective atrial-level communication. This may require performance of a blade or balloon atrial septostomy, a fluoroscopically or echocardiographically-guided method of opening the atrial septum, as described by Rashkind in 1966.[17] Rarely, an open atrial septectomy or temporary mechanical support will be required to stabilize a patient prior to an ASO. In D-TGA/IVS and D-TGA/VSD with mild or no PS, there may be adequate mixing at the atrial and/or ventricular levels to allow for the discontinuation of $PGE_1$. In the presence of significant PS, $PGE_1$ will be necessary to provide sufficient pulmonary blood flow.

For patients escaping early diagnosis, the evolution of the intermediate-term pathophysiology depends on the anatomy. In the majority of patients with D-TGA/IVS, the closure of the PDA with the resultant loss of mixing will lead to severe cyanosis and cardiovascular decompensation. Although they are generally significantly cyanotic, a minority of patients may survive undiagnosed with D-TGA/IVS owing to adequate atrial-level mixing. In these patients, the LV will become deconditioned as it becomes acclimated to ejecting against the low-resistance pulmonary circulation. After 4 to 6 weeks, this deconditioning progresses to the point where an ASO would result in LV failure, as the LV would be abruptly required to assume systemic workloads. These ventricles require reconditioning prior to an ASO, as detailed below.

Patients with D-TGA and a nonrestrictive VSD will have pulmonary overcirculation, as in the case of any patient with a large systemic-to-pulmonary shunt. However, unlike the typical patient with a large VSD, patients with transposition are at significant risk for the accelerated development of pulmonary vascular obstructive disease (PVOD). As early as 2 months of age, 20 percent of patients with D-TGA and a nonrestrictive VSD will have Heath-Edwards grade 3 or greater histologic pulmonary vascular changes.[18] By 12 months, up to 89 percent will have grade 4 changes.[19] Although the LV remains conditioned due to the pressure load from the nonrestrictive VSD, the development of PVOD may preclude anatomic repair. Patients with D-TGA/VSD/PS can have a more benign natural history, as the appropriate degree of PS leaves them well balanced between adequate effective pulmonary blood flow and protection from PVOD. The LV in patients with D-TGA/VSD/PS remains conditioned due to the pressure load of both the VSD and the PS.

## CLINICAL FEATURES

D-TGA is the most common cause of cyanosis in infants and accounts for approximately 10 percent of all congenital cardiovascular malformations.[20] The clinical manifestations of a patient with D-TGA are based upon the amount of intercirculatory shunting of the specific anatomy. In the patient with D-TGA/IVS (or a virtually intact septum), cyanosis is essentially universal. Cyanosis is recognized by nursing or physician staff in 56 percent of neonates within the first hour of life and in 92 percent by 1 day.[21] The remainder of the physical exam is often nondiagnostic. Systolic cardiac murmurs are present in approximately half of the patients, but are usually of grade 2 or less. In the presence of a large VSD, the cyanosis may be very mild and initially overlooked. Signs of congestive heart failure (CHF), including tachycardia and tachypnea, generally become evident by 2 to 6 weeks as pulmonary vascular resistance falls and pulmonary blood flow increases. Murmurs may increase, and other ausculatory findings typically associated with CHF may become evident.

These findings may include a grade III to VI pansystolic murmur, a gallop, a middiastolic rumble, and a narrowly split second heart sound with a prominent pulmonary component. The addition of significant PS leads to diminished pulmonary blood flow and severe cyanosis.

## DIAGNOSTIC MODALITIES

The electrocardiogram (ECG) at birth is generally normal for age. Within the first weeks, abnormal RV hypertrophy with right axis deviation becomes evident with D-TGA/IVS. In the presence of a large VSD, biventricular hypertrophy predominates in the majority of patients, while the axis remains normal in approximately one-third. The chest radiograph (CXR) is often initially normal in D-TGA with IVS or VSD. The classic triad of an egg-shaped heart, mild cardiomegaly, and mildly increased pulmonary vascular markings occurs in only about one-half of patients (Fig. 74-6).[21] With D-TGA/IVS approximately one-half to two-thirds of CXRs demonstrate the classic "egg on a string" sign (globular heart with mild or no cardiomegaly below a narrow mediastinal shadow due to the anteroposterior alignment of the great vessels). The pulmonary vasculature is normal in one-third to one-half of patients and mildly increased in the remainder. Over the first few weeks, cardiomegaly may become more apparent, and the pulmonary vascular markings invariably increase. In the presence of a VSD, the cardiac silhouette is generally noticeably larger and the pulmonary vasculature more prominent than in D-TGA/IVS, as pulmonary vascular resistance falls over the first few weeks of life.

Two-dimensional and Doppler echocardiography is the diagnostic modality of choice. Echocardiography can accurately diagnose the origins of the great arteries arising from the incorrect ventricles. Classically, in a long-axis view, the two great vessels can be seen in parallel rather than wrapping around each other in their normally-related configuration. In the short-axis view, the two semilunar valves, which normally lie in different planes, can be imaged in the same two-dimensional slice, resulting in the "double-barreled shotgun" appearance. Doppler/echocardiography can also accurately diagnose the common associated lesions, including the number, size, and location of VSDs, the degree and cause of LVOTO, and assess the patency of the atrial septum and ductus arteriosus. In addition, coronary anatomy can usually be effectively defined. Cardiac catheterization is rarely required for diagnostic purposes in D-TGA except to define particularly complex coronary anatomy, occasionally to clarify multiple or complex VSDs, and to assess pulmonary vascular resistance or LV pressures in the patient presenting late.

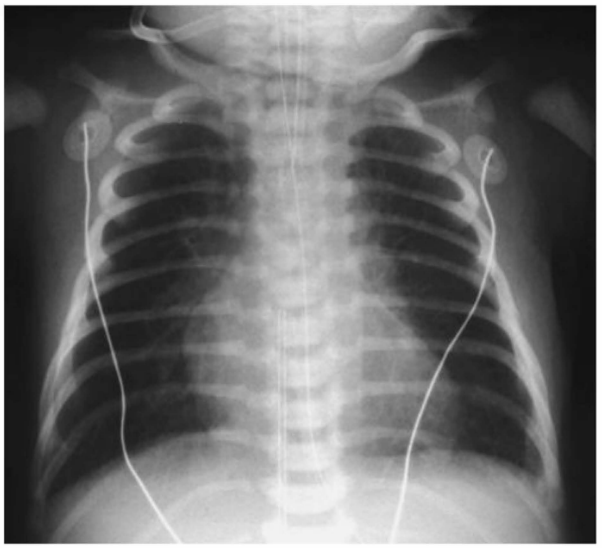

**FIGURE 74-6** Chest radiograph of a patient with D-TGA with intact ventricular septum, demonstrating the classic "egg on a string" radiographic finding.

## MEDICAL THERAPY

Medical management strategies are utilized to palliate the patient until definitive surgical correction can be undertaken. For patients identified at the time of birth or presenting soon thereafter with cardiovascular compromise, $PGE_1$ is instituted to maintain ductal patency. The ASD is examined on Doppler and/or echocardiography. It is essentially always necessary to have a minimally or nonrestrictive ASD to allow adequate mixing. Even in the setting of D-TGA with a large VSD, a significant ASD is usually necessary. This atrial-level shunting is necessary because mixing at the atrial level tends to be more effective, as it occurs in both systole and diastole, unlike the case with a VSD, where shunting occurs primarily during systole. If a restrictive ASD is present, a balloon atrial septostomy is performed under fluoroscopic or echocardiographic guidance. Occasionally, if the atrial septum is particularly thick, a blade and/or static balloon septostomy may be necessary. Rarely is it necessary to proceed with an urgent ASO or an open septostomy for a failed percutaneous intervention. Once a nonrestrictive ASD is identified or created, $PGE_1$ can occasionally be weaned and the PDA allowed to close in D-TGA with a large VSD, while oxygen saturations are closely monitored to ensure adequate intercardiac shunting. This may also be the case for D-TGA/IVS, where atrial-level mixing may be adequate to maintain systemic oxygenation until surgery can be performed.

## SURGICAL THERAPY

In the absence of mitigating factors that would preclude major open-heart surgery—such as poor clinical condition, prematurity, or very low birth weight—our current policy for the treatment of all forms of D-TGA is complete repair in the neonatal period.

## D-Transposition of the Great Arteries Without Pulmonic Stenosis

The current treatment for D-TGA is the ASO, which is performed via a median sternotomy. A portion of autologous pericardium is harvested and placed in dilute glutaraldehyde solution for later use in reconstructing defects created in the proximal aorta where the coronary arteries are removed. Standard techniques of CPB using bicaval cannulation and moderate hypothermia are employed. The arterial cannula is placed slightly higher on the ascending aorta, near the base of the innominate artery, than for other procedures. For straightforward D-TGA/IVS or VSD, deep hypothermic circulatory arrest or low-flow CPB is not necessary. After the initiation of CPB, a left atrial vent is inserted via the right upper pulmonary vein. The antegrade cardioplegia needle is placed in the ascending aorta at the line of planned division or above for later de-airing. The branch PAs are mobilized well past the first order lobar branches. A cross-clamp is applied on the distal ascending aorta and the heart is arrested with antegrade cardioplegia. Interval doses of maintenance cardioplegia may be given throughout the case in a retrograde fashion or administered directly into the coronary ostia. The aorta and main PA are divided (Fig. 74-7A). The PA is translocated anterior to the aorta (Lecompte maneuver) and the distal aorta anastomosed to the proximal PA (Fig. 74-7B). In the technique currently favored at our institution, the neoaorta is reconstructed prior to translocating the coronary arteries. Once the neoaortic anastomosis is completed, the cross clamp can be temporarily removed, allowing the neoaortic root to fill and assume its postrepair three-dimensional shape. We have found that this technique facilitates optimal reimplantation of each coronary artery without tension, kinking, or twisting. The coronary arteries are removed from the aorta

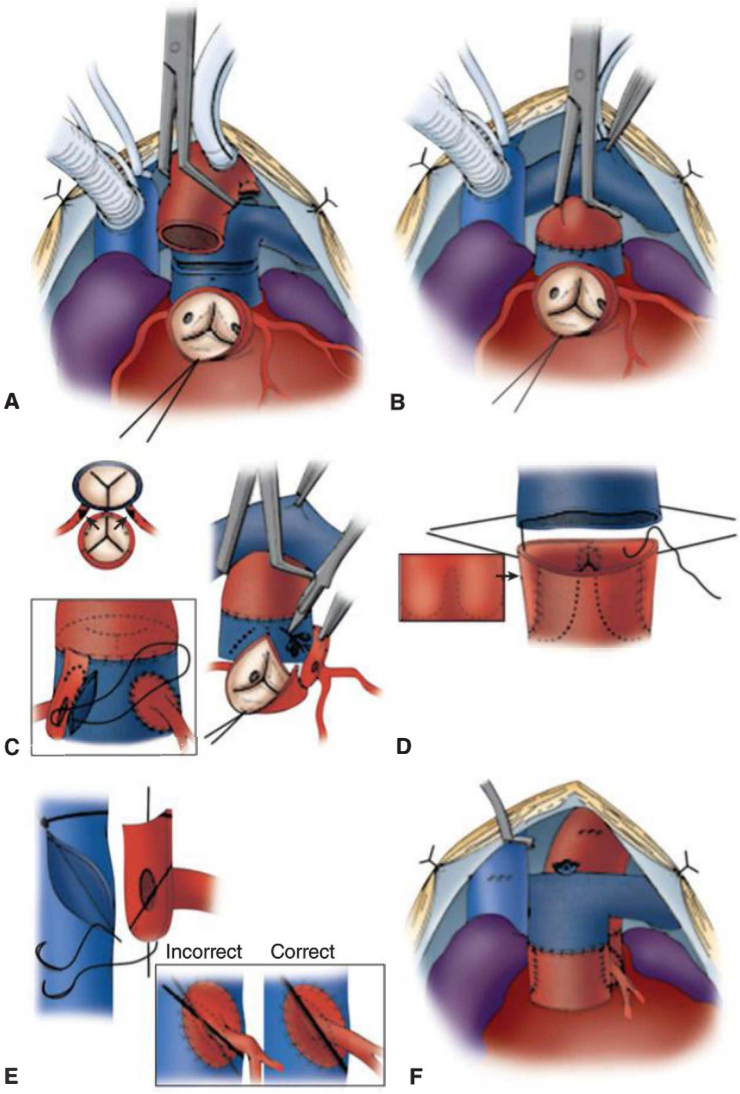

**FIGURE 74-7** The arterial switch operation. **A.** Division of the aorta and pulmonary artery (PA). **B.** The "Lecompte maneuver" with the distal aorta anastomosed to the PA. **C.** Translocation of the coronary arteries. **D.** Reconstruction of the aorta with a pantaloon-shaped patch of autologous pericardium. **E.** Proper alignment of the coronary arteries. **F.** The completed repair. (From Devaney EJ, Ohye RG, Hirsch JC, Bove EL. Congenital heart disease. In: Mulholland MW, Lillemoe KD, Doherty GM, et al. (eds). *Greenfield's Surgery: Scientific Principles and Practice.* Philadelphia: Lippincott, Williams & Wilkins, 2006:1442.)

with buttons of adjacent sinus and transferred to the proximal PA (Fig. 74-7C). The proximal aorta is reconstructed using a pantaloon-shaped patch of autologous pericardium (Fig. 74-7D), and anastomosed to the distal PA. It is important to properly align the coronary buttons in the neoaortic root. As illustrated in Figure 74-7E, the original inferior-most point of the coronary button on the aorta is seldom the same for the new location on the neoaorta. It is imperative to allow the button to sit in the most natural position, which is usually not the same orientation as on the native aorta. The ASD and, if present, the VSD are closed transatrially (Fig. 74-7F).

## D-Transposition of the Great Arteries with VSD and Pulmonic Stenosis

The management strategy of D-TGA with VSD and *significant* PS is determined by the severity and etiology of the PS. Occasionally, in the case of focal subpulmonic stenosis, it may be possible to resect the area of obstruction through the pulmonary valve and proceed with an ASO. However, this resection is technically difficult through the posteriorly located and often hypoplastic pulmonary valve associated with the PS. More commonly, the subvalvar and associated valvar PS precludes an ASO. Although, as mentioned above, our policy is to generally perform complete neonatal repair, there are other options to delay anatomic repair; these may be employed for the management of this particular subset of patients. These strategies are also useful for the patient presenting in poor clinical condition or with prematurity or low birth weight. It is possible for these patients to have well-balanced circulations, with a degree of PS that is significant enough to protect the pulmonary vasculature from the development of PVOD without causing prohibitive levels of hypoxemia. Although the PS tends to be progressive, owing to the continued increase in left ventricular hypertrophy (LVH), it is possible to delay operation in this subset of patients with D-TGA/VSD/PS. Careful monitoring for an increase in cyanosis is, however, imperative. In the presence of severe PS and significant cyanosis, a palliative modified Blalock–Taussig shunt can be performed to delay definitive repair.

Whether performed initially or as a staged procedure, D-TGA in the presence of significant PS and a VSD requires either performance of either a Rastelli or Nikaidoh procedure. The Rastelli operation utilizes the VSD to allow the LV to eject into the aorta. The operation is performed via a median sternotomy with standard aortic and bicaval cannulation. After the initiation of CPB, a left atrial vent and antegrade cardioplegia needle are placed. A cross clamp is applied and the heart is arrested. A right infundibulotomy is performed (Fig. 74-8A). Resection of the infundibular

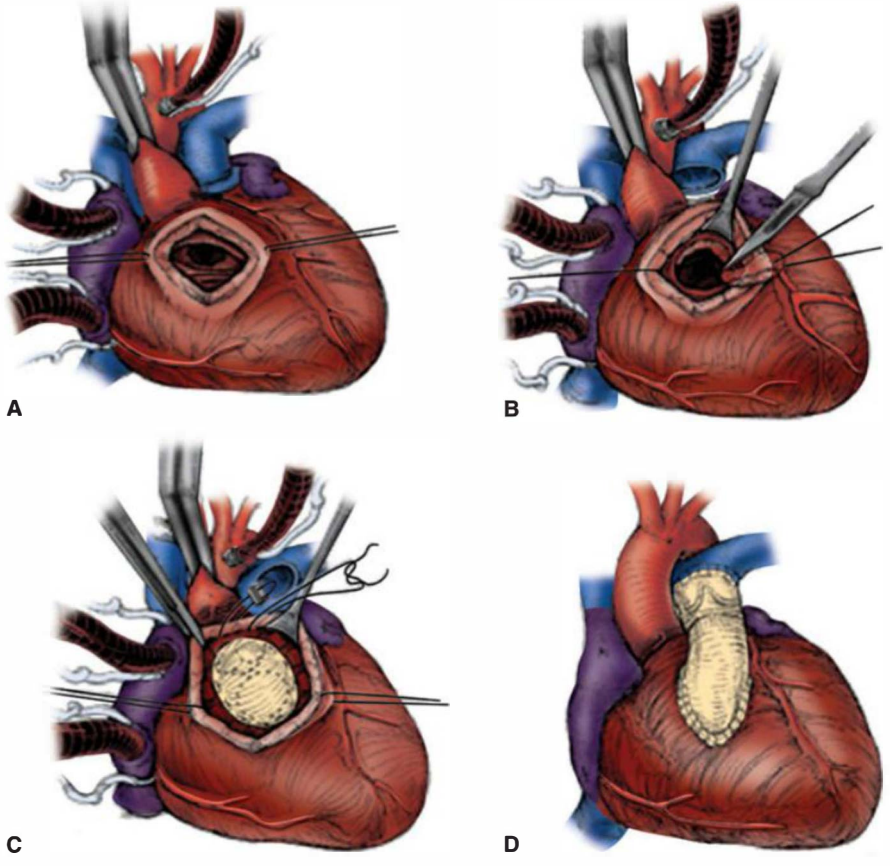

**FIGURE 74-8** The Rastelli procedure. (From Mavroudis C, Backer CL. Transposition of the great arteries. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery,* 3rd ed. Philadelphia: Mosby, 2003:465. With permission.)

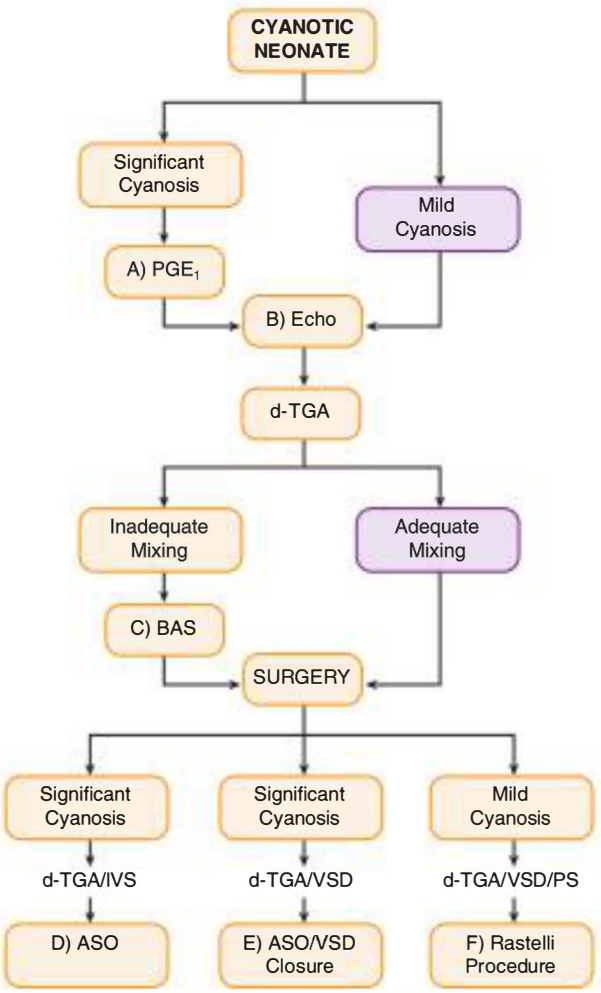

**FIGURE 74-9** Decision-making flowchart.

septum may facilitate the creation of continuity from the LV to the aorta (Fig. 74-8B). The PA is divided at the level of the pulmonary annulus and the proximal end is oversewn. The VSD patch is constructed to incorporate both the VSD and the aortic valve, creating a tunnel from the LV to the aorta (Fig. 74-8C). RV-to-PA continuity is established using a conduit from the RV infundibulum to the distal PA (Fig. 74-9).

The Nikaidoh, or aortic translocation, procedure involves mobilizing the aortic root, either completely or partially leaving a bridge of muscle under the left coronary artery (Fig. 74-10, panels 1 and 3). Standard CPB techniques, as described above for the Rastelli procedure, are employed. The stenotic pulmonary annulus is divided, extending down into the VSD though the conal septum, if present (Fig. 74-10, panel 1). The mobilized aortic root is then sewn into the enlarged pulmonary annulus and the VSD is closed (Fig. 74-10, panels 2, 3, 5, and 6). When aortic root is only partially mobilized, it is pivoted into place in the pulmonary root around the myocardial bridge beneath the left coronary artery (Fig. 74-10, panels 3, 4, and 5). The RCA is reimplanted in this latter technique to prevent excessive tension (Fig. 74-10, panel 5).

## LEFT VENTRICULAR RETRAINING

Because pulmonary vascular resistance falls rapidly during the first days of life, the PA and LV pressures drop. In the absence of a nonrestrictive VSD, significant PS, or large PDA, the LV becomes deconditioned, losing muscle mass and the ability to function at systemic workloads. These LVs require retraining prior to an ASO. The point at which an LV becomes unprepared can be difficult to determine; however, patients presenting after 4 to 6 weeks are certainly of concern. Objective data to make this determination are few, although LV posterior wall thickness or LV muscle mass normal for age suggests that the LV will be able to perform at systemic pressures. For patients with moderate PS or a restrictive VSD, an LV pressure that is 70 percent of the systemic pressure generally indicates a prepared LV. Patients who present with a marginally or clearly unprepared LV require a two-stage approach. The first stage entails the placement of a PA band (PAB) to raise the LV pressure and recondition the ventricle, followed by an ASO. It may also be necessary to add a modified Blalock–Taussig shunt with the PAB to augment pulmonary blood flow. In general, a goal of an LV/RV pressure ratio of 0.7 is desirable. Although this may be achieved in a single banding in patients presenting in the first weeks to months of life, sequential tightening may be necessary in the older patient. Echocardiographic guidance can also be useful during the placement of the PAB to assist in deciding how tight a band will be tolerated. One measure of an effective PAB on echocardiogram is rightward shift of the ventricular septum. The echocardiogram can also be employed to guard against ventricular failure from a PAB that is excessively tight. In patients presenting within the first few weeks to months of life, the retraining process can usually be accomplished within a few weeks. Indications that the LV has been properly reconditioned include an LV/RV pressure ratio of greater than 0.7 and an LV wall thickness or muscle mass that are normal for age.

A particularly challenging group of patients for ventricular retraining are those who present very late or, more commonly, those who present with a failed atrial-level switch. These patients present with RV failure generally associated with severe tricuspid regurgitation. Tricuspid valve replacement has often been unrewarding, as the underlying problem is the RV failure. Among this population of patients, a percentage may be amenable to ventricular retraining. This reconditioning may require several weeks to months, with sequential PAB tightening to achieve a prepared LV. Although similar measures of LV preparedness can be utilized, the determination remains difficult. In addition, many patients may not tolerate the banding and develop biventricular failure. Orthotopic cardiac transplantation remains a viable alternative to ventricular retraining and ASO.

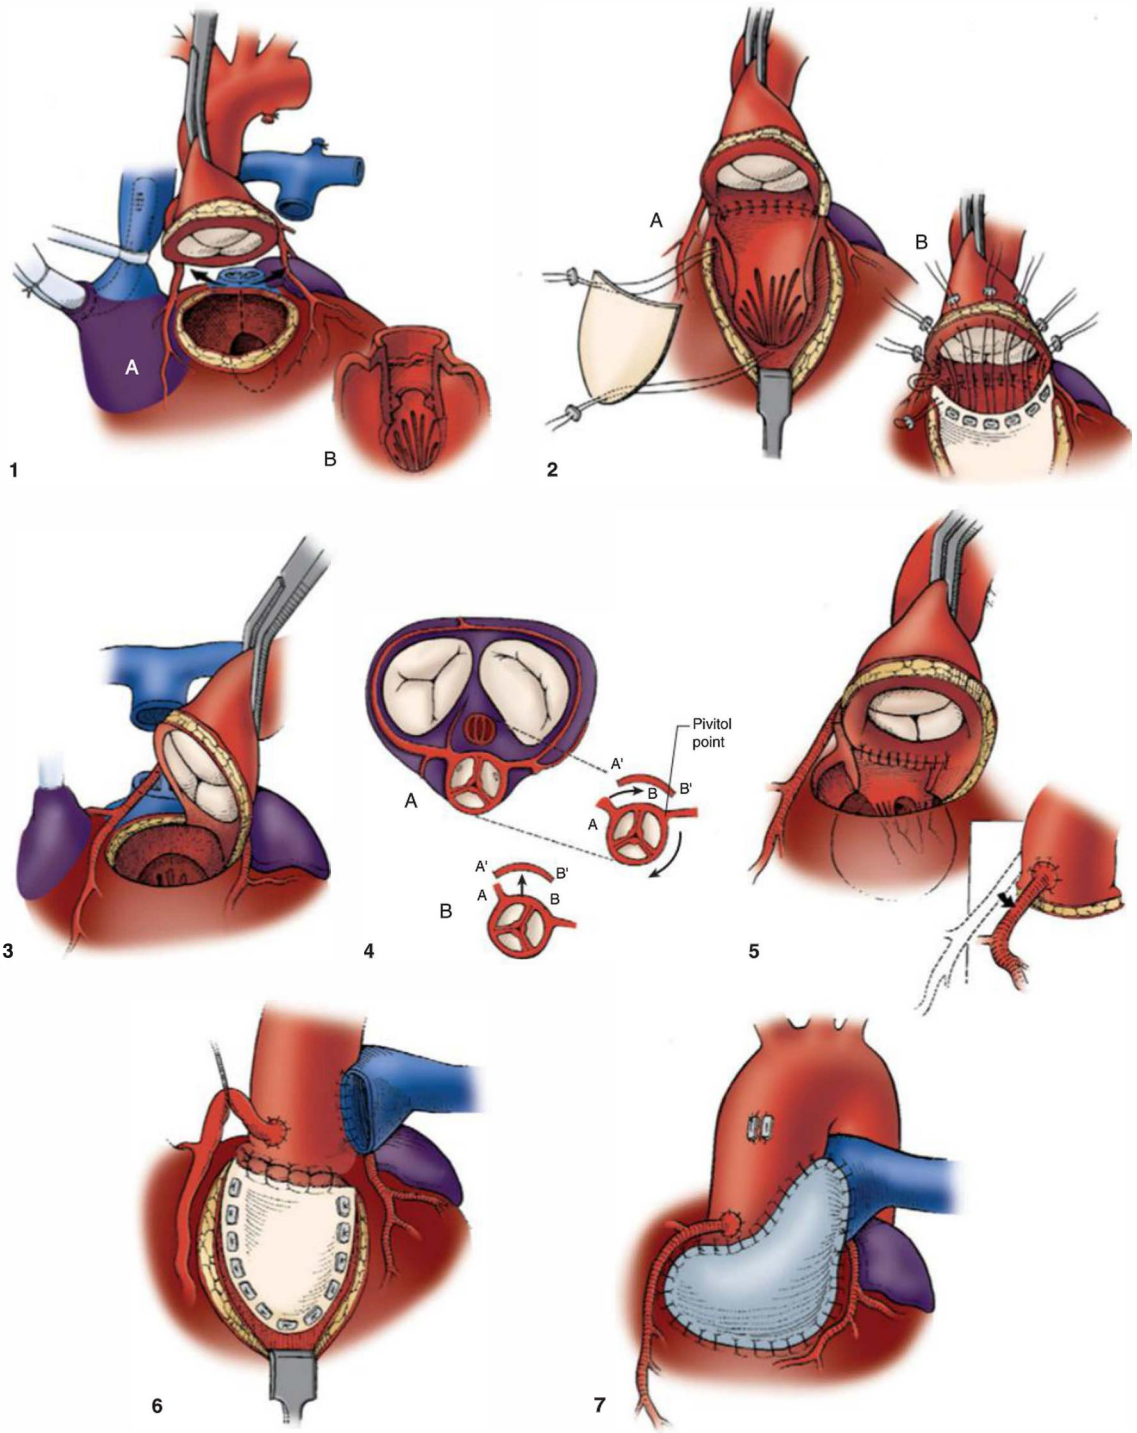

**FIGURE 74-10** The Nikaidoh or aortic translocation procedure. Panel **1A.** The anteriorly located aortic root is fully mobilized (the currently preferred method) and both coronaries are skeletonized. Panel **1B.** Division of the pulmonary annulus and conal septum (when present). Pulmonary–mitral continuity is demonstrated. Panel **2A.** Anastomosis of the aorta to the open pulmonary annulus after posterior translocation. Panel **2B.** Anastomosis of the VSD patch to the anterior rim of the mobilized aortic root. Panel **3.** In the second method of mobilizing the aortic root, partial mobilization of the aortic root is used. A pedicle of myocardium is left intact under the left main coronary artery to decrease the risk of bleeding where the suture lines converge (see Panel **6**). Panel **4B.** The fully mobilized root can shift directly posteriorly without rotation and potentially less distortion of the coronary arteries. Panel **4C.** Partially mobilized roots require rotation of the aortic root around the pedicle of the left main coronary artery. This rotation preserves left main coronary artery alignment, at the expense of the right coronary arterial. Panel **5,** Because of the disproportionate tension on the RCA with partial mobilization and rotation of the root as shown in Panel **4C,** the right coronary artery may require reimplantation. Panels **6** and **7.** The right ventricular outflow tract is reconstructed by anchoring the right lateral wall of the main pulmonary artery to the aortic root and overlaying a patch of pericardium. (From Yeh T Jr, Ramaciotti C, Leonard SR, Roy L, Nikaidoh H. The aortic translocation (Nikaidoh) procedure: Midterm results superior to the Rastelli Procedure. *J Thorac Cardiovasc Surg* 2007;133:461–469. With permission.)

## SPECIAL CORONARY CONSIDERATIONS

Although older series have often identified certain coronary artery patterns, particularly a retropulmonary circumflex or a single left coronary artery from sinus 2 (1L2RCx, 2RLCx, respectively), as risk factors for early mortality, most centers are currently able to perform successful coronary transfers for all arterial patterns.[22–25] Of note, Brown and associates[23] found that the coronary artery pattern was neutralized as a risk factor after switching to the technique of completing the neoaortic anastomosis prior to transferring the aortic buttons, as described above. However, despite these advances, the intramural coronary artery still requires special consideration (Fig. 74-11). Most importantly, the intramural course of the coronary artery must be recognized prior to harvesting the coronary artery button in order to avoid coronary transection. Experienced echocardiographers can usually identify suspicious coronary pathways, but careful intraoperative determination of coronary artery entrance and exit points remains crucial. Once the course of the coronary artery is positively identified, the button can generally be successfully and uneventfully harvested, splitting the aortic wall to elevate valve commissures or cusps as necessary (Fig. 74-12). Unroofing of the coronary orifice might be helpful to ensure a widely patent artery. The two arteries can alternatively be left together and transferred to the neoaorta as a single unit.

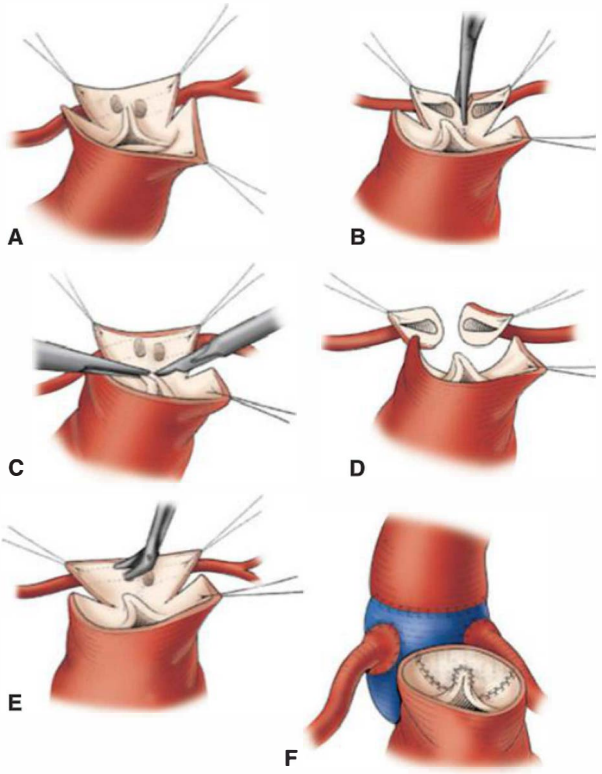

**FIGURE 74-12** The method for coronary transfer of double intramural coronary arteries. **A.** A single button is mobilized. **B.** The commissure is elevated from the aortic wall. **C.** The orifices are unroofed. **D** and **E.** The buttons are excised and divided. **F.** The coronaries are translocated to the neoaorta and the aortic root is reconstructed with autologous pericardium with resuspension of valve commissure. (From Padalino MA, Ohye RG, Devaney EJ, Bove EL. Double intramural coronary arteries in D-transposition of the great arteries. *Ann Thorac Surg* 2004;78:2181–2183. With permission.)

## RESULTS

Currently published hospital survival for the ASO ranges from approximately 90 to 95 percent.[16,23,24,26] D-TGA/IVS has generally a lower mortality than D-TGA/VSD or D-TGA/VSD/PS. Hospital mortality for D-TGA/IVS ranges from 3.5 to 7.6 percent, compared with 9.4 to 13.1 percent for D-TGA/VSD.[23,24] Long-term survival at 5 to 10 years and at 15 years range between 87.9 and 93 percent and 86 and 88 percent, respectively.[23,24,26] The most common cause for reintervention after ASO is supravalvar pulmonic stenosis, occurring in 3.9 to 16 percent.[24,26] A recent study over a 25-year period of 101 patients undergoing a Rastelli operation revealed a hospital mortality of 7 percent, with no deaths in the last 7 years of the study.[27] Actuarial survival at 5, 10, 15, and 20 years was 82, 80, 68, and 52 percent, respectively.

At the C.S. Mott Children's Hospital at the University of Michigan, from January 1999 to January 2004, a total of 114 infants with D-TGA underwent operation. Patients with double-outlet RV or other malformations associated with D-malposition of the great arteries were excluded. Of the 114 patients, 60 had D-TGA/IVS (53 percent); the remaining 54 had D-TGA/VSD (47 percent). Pulmonary

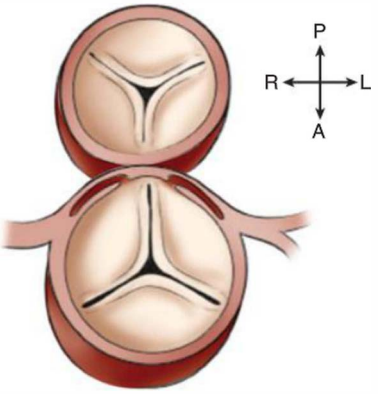

**FIGURE 74-11** An example of double intramural coronary arteries. A, anterior; P, posterior; R, right; L, left. (From Padalino MA, Ohye RG, Devaney EJ, Bove EL. Double intramural coronary arteries in D-transposition of the great arteries. *Ann Thorac Surg* 2004;78:2181–2183. With permission.)

stenosis (PS) was present in 2 patients among those with D-TGA/IVS (3 percent) and in 13 patients with D-TGA/VSD (24 percent). Coronary patterns were 1LCx2R in 75 patients (66 percent), 1L2RCx in 20 (18 percent), and other patterns in 19 patients (16 percent), including 8 intramural coronaries. D-TGA was corrected via a simple ASO in 71 patients (62 percent), ASO with VSD closure in 31 patients (27 percent), and a Rastelli procedure in 12 patients (11 percent). There were two hospital mortalities, both in patients with D-TGA/VSD, for an overall mortality of 1.8 percent. One patient died unexpectedly following an uneventful repair, presumably of cardiac causes, and the second died from necrotizing enterocolitis.

Results for the Nikaidoh procedures were reported by Yeh and colleagues.[28] They described 19 patients undergoing a Nikaidoh procedure at a median age of 3.3 years (range, 0.9–9.3 years) with a median follow-up of 11.4 years (range, 0.1–23 years). There was one hospital mortality due to RCA ischemia, and no late deaths. Five patients have required seven RVOT reinterventions. No patient has required reintervention on the aortic valve or LVOT.

Staged conversion for failed atrial-level switches has been a more challenging problem. In a recent report by Mavroudis and colleagues,[29] 11 patients underwent 15 PA bandings in an attempt at LV retraining; 4 required cardiac transplantation for biventricular failure, 6 have undergone ASO, and 1 awaits conversion. There were no early deaths in the transplanted patients and one late death at 7 years from chronic rejection. There were 2 early and no late deaths in the group undergoing ASO, for an overall successful conversion rate of 40 percent. Overall survival was 64 percent, including the patients awaiting ASO.

## TRANSPOSITION OF THE GREAT ARTERIES BOARD REVIEW QUESTIONS (CHAPTER 74)

1. Which is correct regarding morphologic classification of TGA?

   A. There is generally situs inversus of the atria.
   B. D-TGA is invariably associated with D-looping.
   C. L-TGA is associated with dextro looping.
   D. L-TGA is also known as simple transposition.
   E. D-TGA is also known as corrected transposition.

2. Which is correct regarding the pathophysiology of TGA?
   A. Deoxygenated blood cycles from the LV to the PA.
   B. The effective systemic blood flow is equal to the amount of anatomic left-to-right shunting.
   C. In D-TGA with IVS, there is no need for $PGE_1$.
   D. If uncorrected, LV deconditioning will occur within 1 to 2 weeks in D-TGA/IVS.
   E. The LV in patients with D-TGA/VSD/PS will become deconditioned within 3 to 6 months.

3. Which is not correct regarding the clinical presentation of TGA?
   A. D-TGA is the most common cause of cyanosis in infants.
   B. Cyanosis is virtually universal with patients with D-TGA/IVS.
   C. Cyanosis is recognized in over 90 percent of neonates within the first 24 h.
   D. Systolic cardiac murmurs are present in 90 percent of infants.
   E. Murmurs may increase over time.

4. Which is not part of the surgical strategy for TGA without PS?
   A. The PA is translocated posteriorly.
   B. The distal aorta is anastomosed to the proximal PA.
   C. The neoaorta is reconstructed prior to translocating the coronary arteries.
   D. The proximal aorta is reconstructed using autologous pericardium.
   E. The VSD is closed transatrially.

5. Which is true regarding outcomes after surgical repair of TGA?
   A. The subset of D-TGA/IVS generally has a higher mortality.
   B. The most common cause for reintervention after arterial switch is supravalvar PS.
   C. Actuarial survival at 10 years for arterial switch is 80 percent.
   D. Actuarial survival at 10 years for Rastelli procedure is 70 percent.
   E. The Nikaidoh procedure eliminates RVOT reintervention.

## ANSWERS

1. **Answer: B.** D-TGA is invariably associated with D-looping. There is generally situs solitus of the atria. D-TGA is also known as simple transposition. L-TGA is associated with L-looping and is known as corrected transposition.

2. **Answer: B.** The effective systemic blood flow is equal to the amount of anatomic left-to-right shunting. Oxygenated blood cycles from the LV to the PA. In D-TGA with IVS, adequate mixing must be maintained by use of $PGE_1$ to maintain ductal patency. LV deconditioning will occur by 4 to 6 weeks in D-TGA/IVS if left uncorrected. The LV in patients with D-TGA/VSD/PS remains conditioned due to the pressure load of both the VSD and PS.

3. **Answer: D.** Systolic murmurs are present in about 50 percent of infants. D-TGA is the most common cause of cyanosis in infants and is virtually universal with an IVS. The cyanosis is recognized in over 90 percent of infants within the first 24 h. Murmurs may increase over time as CHF symptoms develop.

4. **Answer: A.** The PA is translocated anteriorly (LeCompte maneuver). The remaining steps are all standard during the ASO.

5. **Answer: B.** The most common cause for reintervention after arterial switch is supravalvar PS. The subset of D-TGA/IVS has the lowest mortality. Actuarial survival at 10 years after arterial switch is greater than 85 and 80 percent after Rastelli procedure. The Nikaidoh procedure does not eliminate RVOT reintervention.

# Congenitally Corrected Transposition

*Emile A. Bacha*

***"Corrected transposition, when first encountered, resembles an unreal apparition.... All of the important people were there doing their expert job. The operation began well. The individual cardiac chambers and structures were present and accounted for, and the ventricular septal defect was in the perimembranous location. But something else was fundamentally wrong. Almost everything was out of place in a weird mime of normal, clearly an illusion characteristic of another nightmare. There seemed no choice but to press on even in the face of this confusion, hoping as always that by applying basic principles one could win out. The ventricular septal defect was therefore carefully patched so as to avoid the conduction system, and perfusion was discontinued. Heart block ensued, cardiac output became poor, and tragedy loomed."***

Dwight McGoon, 1983[1]

## KEY CONCEPTS

- Epidemiology
  - Congenitally corrected transposition of the great arteries (CC-TGA) is a rare condition, comprising less than 1 percent of all congenital heart defects.
- Morphology
  - In the most common variety, there is *situs solitus* with discordant atrioventricular (AV) and ventriculoarterial connection (double discordance). Associated anomalies include Ebstein malformation of the tricuspid (systemic) valve, ventricular septal defect (VSD), obstruction of the right ventricular outflow tract, *situs inversus*, and anomalous course of the AV conduction system.
- Pathophysiology and clinical features
  - These are based on the cumulative effects of the associated lesions and the long-term performance of a morphologic right ventricle (RV) facing systemic afterload. Cyanosis and pulmonary overcirculation can ensue, with great variability in the timing of presentation.
- Diagnosis
  - Chest x-ray usually discloses mesocardia.
  - Echocardiography and cardiac catheterization are complementary in determining the necessity and timing of intervention. More recently, cardiac magnetic resonance imaging can be very helpful in determining respective right and left ejection fractions, volumes and help with surgical planning.
- Treatment
  - Some patients may remain asymptomatic, whereas others will only require pacemaker insertion for heart block. Early in infancy, shunting or pulmonary artery (PA) banding (PAB) of symptomatic patients is indicated. Eventually, depending on the timing of presentation and the type of pulmonary outflow, one of three pathways can be chosen: (1) conventional physiologic repair (the RV remains in the systemic circulation); (2) anatomic repair, with recruitment of the morphologic RV and left ventricle (LV) to the pulmonary and systemic circulations; and (3) staged palliation to single-ventricle physiology.
- Outcomes
  - Anatomic repair is technically more challenging but offers the long-term advantage of biventricular physiology. Fontan palliation can be a valid alternative to repair, with acceptable outcomes. Heart transplantation can be indicated in end-stage scenarios (see Chapter 77).

## DEFINITION AND SEQUENTIAL ANALYSIS

The classic definition of "congenitally corrected transposition of the great arteries" (CC-TGA) derived from the observation that the effects of such transposition are "corrected" by the congenital inversion of the two ventricles, with the two circulatory pathways "physiologically" in series despite morphologic derangements. Basically the same as "two negative gives a positive," this condition comprises less than 1 percent of all congenital heart defects.

CC-TGA is created by a "double discordance" between the atria and ventricles on the one hand [atrioventricular (AV) discordance], and the ventricles and the great vessels on the other (ventriculoarterial discordance). Thus, the right atrium is connected through a mitral valve to a morphologic left ventricle (LV), from which the pulmonary artery (PA) arises; conversely, the left atrium is connected via a tricuspid valve (TV) to the anatomic right ventricle (RV), from which the aorta arises. To avoid confusion throughout this chapter, we will try to avoid the use of the terms "left ventricle" and "right ventricle," calling them either morphologically left or subpulmonary ventricle, and morphologically right or subaortic ventricle.

The AV and ventriculoarterial sequence is most frequently associated with a visceroatrial "situs solitus," in which the ventricular loop (see Chapter 59) is located on the left side (L-loop). The concept of "loop" and "handedness" is simplified in Fig. 75-1 by imagining a hand positioned on the convexity of the septum, with the thumb through the AV valve and the index finger through the ventriculoarterial connection. The hand that can be placed with the palm following the convexity of the septum defines the loop. In normally connected hearts, the right hand will be positioned on the septum, the index finger through the pulmonary valve, and the thumb through the TV (D-loop) (Fig. 75-1). L-loop is seen in CC-TGA, where the left hand is positioned on the septum and the thumb goes through the TV (morphology of the AV valve follows and defines that of the underlying ventricle) and the index through the aortic valve.

Rarely, CC-TGA can present with visceroatrial *situs inversus*, with a normal ventricular "loop" (D-loop). The segmental anatomy is then (I,D,D), that is atrial *situs inversus*, D-looped ventricles (normal), and D-transposed great arteries. This type of physiologically corrected transposition (sometimes called "mirror-image" form of (S,L,L) CC-TGA) is often accompanied by additional cardiac malformations such as pulmonary valve stenosis, hypoplastic ventricles and AV valves. Dextrocardia is often seen. Frequently, a single-ventricle approach is necessary in (I,D,D) hearts. This chapter will be dealing with the most common form of corrected transposition, namely (S,L,L) CC-TGA.

The cardiac apex in the most common form of CC-TGA is related to the peculiar position of the anatomic LV, and it is located in a more central position than normal (Fig. 75-2). This location exists even in *situs inversus*, where the cardiac apex is rotated on the right side and more centrally. Heterotaxy is not observed in CC-TGA.

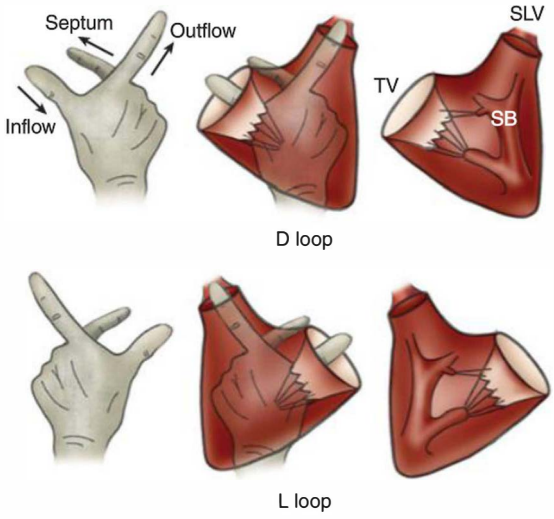

**FIGURE 75-1** Hand topology (loop) in normally connected hearts (D-loop, top) and congenitally corrected transposition (L-loop, bottom). Explanation in text. (From Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott–Raven, 2007. With permission.)

## PATHOPHYSIOLOGY

In isolated CC-TGA, blood from inferior and superior venae cavae and from the coronary sinus drains into the right atrium and then through a bicuspid (mitral) AV orifice into the morphologic LV (physiologic RV, or subpulmonary

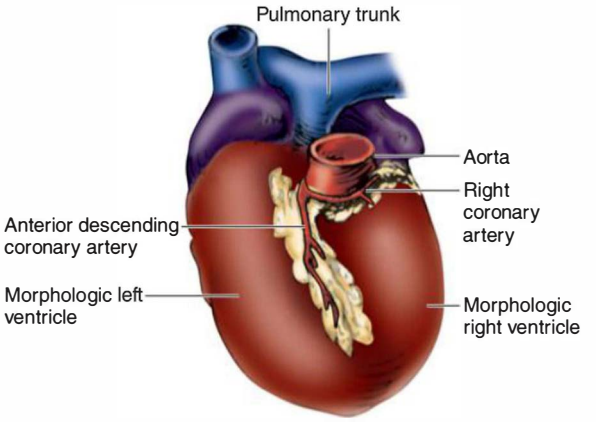

**FIGURE 75-2** Most common external cardiac anatomy in congenitally corrected transposition, with the aorta anterior and to the left, the pulmonary trunk centrally, and mesocardia. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

ventricle). The pulmonary veins drain into the left atrium and blood is transported via the tricuspid AV orifice into the morphologic RV (physiologic LV, or subaortic ventricle). This ventricle pumps the blood into the aorta and therefore into the systemic and coronary circulation. Thus, in CC-TGA, the physiology of the circulation is normal. As a consequence, oxygen saturation within the heart chambers and in the great arteries is normal, even if the blood flows through "wrong" AV valves and ventricles. The PA is in the pathway of the unsaturated blood, while the aorta in the pathway of oxygenated blood. In these hearts one of the most important physiologic aspects that dominates the natural history of CC-TGA is the fact that the morphologic RV has to propel blood into the aorta against systemic resistance and high afterload.

## ASSOCIATED LESIONS

Patients with CC-TGA are usually seen because of the additional lesions that are commonly associated. The most relevant associations are TV regurgitation (the systemic AV valve), often associated with varying degrees of Ebstein malformation of the tricuspid valve, ventricular septal defect (VSD), right ventricular outflow tract obstruction [RVOTO, typically pulmonary stenosis (PS) or atresia], malposition of the cardiac apex, and conduction defects (more frequently complete heart block). The clinical presentation of CC-TGA is dependent on the cumulative effect of associated lesions on pulmonary blood flow. Indication for surgery is also determined by the nature and severity of the associated cardiac defects.[2–4]

## CONDUCTION TISSUE

As mentioned above, the most frequent form of "double discordance" occurs with *situs solitus* and L-loop of the ventricles. The course of the AV conduction tissue therefore differs from that in the normal heart with ventricular D-loop. Although the sinus node is normally located at the superior atriocaval junction, the AV conduction tissue is grossly abnormal. Because of its malalignment with the ventricular septum, the node fails to give rise to a penetrating bundle.[5–8]

In the normal heart, the bundle of His runs in an inferoposterior position with respect to the membranous septum; in SLL CC-TGA, however, the bundle of His is located in an anterosuperior position and has a much longer course than normal. Such a condition poses the risk that the subject with CC-TGA will go on to develop complete AV block, either spontaneously or postoperatively. On the other hand, when CC-TGA presents with *situs inversus* (I,D,D segmental anatomy), the normal anatomic position of the RV (D-loop) allows the bundle of His to follow a normal course. Anderson and coworkers in 1973 first clarified the distribution of the conduction tissue is this anomaly (Fig. 75-3).[8–10]

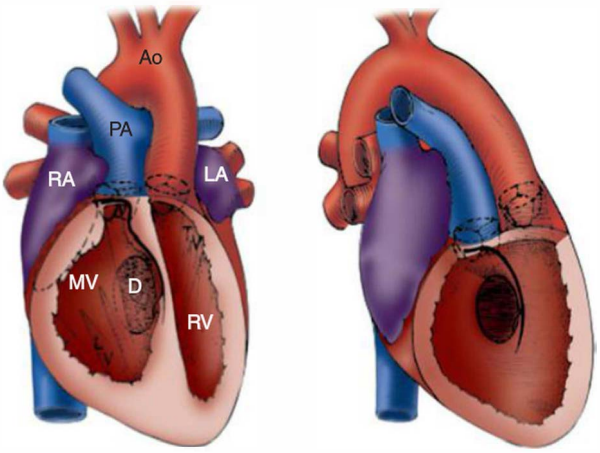

**FIGURE 75-3** Conduction tissue in congenitally corrected transposition with *situs solitus*. The bundle of His courses in a superoinferior trajectory along the leftward margin of the VSD. Ao, aorta; D, ventricular septal defect; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; TV, tricuspid valve; conduction system in black.

## DIAGNOSIS AND CLINICAL PRESENTATION

When CC-TGA is isolated (without associated cardiac defects) it can remain totally asymptomatic for life, and the diagnosis is often incidental. The electrocardiogram (ECG) is typical for the absence of a QRS transition complex in the precordial leads. The chest x-ray shows a midline cardiac position in the frontal view, with a linear left upper cardiac border due to the levoposition of the aorta.

The subxiphoid and apical four-chamber echocardiographic views allow identification of the sequential anatomy and visualization of associated ventricular perimembranous defects, valvar and subvalvar pulmonary obstruction, and TV morphology and function.

Cardiac catheterization and angiography and/or cardiac magnetic resonance complete the functional and structural assessment. The clinical presentation depends on the associated defects and pathophysiologic patterns.

In forms associated with a nonrestrictive VSD, pulmonary overcirculation with left-to-right shunting is observed, with elevated pulmonary blood flow (PBF) and various degrees of pulmonary hypertension. In such cases, the infant may present with active precordium, tachypnea, failure to thrive, and recurrent pulmonary infections.

When the VSD is associated with valvular and/or subvalvular PS, progressive cyanosis secondary to right-to-left shunting is seen.

## NATURAL HISTORY

In the isolated form, symptoms may be absent until the sixth or seventh decade of life, and the individual may have a near normal life expectancy. Onset of complete AV block

or systemic AV valve incompetence with congestive heart failure is fairly frequent. However, in atrial *situs inversus*, because of the considerably higher prevalence of a normally positioned AV node, there is less likelihood of the spontaneous development complete heart block. When heart block develops, pacemaker implantation is of course necessary.

## SURGICAL TREATMENT

The surgical history of patient with double discordance can start either with palliative procedures and continue with intracardiac repair or begin with primary complete surgical correction.

### Palliative Procedures

Depending on the initial anatomy (RVOTO, VSD, etc), and on the clinical presentation, many patients first undergo an initial palliative operation such as a systemic to pulmonary shunt, PA band, or even stage I Norwood. If they are not slated for single-ventricle pathway, they receive an anatomic or physiologic intracardiac repair after one or more surgical palliative operations (see below). Correct timing of surgery in such patients is another determining factor of early and late outcome, with the goal of preserving biventricular systolic and diastolic function. If any surgical palliation should be needed before repair, it should aim at obtaining a $Q_p/Q_s$ of approximately 1:1.[11]

In general terms, two major categories can be identified according to the pattern of PBF: (1) those with restrictive PBF and (2) those with unrestricted PBF. Patients with restrictive PBF, depending on the severity of PS, might require surgical palliation at different ages. A systemic-to-PA shunt should be preferred in patients younger than 4 to 6 months. In older patients, a bidirectional superior cavopulmonary anastomosis (Glenn shunt, see Chapter 62) should be the palliation of choice, allowing growth and protection of the pulmonary vascular bed. A bidirectional cavopulmonary anastomosis brings the advantage of dramatically reducing the volume load of the RV to normal values and diverting desaturated blood directly to the lungs, thus increasing effective pulmonary blood flow. Patients with unrestricted PBF have a rather usual clinical presentation, with congestive heart failure during the first months of life and failure to thrive: These are babies with a $Q_p/Q_s$ often greater than 2:1. This represents a significant volume overload, which, in the long run, may impair ventricular function. All these findings indicate the need for surgical intervention early in life. If the great arteries do not show severe discrepancy in size (aorta not too small compared with PA) PA banding (PAB) may represent a good surgical option.

### Intracardiac Repairs

Biventricular repair of CC-TGA is possible, but complete physiologic or anatomic connections are complex and associated with significant long-term problems, such as arrhythmias, subaortic obstruction, valvular dysfunction, obstruction of the ventricular-to-PA conduit, and deteriorating ventricular function. Recent advances have supported a variety of surgical strategies, with outcomes heavily correlated to the experience of the surgeon and institution in which the child is cared for.

### Physiologic Biventricular Repair

Intracardiac repair of VSD in CC-TGA has presented technical problems and has been associated with a high operative risk. Progressive definition of the relative merits of the different approaches to the VSD, the use of conduits in establishing unobstructed flow between the subpulmonary ventricle and the PA, and better knowledge of the anatomic relations of the conduction system to the VSD and pulmonary outflow tract have provided a more favorable basis for physiologic repair of this malformation.

#### VENTRICULAR SEPTAL DEFECT

The approach for VSD closure can be through the right-sided mitral valve, through the aorta, or through the left-sided TV. Exposure of the VSD through a right atriotomy can also be enhanced by partially detaching the leaflet of the right AV valve. In patients in whom replacement of the right AV valve is required, the valve can be excised before VSD closure. If an initial atriotomy gives inadequate exposure, a ventriculotomy on the subpulmonary ventricle may be necessary to allow closure of the defect.

#### RIGHT VENTRICULAR OUTFLOW TRACT

As Anderson and colleagues[12] have indicated, in CC-TGA "as a consequence of malalignment of interatrial, interventricular, and conal septum, the pulmonary outflow tract is an obliquely oriented channel which is particularly prone to obstruction." RVOTO may be at valvular or subvalvular level.[9–15]

It is also to be recalled that in CC-TGA, the abnormal origin of the PA is just posterior to the right coronary artery: The pulmonary outflow tract is wedged deeply into the ventricular chamber between the AV valves. Pulmonary valvular stenosis in the absence of annular hypoplasia is managed by valvotomy. Relief of subvalvular or annular stenosis by direct resection of the conal septum is contraindicated because of the presence of specialized conduction tissue in this region. Patch enlargement of the pulmonary outflow tract is further contraindicated because of the overlying coronary artery. Thus an extracardiac conduit extending from the morphologic LV (pulmonary ventricle) to the PA seems to provide the most effective means for relief of isolated RVOTO.[16]

A particular technique has been developed in order to reduce the risk of heart block in attempting relief of PS in CC-TGA by means of a valved conduit. The VSD is closed

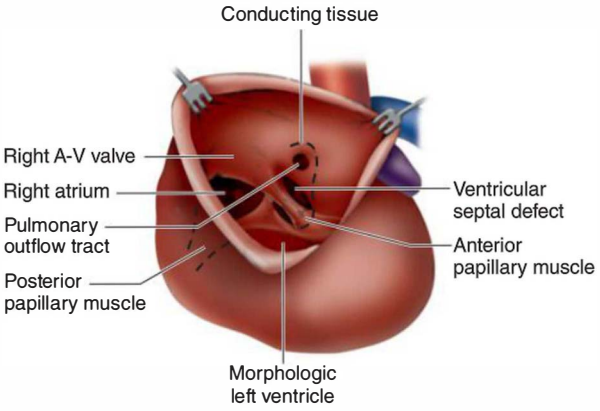

**FIGURE 75-4** Exposure of the VSD through a ventriculotomy (oversized for graphic purposes) in the right-sided morphologic LV. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

with a large patch in such a way that both great arteries and the major conduction bundles lie to the left of the patch. This technique requires use of an extracardiac conduit to reconstruct the RVOT. The procedure is completed by dividing the pulmonary trunk and closing its proximal stump or by ligating it (Figs. 75-4, 75-5, and 75-6).

Despite knowledge of the anomalous location of the conduction system[9,13,16] in CC-TGA, the risk of heart block remains a major concern.[6,17–20] Nevertheless, physiologic repair by means of VSD closure and RVOT reconstruction in patients with CC-TGA/VSD/RVOTO can be recommended with greater optimism than earlier experience would justify.

AV valve malformation was first reported by Edwards.[21] Becu[2] and Allwork[13] have recently demonstrated the high frequency of associated left AV valve anomalies resembling Ebstein malformation (see Chapter 85) and suggest that the morphologic TV is anatomically abnormal in the majority of cases but functionally deficient in only about one-third.[12] Depending on the anatomy encountered, incompetence of one or both AV valves can be managed by valvuloplasty, annuloplasty, or, most frequently, valve replacement.

## Anatomic Biventricular Repair

In patients with AV and ventriculoarterial discordance and following physiologic repair, the morphologic RV and TV may progressively deteriorate while functioning in the systemic circuit. Both the RV and the TV are not designed to be on the systemic side of the circulation. The RV has only one coronary as opposed to the two for a LV. Contrary to the mitral valve, which has no attachments to the septum, the TV subvalvar apparatus is partially based on the septum (muscle of Lancisi and septal papillary muscle), therefore being more susceptible to shifts in the septum. Therefore, the strategy of placing the morphologic LV and mitral valve into the systemic circulation is a better physiological proposition, and can be achieved only by a *double-switch operation*, which has been proposed by Ilbawi and associates[22] and Marcelletti and colleagues.[23] It consists in switching both venous return and arterial outflow. The concept of a double switch was initially suggested for patients with CC-TGA, VSD, and PS and subsequently applied to CC-TGA without PS, with or without VSD.

In this setting, a Mustard or Senning intraatrial transposition of venous return is performed as usual for simple TGA. It is not uncommon for CC-TGA of the S,L,L and I,D,D types to have associated cardiac positioning abnormalities, such as mesocardia or apicocaval juxtaposition. In these cases the free wall of the systemic venous atrium is likely to be deficient, making the Mustard preferable to the Senning technique, because the Mustard entails pericardial patch reconstruction of the atrium.[24]

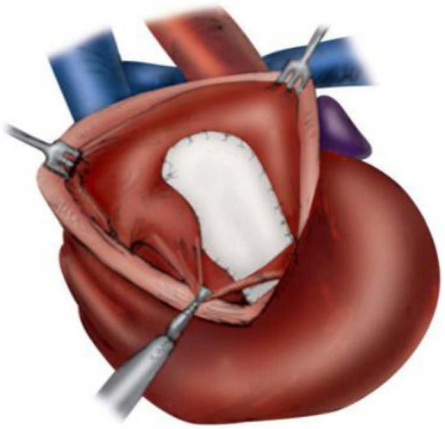

**FIGURE 75-5** The VSD is closed with a patch, then secured anteriorly and to the left away from the conduction system. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

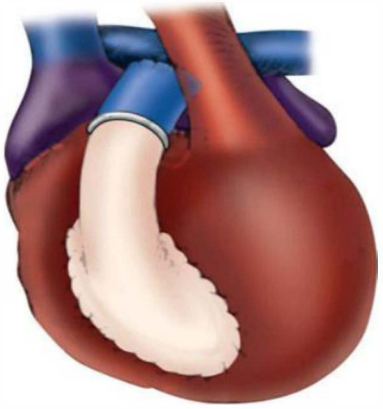

**FIGURE 75-6** A valved conduit is interposed between the subpulmonary ventricle and the pulmonary arterial confluence; the proximal PA stump is then over-sewn. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

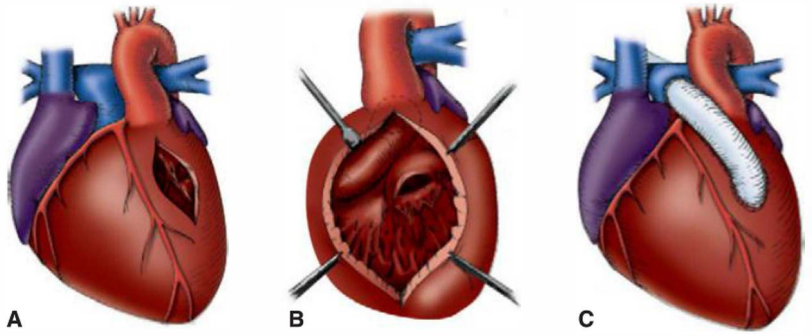

**FIGURE 75-7** Anatomic correction of congenitally corrected transposition with VSD. A subaortic ventriculotomy is made in t he morphologic RV (**A**). A baffle is created, channeling blood from the subpulmonary morphologic RV (**B**). Continuity between morphologic RV and PA is established with a valved conduit (**C**). In cases without *situs inversus*, a Mustard intraatrial baffle is also placed to redirect venous return (not seen in the illustration). (From Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott–Raven, 2007. With permission.)

For patients with VSD and PS, a morphologic LV–to–aortic intracardiac baffle is accomplished through a subaortic incision in the infundibulum of the morphologic left-sided RV. Finally, a LV–to–pulmonary trunk conduit is placed (Rastelli operation, Fig. 75-7).[23]

A connection from the superior vena cava to the PA (Glenn anastomosis) may be associated with a double-switch procedure (in which the pulmonary ventricle is made anatomically and functionally smaller by the intracardiac baffle and ventriculotomy) so as to unload the systemic venous atrium and subpulmonary ventricle. With this approach, the superior limb of the atrial switch is eliminated, the atrial baffle is simplified, the number of atrial suture lines is diminished, and the aortic cross-clamp time is shortened. Furthermore, less sinus node dysfunction and atrial dysrhythmias can be expected.[27]

For patients without PS, a classic arterial switch operation is performed (see Chapter 74). If a VSD is present, it is closed as described previously. When these procedures are considered for patients without VSD, in whom the morphologic LV is working at low pressure, preparation of the LV for systemic workload can be done by progressively increasing afterload by means of a PA band (ventricular retraining).

When severely unbalanced ventricles exist and a biventricular repair is not reasonable, a single-ventricle repair is indicated. Also, in case of straddling AV valves or an uncommitted VSD, a single-ventricle approach is preferable to complex biventricular repair.[11] The Fontan principle is, even in the best of circumstances, a palliative one, although most biventricular repairs requiring a valved conduit are palliative as well. A biventricular repair has the advantage of maintaining normal physiology, thus leading to better exercise tolerance and fewer atrial arrhythmias. In physiologic terms, the incorporation of a ventricle in the pulmonary circulation allows lower central venous pressure and better adaptation to exercise. There are situations in which the short- and intermediate-term results after a complex biventricular repair have been suboptimal. In such cases, the application of the Fontan principle, even in the presence of two well-balanced ventricles, may improve results.

## Physiologic Versus Anatomic Repair: Controversies and Future Guidelines

There is currently a tendency to prefer the anatomic repair (double-switch procedure). The fact that anatomic repair was first described for CC-TGA with PS is not surprising since in that situation, the LV is exposed to systemic pressures all along, without deconditioning. Thus, LV retraining, one of the major issues for CC-TGA with intact ventricular septum and no PS, is not an issue. The principles of the correction are as follows: (1) rerouting of venous flows at the atrial level; (2) patch closure of the VSD through a right ventriculotomy, baffling the LV to the aorta; and (3) conduit interposition between the morphologic RV and the PA.

If the VSD is restrictive, it can be safely enlarged by extensive resection of the anterosuperior border because of the posteroinferior location of the His bundle in the presence of *situs inversus*. With this technique, the morphologic LV and the native mitral and aortic valves are recruited for systemic work, with intrinsic long-term advantages. It is, however, a complex procedure involving substantial use of prosthetic material. Recent experience suggests that, in the appropriate patient, this approach is superior to the physiologic repair.[25–27]

Physiologic repair of CC-TGA (leaving the morphologic RV in support of the systemic circulation) has been accomplished by different techniques of VSD closure combined with relief, or bypass, of associated RVOTO. Although TV anomalies resembling Ebstein anomaly are not prevalent in *situs inversus*, this approach is potentially frustrated by progressive RV failure and ensuing complete heart block. Accelerating tricuspid regurgitation (TR) is often seen after VSD closure. Thus, one could argue that a "good" Fontan operation may be a better choice than a physiologic repair.

The main theoretical advantage of anatomic correction (double switch or Senning–Rastelli) arises from its use of the LV as the systemic pumping chamber and of the mitral valve

as the systemic AV valve. Performance of an anatomic correction should be strongly considered for patients with TR before surgical intervention, Ebstein malformation of the TV, and RV dysfunction. Heart transplantation remains another option for this difficult patient population but is associated with the drawback of immune suppression. Systemic RV and TV dysfunction (especially if requiring valve replacement) predicts a poor prognosis for many of these patients.

## VENTRICULAR RETRAINING IN THE DECOMPENSATED LEFT VENTRICLE

Ventricular retraining of a decompensated LV is achieved using gradual main PA obstruction by banding. Often, several steps of tightening are necessary, as the LV will not tolerate a sudden jump to near-systemic pressures. Results in older children and adolescents have been disappointing, and typically, a patient should be less than 15 years old. The younger the patient, the better the outcome. Banding is performed under transesophageal echocardiographic guidance, while observing the septal position and measuring LV pressure directly with a needle. If TR has developed with still acceptable RV function, placing a PA band will often reverse the septal shift, thus allowing the septal papillary muscle of the TV to come closer to the other two with improvement in TR.[28] The time of when the LV is ready for taking on all systemic work after a double switch is another difficult clinical question. Typically, it takes at least 6 to 18 months. A catheterization is performed and at least two-thirds systemic pressure with good ventricular function is required. Ventricular wall thickness is also a critical factor, and can be seen on magnetic resonance imaging (MRI) (indexed LV mass to LV volume ratio above 1.5).[27] The largest experience to date is from Dr. Roger Mee's at the Cleveland Clinic.[29]

## THE ASYMPTOMATIC PATIENT WITH CC-TGA

Every so often, one is confronted with a young patient, usually less than 7 years old, with incidental discovery of CC-TGA, intact ventricular septum, and no more than mild TR. The TV may be slightly abnormal. This is a difficult decision-making situation. On one hand, it is impossible to predict who will develop symptoms, and there are reports of individuals who died at an old age with incidental discovery at autopsy of CC-TGA.[30] On the other, development of symptoms usually predicts severe changes, and places the patient in a much higher surgical risk category. Finally, passing the 10 to 15 year of age mark means that ventricular retraining will become much harder if not impossible. Our approach has been to not operate on asymptomatic young patients with no more than mild TR and a well-formed tricuspid valve. We recommend very close cardiology follow-up, and a complete review of the anatomy with MRI also at around age 7. Should the TR progress, even in the absence of symptoms, we recommend embarking on LV retraining and, eventually, the double-switch procedure especially if the TV is morphologically abnormal. This recommendation is bolstered by the fact that development of TR usually precedes RV dysfunction, which is very difficult to manage.[31]

## THE OLDER PATIENT WITH TRICUSPID REGURGITATION

A particular problem seen with more frequency is the case of an adult with recently diagnosed CC-TGA and severe TR in conjunction with RV (subaortic ventricle) dysfunction. Symptoms are exactly the same as those observed in an adult with severe mitral regurgitation and LV dysfunction. It is recommended to proceed to TV replacement early, prior to onset of significant RV dysfunction. Heart transplantation is a good option for end-stage cases. Patients with significant systemic ventricular dysfunction requiring TV replacement are at high operative risk.[31,32] TV repair is not recommended in those cases.

## CONCLUSION

In conclusion, the management of CC-TGA should proceed as follows:

1. Postponement of surgery until the patient becomes symptomatic. AV block remains a risk factor before, during and after surgery.
2. Anatomic repair is preferred. If the LV is under systemic pressure (presence of VSD and/or pulmonary outflow tract obstruction), then a double-switch procedure or an atrial switch with RV–PA conduit is preferred. Recently, aortic translocation with atrial switch has been successfully employed for this subset. If the LV is decompensated, then LV retraining is needed. LV retraining works best in prepuberal patients, and long-term outcomes, even after initial successful LV retraining and double-switch, have been mitigated in terms of late LV dysfunction.[33] Other palliative steps include systemic-to-PA shunt and bidirectional cavopulmonary anastomosis, depending on the age, anatomy, and hemodynamic status.
3. When one or more of the mentioned risk factors would make anatomic correction prohibitive, single-stage palliation should be considered as a preferred alternative to anatomic repair.

## CONGENITALLY CORRECTED TRANSPOSITION BOARD REVIEW QUESTIONS (CHAPTER 75)

1. Which of the following is not typically associated with CC-TGA?
   A. Ebstein anomaly
   B. VSD
   C. PS
   D. Supravalvar aortic stenosis
   E. Complete heart block

2. Which of the following is correct regarding conduction tissue in CC-TGA?
   A. The sinus node is abnormally positioned.
   B. The AV conduction tissue is grossly normal.
   C. The bundle of His is anterosuperior to the membranous septum.
   D. There is usually a much shorter course of the His bundle.
   E. In *situs inversus*, the bundle of His is remote from the membranous septum.

3. Which is not an appropriate palliative procedure for CC-TGA?
   A. Systemic–pulmonary shunt
   B. Stage I Norwood
   C. PA banding
   D. Balloon septostomy
   E. Bidirectional Glenn shunt

4. Which is correct regarding physiologic biventricular repair?
   A. A ventriculotomy in the subaortic ventricle may improve exposure of the VSD.
   B. Pulmonary valvular stenosis is managed by valvotomy in the absence of annular hypoplasia.
   C. Relief of subvalvular or annular stenosis is best addressed through direct resection of the conal septum.
   D. Patch enlargement of the pulmonary outflow tract should be routinely performed.
   E. The VSD is closed to place the great arteries and conduction system to the right of the patch.

5. Which of the following is not performed during an anatomic biventricular repair?
   A. An intraatrial switch
   B. An LV to aortic intracardiac baffle in the setting of VSD and PS
   C. A Rastelli procedure
   D. A Glenn anastomosis
   E. An extracardiac Fontan procedure

## ANSWERS

1. **Answer: D.** Ebstein anomaly, VSDs, RVOTO, and conduction defects are all associated with CC-TGA; supravalvar aortic stenosis is not.

2. **Answer: C.** The bundle of His typically is located anterosuperior to the membranous septum. The sinus node is normally positioned, but the AV conduction tissue is grossly abnormal due to its malalignment to the membranous septum. The His bundle has a much longer course than normal. In *situs inversus*, the bundle of His follows a normal course.

3. **Answer: D.** Intracardial mixing is not the underlying pathophysiologic problem in CC-TGA, and therefore balloon septostomy is not indicated. Palliative procedures for ccTGA focus on either increasing or limiting pulmonary blood flow, depending on the clinical setting.

4. **Answer: B.** Pulmonary valvular stenosis is managed by valvotomy in the absence of annular hypoplasia. Improved exposure of the VSD can be obtained by ventriculotomy in the subpulmonary ventricle, and the VSD is closed to place the great arteries and conduction system to the left of the patch. Direct resection of the conal septum is contraindicated to avoid damage to the conduction system. Patch enlargement of the pulmonary outflow tract is also contraindicated to avoid coronary artery injury.

5. **Answer: E.** During an anatomic biventricular repair, both atrial and ventricular procedures are required (double-switch operation). An intraatrial switch (Mustard or Senning procedure) is combined with either a classic arterial switch or an intraventricular baffle and Rastelli procedure. A Glenn anastomosis can be used to unload the systemic atrium and ventricle. An extracardiac Fontan procedure is not typically performed, as this is used for patients with single-ventricle physiology.

# 76 Hypoplastic Left Heart Syndrome

*Peter J. Gruber*
*Thomas L. Spray*

## KEY CONCEPTS

- Epidemiology
  - Hypoplastic left heart syndrome (HLHS) accounts for 5 percent of all congenital heart anomalies and is responsible for 25 percent of cardiac deaths in the first week of life. Its incidence is 1.8 in 10,000 live births, with 25 percent of cases showing associated noncardiac malformations and 5 percent associated with chromosomal abnormalities.
- Morphology
  - HLHS includes a wide spectrum of anatomic abnormalities with the common feature of hypoplasia of the left ventricle (LV) and the ascending aorta. At one end of the spectrum there may be some mild LV hypoplasia, mild aortic stenosis, and aortic coarctation. At the other end there is complete absence of the LV, aortic atresia, and aortic arch interruption.
- Pathophysiology
  - Systemic venous return is channeled via an interatrial communication to the right ventricle (RV) and, through the pulmonary artery (PA) and patent ductus arteriosus (PDA), to the systemic and pulmonary circulations. Balanced physiology ensues, with $Q_P$:$Q_S$ varying according to systemic and pulmonary vascular resistance (PVR) as well as with the unrestrictive nature of the atrial septal defect (ASD).
- Clinical features
  - As a result of ductal closure in the postnatal period, HLHS is uniformly fatal if not treated. Evidence of pulmonary overcirculation is evident on clinical examination once PVR diminishes in early post-natal life.
- Diagnosis
  - Prenatal echocardiography can be used to detect unbalanced ventricles as early as 20 weeks of gestational age. Postnatal echocardiography readily establishes the diagnosis and guides medical and surgical decision-making.
- Treatment
  - Prostaglandin $E_1$ ($PGE_1$) infusion is the cornerstone of early resuscitation, coupled with balloon atrial septostomy in case of a restrictive ASD. A three-stage single-ventricle palliation approach has been adopted by most centers. The first stage involves aortic arch reconstruction and establishment of a reliable source of pulmonary blood flow, and the second and third stages consist of sequential partitioning of the systemic and pulmonary circulations. Transplantation has been used as the initial approach or, more commonly, for those who fail palliative strategy. In high-risk neonates, initial palliation with a hybrid approach (stenting of coarctation and PA banding) should be considered.
- Outcomes
  - Operative survival of stage I Norwood palliation depends on several variables, including anatomic factors (diameter of ascending aorta, operative weight, restrictive ASD, associated anomalies), and nears 80 percent in several series. Operative mortality between 5 and 10 percent has been observed for second- and third-stage palliation. Long-term complications [ventricular failure, atrioventricular (AV) valve regurgitation, arrhythmias, and protein-losing enteropathy, among others] dictate late prognosis and the need for reintervention or transplantation.

## DEFINITION

Hypoplastic left heart syndrome (HLHS) is a challenging disease that includes a wide spectrum of anatomic abnormalities with the common feature of left ventricular (LV) hypoplasia and hypoplasia of the ascending aorta. At one end of the spectrum there may be mild (LV) hypoplasia, mild aortic stenosis, and aortic coarctation. At the other end of the spectrum, there may be complete absence of the LV, aortic atresia, or an association with interrupted arch. All these neonates present a serious challenge to congenital heart surgeons, cardiologists, anesthesiologists, critical care specialists, nurses, and families. HLHS is uniformly fatal in the absence of intervention. There is now little argument about the utility of staged operative repair in these children as a result of continued improvements in operative techniques and perioperative care.

## HISTORICAL HIGHLIGHTS

Therapy for HLHS has been one of the great successes in the treatment of congenital heart disease (CHD). Before the 1980s, HLHS was a uniformly lethal condition. Over the past 30 years, palliation of HLHS has become a standard operation in nearly all institutions. In 1952, Lev[1] first described maldevelopment of the left-sided cardiac structures in combination with a small ascending aorta and transverse arch. By 1958, Noonan and Nadas had further defined the syndrome to include a variety of cardiac malformations of left heart structures.[2] The first report of any attempt to palliate a patient with mitral atresia was in 1961 by Redo and associates, who performed an atrial septectomy using inflow occlusion through a right thoracotomy; the patient died soon after the operation.[3] In 1968, Sinha and coworkers outlined management principles that remain in use today that include creation of an unobstructed atrial communication, unrestrictive systemic flow, and control of pulmonary blood flow.[4] Cayler and colleagues described an anastomosis between the right pulmonary artery (PA) and the ascending aorta with banding of both right and left PAs.[5] Interestingly, 40 years later, PA banding is being employed for selected children in whom medical conditions or anatomic substrates render them unsuitable for stage 1 Norwood reconstruction. This first-stage hybrid procedure involves stenting the ductus arteriosus and atrial septal defect, with placement of bilateral PA bands.[6,7] Litwin, Mohri, and others all performed unsuccessful operations that were variations of these principles, which nevertheless contributed to the development of the knowledge of the disease and its palliation.[8,9] In 1977, Doty and Knott described primary reconstruction that included atrial septation and a right atrium (RA)-to-PA Fontan circuit.[10] Again, though no patients survived, this experience confirmed that one-stage reconstruction would not be successful because of high neonatal pulmonary vascular resistance (PVR). Levitsky, Behrendt, and others described multiple, possible surgical procedures.[11,12] Although the procedures demonstrated no long-term success, they established the principle of staged reconstruction as first described for tricuspid atresia by Fontan and Kreutzer. This included a strategy of initial palliation followed by eventual separation of the systemic and pulmonary circulations.[13,14] However, it was William Norwood who provided the seminal contribution in 1980 and in 1983, with the first report of a successful staged approach.[15,16] The Norwood procedure remains the primary reconstructive approach to this day.

## EMBRYOLOGY AND ANATOMIC CONSIDERATIONS

From a molecular standpoint, the developmental mechanisms that underlie HLHS remain obscure, although steady progress continues.[17] Multiple genetic loci are associated with HLHS including the chromosomal abnormalities of trisomy 13 and 18, Turner (XO), and Jacobson (11q deletion) syndromes. Single gene defects with potential associations include GJA1,[18] NKX2-5,[19] NOTCH1,[20] and HAND1.[21] Furthermore, using a genome wide linkage approach, two loci (10q and 6q) have been associated with HLHS, suggesting that new technologies may provide important information.[22] Embryologically, there are additional clues. The severe hypoplasia of left heart structures is associated with, and likely a consequence of, limited flow during development secondary to a primary abnormality of either LV inflow or outflow. Primary defects of myocardial growth are unlikely to be a mechanism for this disease, since the myocardium appears normal.[23,24] In addition, in approximately 5 percent of patients with aortic atresia, an unrestrictive ventricular septal defect coexists and, in such cases, there is nearly always normal development of the LV and mitral valve.

Patients can be categorized on the basis of atrioventricular (AV) and semilunar valvular morphology into three primary subsets: (1) aortic atresia with mitral atresia (40 percent), (2) aortic stenosis with mitral stenosis (30 percent), and (3) aortic atresia with mitral stenosis (30 percent) (Fig. 76-1). Aortic stenosis with mitral atresia is rare. HLHS variants include a malaligned AV canal; double-outlet right ventricle (RV) with mitral atresia; tricuspid atresia with transposed great arteries, and a univentricular heart with aortic stenosis. There is frequently leftward and posterior deviation of the septal attachment of septum primum, but this is unlikely to be a common developmental mechanism, since it is seen commonly in other CHD patients. Usually, the superior and inferior venae cavae (SVC and IVC) are connected normally to the RA, although in about 15 percent of patients a left SVC draining to the coronary sinus is present. Other structural abnormalities of the heart are rare, with less than 5 percent of patients demonstrating valvular dysplasia. Also rare (less than 5 percent) is the association with abnormalities of pulmonary venous return or interruption of the aortic arch. Abnormalities in brain development have been reported

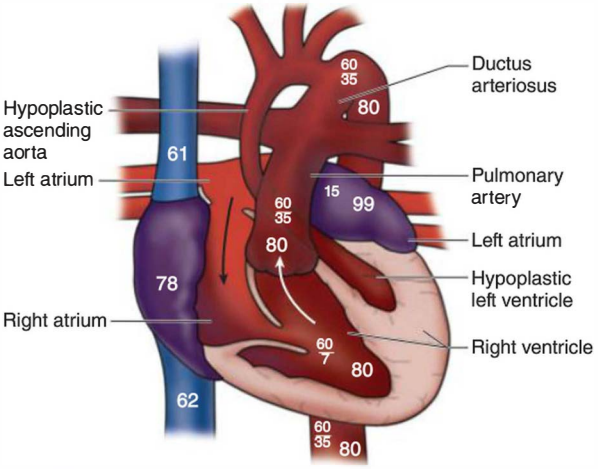

**FIGURE 76-1** Anatomy and physiology of hypoplastic left heart syndrome. Hypoplastic left-sided structures force pulmonary venous blood to flow from the left atrium through the interatrial communication to the right atrium (downward arrow). Blood from the right ventricle flows both to the pulmonary circulation via the pulmonary artery (upward arrow) and to the systemic circulation via the ductus arteriosus. Maintenance of ductal patency is critical for survival. The surgical principles of repair aim at maintaining this stable physiology. (Reprinted with permission from Gruber P, Spray T, et al. Hypoplastic left heart syndrome. In: Kaiser LK, Kron IL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2007:936.)

with increasing frequency in children with severe CHD, and may define a high-risk group for operative repair.[25] The pulmonary vascular tree also harbors abnormalities, with an increase in number and muscularity of vessels.[26,27]

## PATHOPHYSIOLOGY

A normal fetus has a parallel circulation that adequately supports single-ventricle physiology before birth. Three communications (the ductus venosus, foramen ovale, and ductus arteriosus) shunt oxygenated placental blood largely past the hepatic and pulmonary beds to supply the splanchnic circulation. HLHS is well supported in this situation and, as a result, it is rarely a cause of fetal demise. HLHS may be a secondary result of early obstructive lesions of either mitral or aortic valvular development, and this hypothesis has been supported in animal models of mitral or aortic stenosis with resulting LV hypoplasia.[24] However, the primary cause of the obstructive flow lesion that may secondarily lead to HLHS is unknown. Interestingly, there are no known genetic animal models that recapitulate HLHS despite the existence of a large number of mutations that affect valvular development. This argues for a complex early multifactorial event or a transient early insult.

## EPIDEMIOLOGY

HLHS is a uniformly fatal disease if untreated. It represents 5 percent of all cases of CHD and is responsible for nearly 25 percent of cardiac deaths in the first week of life. Among 10,000 live births, approximately 1.8 are born with HLHS, with a slight male predominance. Of these, 25 percent will also have a noncardiac anomaly, and 5 percent a chromosomal abnormality (most typically trisomy 13, 18, or 21). Syndromic lesions are rare but, among these patients, Turner syndrome (monosomy X) is the most common. The recurrence risk is 2.2 percent for one affected sibling and 6 percent for two affected siblings, suggesting a genetic predisposition but arguing against a simple effect.

## CLINICAL PRESENTATION

The presentation of infants with CHD has changed dramatically over the past 15 years. In most large centers, the majority of patients are identified through prenatal echocardiography; this early identification has not been correlated consistently with a better outcome. Although some tachypnea and mild cyanosis may be present, it is not until the ductus arteriosus begins to close that children with HLHS manifest evidence of impaired systemic perfusion with pallor, lethargy, and diminished femoral pulses. Cardiac examination reveals a dominant RV impulse, a single second heart sound, and often a nonspecific soft systolic murmur. Electrocardiographic examination reveals RA enlargement and RV hypertrophy. Chest x-ray occasionally shows mild cardiomegaly and increased pulmonary vascular markings.

## DIAGNOSIS

Physical examination of children with HLHS is usually normal. The examination is determined by the underlying anatomy as well as the chronicity of the disease (ductal closure and PVR). Poor perfusion, weak distal pulses that may not be present because of the size of the ductus, acidosis, and a sepsis-like picture may confound the diagnosis. In the absence of risk factors or laboratory findings consistent with sepsis, one should look for left-sided obstructive lesions.

There are no specific laboratory indicators of HLHS. These patients usually exhibit normal values. With ductal closure and malperfusion, end-organ compromise may be reflected by evidence of metabolic acidosis as well as altered hepatic and renal function tests.

At 20 weeks of gestation, a fetal echocardiogram has reasonable visualization of the cardiac structures. It is, however, neither feasible nor cost-effective to screen all pregnancies. Therefore, a selective approach is currently taken by which only mothers at high risk are screened. Ventricular size discrepancy is frequently the first hint of impending problems. Certainly, the presence of an intact or restrictive atrial septum should prompt term high-risk delivery in an institution

where an urgent postdelivery atrial septectomy or catheter-based septostomy and atrial stenting can be rapidly performed. The use of prenatal screening improves the prenatal condition of the child but may not translate into an improved outcome (at least in cases of transposition of the great arteries or HLHS).[28,29] After delivery, the infant should undergo two-dimensional and Doppler echocardiography to define anatomy to an extent sufficient for medical and surgical decision-making. It is important to distinguish HLHS from other diseases that may mimic certain of its features, as their management may differ substantially.

Chest radiography often demonstrates mild cardiomegaly and excessive pulmonary blood flow. A head ultrasound should be obtained in all patients to rule out intracranial hemorrhage and minimize the risks of heparinization. Patients with medical necrotizing enterocolitis should have a course of intravenous antibiotics before first-stage palliation.

## MEDICAL THERAPY

Regardless of the anatomic subtype, preoperative stabilization is critical to the ultimate outcome of patients with HLHS. Nearly all patients with suspected HLHS are transported on prostaglandin E1 ($PGE_1$) at a dose of 0.01 to 0.025 μg/kg/min. Two clinically dose-dependent side effects of $PGE_1$ are hypotension and apnea, though they are infrequently clinically significant. Umbilical arterial and umbilical venous lines are used for monitoring and central access in most patients. Most infants can ventilate with a natural airway and indeed will often have more favorable hemodynamics while extubated. Supplemental oxygen should generally be avoided, as it will act as a pulmonary vasodilator, decreasing PVR, increasing $Q_p$:$Q_s$, and thus decreasing systemic perfusion. Inotropic support is required in patients who have had a perinatal insult, but is otherwise rarely necessary. The goal of these maneuvers is to get the patient to the operating room as stable as possible.

## SURGICAL THERAPY

There are two primary therapies for HLHS: (1) staged reconstructive surgery leading to a modified Fontan–Kreutzer procedure and (2) heart transplantation. Heart transplantation is discussed in detail in Chapter 89; this chapter focuses on staged reconstructive surgery.

Over the past 25 years, the Norwood procedure has evolved to become the standard approach in nearly all institutions that care for neonates and infants HLHS. There are three primary goals of first-stage palliation: (1) establishment of unrestricted interatrial communication to provide complete mixing and avoidance of pulmonary venous hypertension, (2) establishment of reliable source of pulmonary blood flow, allowing for the development of pulmonary vasculature and for the minimization of the volume load on the single ventricle, and (3) provision of unobstructed outflow from the ventricle to the systemic circulation. Most institutions will offer surgical palliation to nearly all patients with HLHS, very low-birth-weight infants, and those with nonlethal genetic syndromes.

### Stage I Reconstructive Procedure

Two perfusion techniques can be used for first-stage palliation: deep hypothermic circulatory arrest (DHCA) and selective antegrade continuous cerebral perfusion. At present, there is no consensus on the superiority of one approach over the other.[30]

The child is brought to the operating room and ventilated on room air, with care taken to avoid hyperventilation. A full midline sternotomy is performed, and the thymus is removed in its entirety, with care being taken to avoid the phrenic nerves. The pericardium is opened and an obligatory mediastinal inspection is performed to confirm the echocardiographic findings and, in particular, to identify abnormalities of the aortic arch and coronary arteries. The ascending and descending aorta, head vessels, ductus arteriosus, and PAs are mobilized extensively with care taken to preserve the integrity of the recurrent laryngeal nerve. No attempt is made to dissect the systemic veins. Purse-string sutures are placed in the proximal main pulmonary artery (MPA) and generously around the RA appendage, through which heparin is administered. A previously thawed pulmonary homograft hemiartery patch is trimmed in an extended arrowhead shape and set aside.

After the activated clotting time reaches 300 seconds, the patient is cannulated, with the arterial cannula inserted at the base of the MPA and a single venous cannula inserted in the RA (Fig. 76-2). Cardiopulmonary bypass (CPB) is initiated, and snares are brought down around the branch PAs. The patient is cooled to 18°C over 15 min, during which time any remaining dissection is performed. A side-biting clamp is placed on the innominate artery, and a Gore-Tex graft (usually 4.0 mm patients over 3.2 kg) is anastomosed in an end-to-side fashion to the artery; this can be done either while cooling or before commencing cardiopulmonary bypass. The clamp is removed, and flow is assessed. If blood does not flow easily out of the open shunt, the anastomosis should be revised. A large hemoclip is placed to temporarily occlude the shunt. An alternative source of pulmonary blood flow is a 5.0-mm RV–PA shunt described initially by Norwood and repopularized by Sano. Some institutions have reported that this technique provides a smoother postoperative course and it has gained wide popularity.[31,32]

On initiation of circulatory arrest, snares are brought down around the brachiocephalic vessels, and a spoon clamp is placed on the descending aorta distal to the ductal insertion site. Cardioplegia is administered in a retrograde fashion through a side port on the arterial cannula. After the patient's blood volume has been drained into the reservoir, all cannulae and PA snares are removed. The ductus arteriosus is

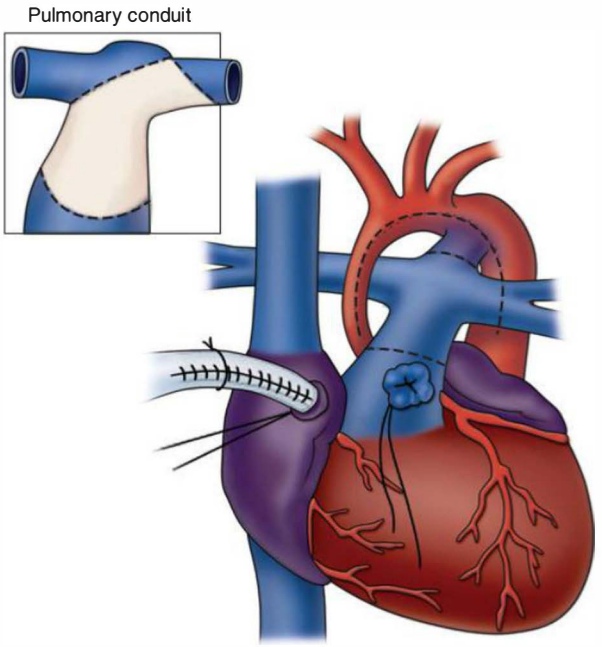

**FIGURE 76-2** Incisions for hypoplastic left heart syndrome first-stage palliation. Cannulation is performed with an arterial cannula in the base of the main pulmonary artery and a single venous cannula through a generous purse string around the right atrial appendage. Subsequent incisions, as described in the text, are indicated by the dotted lines. The patch for aortic augmentation and completion of the aortopulmonary anastomosis is fashioned from a pulmonary homograft (insert). (Reprinted with permission from Gruber P, Spray T, et al. Hypoplastic left heart syndrome. In: Kaiser LK, Kron IL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2007:938.)

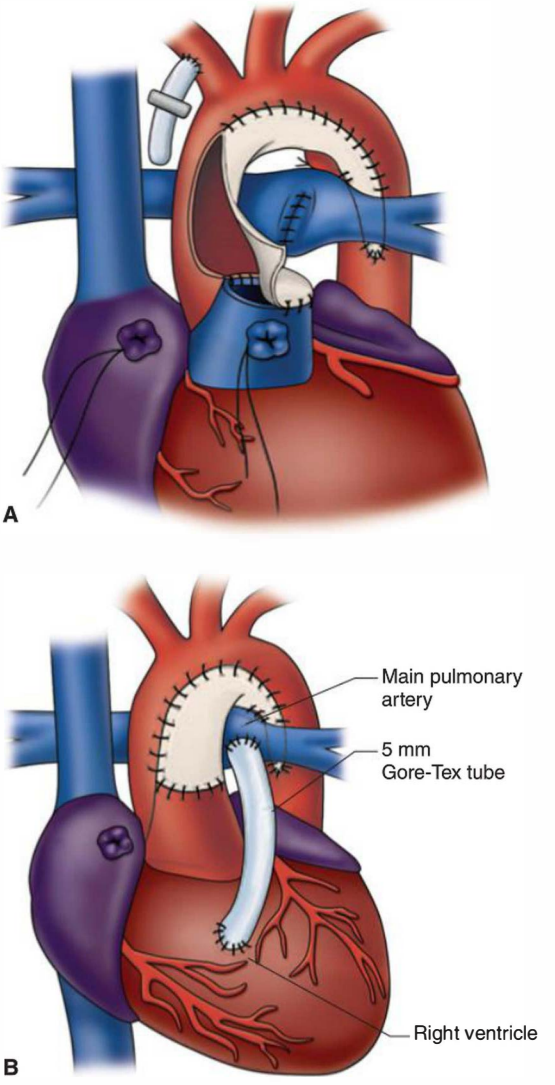

**FIGURE 76-3** Damus–Kaye–Stansel anastomosis (DKS) and aortic arch reconstruction. After complete excision of ductal tissue and an interrupted anastomosis of the medial aspects of the aorta and the main pulmonary artery, the homograft patch is used to augment the hypoplastic aortic arch and complete the DKS. The modified right Blalock–Taussig shunt is completed from the innominate artery to the right pulmonary artery (**A**). An alternative approach (Sano modification, **B**) substitutes a right ventricle–pulmonary artery Gore-Tex conduit for the Blalock–Taussig shunt. (Reprinted with permission from Gruber P, Spray T, et al. Hypoplastic left heart syndrome. In: Kaiser LK, Kron IL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2007:938–939.)

ligated on the PA side and divided on the aortic side. The atrial septum is excised completely, working through the atrial purse-string sutures. Though it is seldom necessary, visualization can be improved through a right atriotomy. Next, the main PA is divided close to the branch PAs, and the defect in the distal main PA segment is closed with an oval homograft patch or primarily, in a vertical fashion. At a point beginning immediately adjacent to the divided MPA the diminutive aorta is incised medially and the aortotomy is carried superiorly along the underside of the transverse arch through the ductal insertion site to a point approximately 1 cm distal. Importantly, all redundant ductal tissue is excised and the coarctation shelf is sometimes debrided (alternatively, the segment is excised and the isthmus and the dorsal portion of the proximal descending aorta are reanastomosed). The proximal aortic to proximal PA connection is performed using interrupted fine polypropylene sutures to connect the root of the great vessels. Next, the arch is reconstructed using the homograft patch, carrying this suture line down to complete the Damus–Kaye–Stansel (DKS) anastomosis proximally (Fig. 76-3). The distal Blalock–Taussig (BT) shunt anastomosis is performed to the origin of the right PA, although one can also do this during rewarming after removal of the aortic cross-clamp. The arch is infused with cold saline to assess the geometry and rule out kinking or residual obstruction. The atrium is infused with cold

saline to de-air, and the cannulae are repositioned. CPB is begun, and the patient is warmed to 37°C over 20 min. At this point, it is important to assess prompt and equivalent filling of the coronary distributions, and any perfusion defect should be addressed immediately with revision of the aortopulmonary anastomosis. During warming, obvious bleeding should be controlled.

As noted above, in an increasing number of institutions, the RV–PA shunt (Sano modification) is used as a source of pulmonary blood flow. Numerous modifications have been employed, although the learning curve is not as steep as with the classic Norwood procedure using the right-modified BT (mBT) shunt. These refinements include shunt size and structure (e.g., ringed vs non-ringed), PA and ventricular shunt anastomotic techniques (e.g., patch augmentation, bevel size and suture technique), and shunt location (routed to the right or left side of the aorta). Operatively, the other two principal components (atrial septectomy and arch reconstruction) of stage I palliation are identical. The RV–PA conduit is constructed from a 5.0-mm-ringed Gore-Tex graft. The distal end is either sewn directly to the PA at the distal, divided insertion site of the MPA, or sewn into an oval homograft patch. This patch is then used to augment the PA. The RV is then inspected to determine the site of ventriculotomy. The proper site is usually obvious but may entail insertion of a right-angled clamp through the pulmonary valve to aid identification. The anastomosis of the proximal end of the shunt is performed with the heart arrested. There are a variety of techniques that can be employed for the proximal anastomosis, including various bevels, patch augmentation (as with the distal anastomosis), or insertion of the proximal end of the shunt below the epicardial surface into the ventricular cavity. In all cases, the goal is to prevent the occurrence of RV–PA shunt obstruction requiring intervention that is more common with this technique.

A third staged palliative strategy gaining popularity in many centers for a variety of indications is the hybrid procedure.[6,33] Here, the physiological principles are inviolate (unrestricted systemic blood flow, a reliable and measured source of pulmonary blood flow, and an unrestrictive interatrial communication). However, in contrast to the Norwood procedure, the hybrid technique does not require cardiac arrest in the neonatal period. The following strategy is utilized: First, unrestricted atrial communication is achieved by atrial septostomy usually supported by an intraatrial stent. Second, systemic outflow is achieved by ductal stenting. Third, pulmonary blood flow is controlled by placement of bilateral PA bands. There are cogent arguments for why one might want to either perform or delay the large, definitive operation that entails arch reconstruction. However, there are no existing data to definitively support either strategy. Regardless, the hybrid strategy, with a comprehensive stage II palliation (that includes DKS and arch reconstruction along with all the components of the classic stage II cavopulmonary anastomosis) can be performed safely and provides another alternative in cases where stage I might be deemed high risk. One drawback unique to this procedure is the relatively common occurrence of reverse coarctation that occurs in approximately 25 percent of patients.[34] The distal end of the ductal stent can obstruct the more proximal aorta (retrograde aortic arch obstruction, RAAO) potentially limiting coronary and brachiocephalic blood flow, especially in cases of aortic atresia. A number of temporizing solutions to reverse coarctation have been advocated including reverse stenting of the aortic isthmus through the ductal stent as well as reverse BT or central shunts. Future studies will be required to delineate and customize each palliative approach to a particular patient, as it is unlikely that a single strategy will suit all.[35]

Regardless of surgical modification, the average duration of hospitalization is 7 to 21 days, with the limiting factor often being the establishment of adequate oral intake.

## Stage II Procedure

Two important observations by Norwood and colleagues early in the reconstructive experience prompted the institution of an intermediate stage between the initial palliation and the completion of a total cavopulmonary connection. The first observation was that there was time-related interstage mortality; the second was that the chronic volume load of a systemic-to-pulmonary shunt could create diastolic ventricular dysfunction. Thus, an intermediate stage was initiated as either a bidirectional cavopulmonary anastomosis (Glenn shunt) or a hemi-Fontan procedure. A bidirectional cavopulmonary anastomosis sets the patient up for an extracardiac conduit, whereas a hemi-Fontan procedure sets the patient up for a lateral tunnel completion Fontan. No long-term data prove the superiority of one approach over the other. In general, at approximately 4 to 6 months of age, stage I survivors are catheterized to evaluate both pressures throughout the heart and the anatomy of the PAs. The use of a cavopulmonary anastomosis before 3 months of age is usually associated with increased hypoxia and upper-body venous congestion. The technique for a bidirectional cavopulmonary anastomosis is fairly standard (Fig. 76-4A). The approach is through a reoperative median sternotomy, during which care is taken in regard to the dissection of the neoaorta, which is often adherent to the left side of the sternum and somewhat fragile. The patient is cannulated in a standard fashion with an arterial cannula in the neoaorta, a small-angled venous cannula in the SVC, and a straight cannula in the body of the RA. Although it is possible to perform this procedure without CPB, the authors find it considerably easier to use CPB and believe that the anatomic result is improved. Extracorporeal circulation is begun, and a snare is brought down around the SVC cannula after ligation and division of the azygous vein. The previous shunt is divided and ligated near the innominate artery. A vascular clamp is placed at the SVC–RA junction, and the SVC is divided with great care in not injuring the sinus node. The atrial portion is closed in two layers with fine monofilament sutures. The PA is opened at the superior

portion and inspected carefully. If preoperative catheterization revealed PA stenosis, this is addressed with pulmonary homograft patch augmentation. The SVC is then anastomosed to the superior aspect of the right PA as medially as possible toward the left PA. The snare is removed from the SVC cannula, and one or two RA lines are brought into the mediastinum percutaneously from the right and inserted in the body of the RA. The patient is weaned from CPB, and the SVC cannula is removed. Modified ultrafiltration is performed during which all suture lines are checked for hemostasis. At the completion of modified ultrafiltration, the SVC pressure can be measured directly. In general, these patients can be extubated soon after their return to the intensive care unit (ICU).

An alternative operative approach is the hemi-Fontan procedure, which the authors perform under DHCA. The details of this procedure are summarized in Figure 76-4B. The hemi-Fontan is usually performed under DHCA, using a piece of folded homograft to augment the PAs and create the superior cavopulmonary anastomosis and the RA–PA dam simultaneously. This dam subsequently will be removed for the lateral tunnel, completion Fontan operation.

For patients who have undergone a first-stage hybrid procedure, stage II palliation is considerably more complex. Here the following components must be achieved: removal of the atrial stent and septectomy, completion of the DKS anastomosis, stent removal from the duct and aorta that must be reconstructed, and removal of the PA bands with patch pulmonary arterioplasty, if needed.

## Stage III Procedure

Between ages 2 and 5, usually on the basis of a combination of the patient's weight, growth characteristics, and arterial saturations, the patient is reimaged by echocardiography and, occasionally, with cardiac catheterization or magnetic resonance imaging (MRI). If there are no anatomic issues to be addressed with catheter-based intervention (e.g., distal arch coarctation), the patient is referred for Fontan completion via an extracardiac conduit or a lateral tunnel Fontan. For the extracardiac conduit, DHCA or continuous mild–moderate hypothermic bypass with or without aortic cross-clamping is employed, whereas DHCA is used for the lateral tunnel. The approach is through a reoperative median sternotomy. The following paragraph describes the basic steps of the extracardiac Fontan.

The patient is bicavally cannulated in a standard fashion, and an arterial cannula is placed high in the aortic reconstruction. CPB is begun, and tourniquets are applied around the caval cannulae. A vascular clamp is placed at the IVC-RA junction, and the IVC is divided. The atrial portion is closed partially in two layers with fine monofilament sutures. The conduit (18–22-mm Gore-Tex) is trimmed to the appropriate length to avoid compression of the right pulmonary vein (which typically is shorter than one might expect), and a 4-mm fenestration is punched in the medial aspect near the IVC portion. The IVC-conduit anastomosis is completed with monofilament sutures, followed by a side-to-side anastomosis of the remaining cardiac portion of the IVC opening

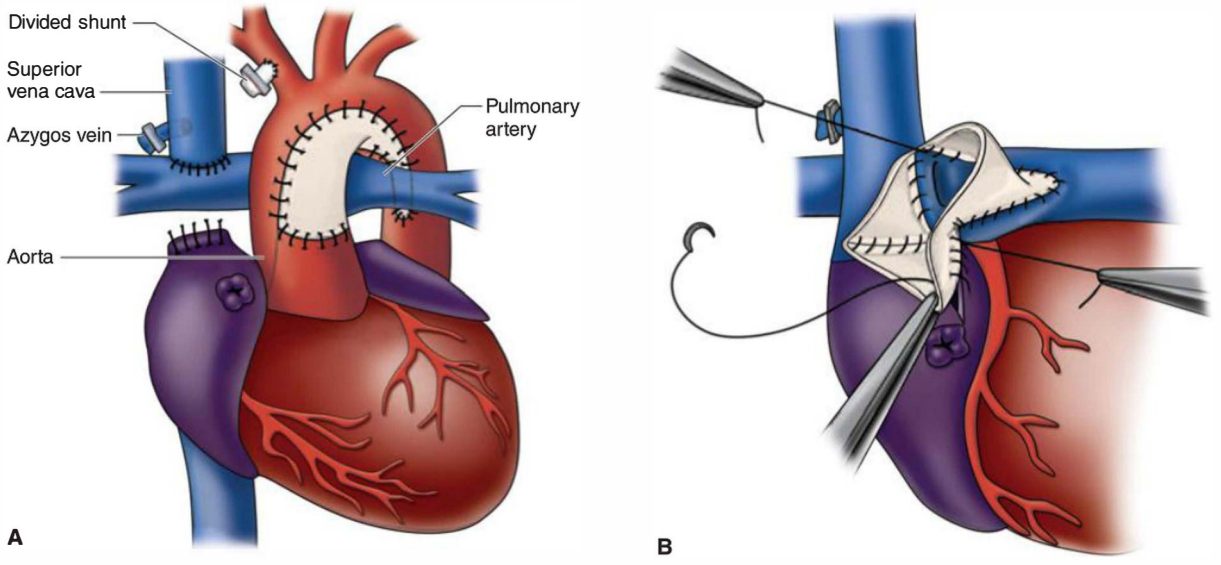

**FIGURE 76-4** Superior cavopulmonary anastomosis. **A.** The bidirectional Glenn replaces the source of obligatory pulmonary blood flow from the Blalock–Taussig shunt to the superior vena cava. **B.** The hemi-Fontan results in precisely the same physiology but uses a single piece of homograft to augment the pulmonary arteries, complete the superior cavopulmonary anastomosis, and create the right atrium–pulmonary artery dam simultaneously. (Reprinted with permission from Gruber P, Spray T, et al. Hypoplastic left heart syndrome. In: Kaiser LK, Kron IL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2007:940–941.)

with the conduit, leaving a rim of conduit around the fenestration. Next, the PAs are opened in the inferior portion and inspected directly. If preoperative studies revealed any PA stenosis and the beveled end of the Gore-Tex conduit would not span the area of stenosis, this situation is addressed with pulmonary homograft patch augmentation. The conduit is then anastomosed to the inferior aspect of the PAs, angled slightly medially toward the SVC. The angled nature of the superior portion of the conduit effectively augments the pulmonary confluence from the right to the left PA (Fig. 76-5A). The conduit is infused with saline to de-air, and the patient is weaned from CPB. The SVC cannula is removed, and a period of modified ultrafiltration is begun. All suture lines are checked for hemostasis. At the completion of modified ultrafiltration, the SVC pressure is measured directly with a transthoracic line. An additional monitoring line is placed in the RA. All cannulas are removed, and protamine is administered. In general, these patients can be extubated soon after their return to the ICU.

An alternative operative approach is the lateral-tunnel Fontan, which the authors perform under DHCA. The technical details of this procedure are summarized in Figure 76-5B. The lateral tunnel Fontan is performed under DHCA, using a piece of fenestrated Gore-Tex patch to baffle blood from the IVC to the PAs. The previously constructed PA–RA homograft dam is excised. There are no long-term data suggesting the superiority of one technique over the extracardiac Fontan. Advantages of the extracardiac Fontan include the lack of an atrial suture line and the ability to perform the procedure at mild hypothermia without DHCA or aortic cross-clamping. On the other hand, the lateral tunnel Fontan results in a more reliable fenestration, is faster, and poses no risk of compression to the right superior pulmonary vein.

## OUTCOMES

Despite continued improvement in outcomes, patients with HLHS continue to present a formidable challenge. The authors' group reported the results of the 15-year Children's Hospital of Philadelphia (CHOP) experience with 840 patients undergoing stage I surgery for HLHS between 1984 and 1999. The 1-, 2-, 5-, 10-, and 15-year survivals for the entire cohort were 51, 43, 40, 39, and 39 percent, respectively. A later era of stage I palliation was associated with significantly improved survival, with 3-year survival for patients undergoing stage I reconstruction from 1995 to 1998 of 66 versus 28 percent for those undergoing surgery between 1984 and 1988.[36] More recent studies have shown further improvement and demonstrated that the variability in outcome may be influenced by anatomy. One retrospective study of risk factors for operative and 1-year mortality in 158 patients who underwent the Norwood procedure demonstrated that the diagnosis of HLHS is not a predictor of mortality. HLHS was present in 102 patients, and other forms of functional single ventricle with systemic outflow tract obstruction were observed in the remaining 56. Operative survival for the entire cohort was 77 percent (78 percent for patients with HLHS and 75 percent for patients with other diagnoses). Birth weight, associated cardiac anomalies, total support time, and the need for extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD) support were predictors of operative mortality. Survival to 1 year was 86 percent after successful first-stage palliation,

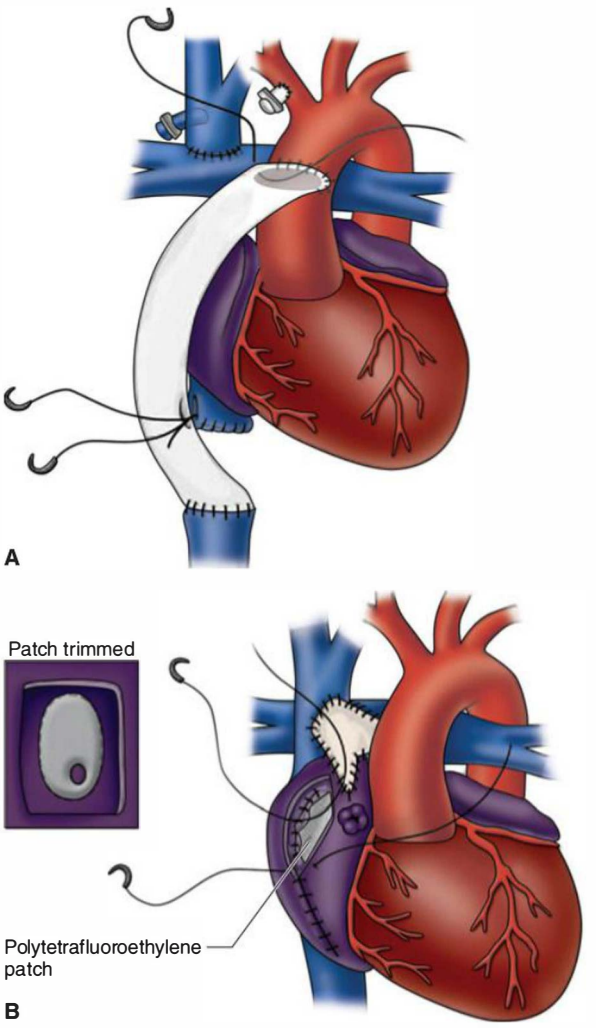

**FIGURE 76-5** Fontan completion. **A.** The extracardiac Fontan uses a Gore-Tex tube graft to channel IVC blood outside the heart to the pulmonary circuit. A 4-mm fenestration is fashioned between the remnant cardiac portion of the IVC and the side of the conduit. **B.** The lateral tunnel Fontan baffles blood from the IVC along the lateral aspect of the atrium inside the heart to the pulmonary circuit. The homograft dam created during the hemi-Fontan is excised to create continuity with the pulmonary arteries. Fenestration patency has proved more reliable in this procedure than in the extracardiac Fontan. (Reprinted with permission from Gruber P, Spray T, et al. Hypoplastic left heart syndrome. In: Kaiser LK, Kron IL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2007:943–944.)

although the presence of an extracardiac anomaly, a genetic syndrome, or an additional cardiac defect was predictive of worse survival in the first year of life.[37]

Additional perioperative or operative treatment strategies may improve morbidity and mortality rates. A consecutive series of 115 patients who underwent staged palliation from Milwaukee identified the risk factors for mortality and the impact of new treatment strategy. Between 1996 and 2001, hospital survival was 93 percent compared with 53 percent for the time interval between 1992 and 1996. Survival to stage II palliation was also significantly improved, increasing from 44 to 81 percent. Anti-inflammatory treatment strategies, continuous saturated venous oxygen ($Svo_2$) monitoring, and the use of phenoxybenzamine were factors favoring survival to stage II.[38]

Another approach has been the development of home surveillance programs. One study compared patients discharged before the initiation of home surveillance to those discharged with an infant scale and a pulse oximiter. The parents maintained a daily log of weight and arterial oxygen saturation and were instructed to contact their physicians in case arterial oxygen saturation less than 70 percent, an acute weight loss of more than 30 g/24 hours, or failure to gain at least 20 g during a 3-day period. Interstage mortality was 15.8 percent in the historic group and zero in the monitored group, suggesting that monitoring programs may provide significant benefit in reducing interstage attrition.[39]

As briefly mentioned above, recent reports advocate that an RV–PA conduit (rather than a mBT shunt) may improve the outcome after stage I reconstruction. However, further studies have indicated the need for caution before broad adoption of the RV–PA conduit.[40] The CHOP group compared the outcomes of all neonates who underwent stage I reconstruction between 2002 and 2004 with the use of the RV–PA shunt and mBT shunt. In all, 149 infants underwent a stage I reconstruction for HLHS or its variants. There was no difference in surgical mortality, time to extubation, or length of hospital stay between the two techniques. Although there were no differences in overall mortality, patients with an RV–PA conduit required more conduit-related reinterventions and returned earlier for stage II reconstruction.[41]

The most important individual study to address the value of shunt types is the single ventricle reconstruction (SVR) study. This prospective, randomized, multi-institutional NIH trial that has comprehensively compared the mBT shunt to the RV–PA conduit as sources of pulmonary blood flow in staged palliation for HLHS.[42] The initial report demonstrated that transplantation-free survival at 12 months was higher with the RV–PA conduit than with the mBT shunt (74 vs 64 percent, $P = 0.01$). However, the RV–PA shunt group had more unintended interventions and complications. After 12 months, available data showed nevertheless no significant difference in transplantation-free survival between the two groups. Ongoing a nalysis will determine if the early survival benefit of the RV–PA conduit approach will translate into a long-term survival advantage. For now, the authors feel these should be considered as important experiments in progress. In addition, there may be institution-specific factors for which these multi-institutional studies may not be able to answer.

Patients who have completed staged palliation for HLHS will frequently require reintervention. A study examining these reinterventions during a 6-year period between 1995 and 2001 found that 123 procedures were performed in 71 patients. The median time from Fontan completion to reoperation was 3.6 years, with indication for reintervention including arrhythmia, cyanosis, exercise intolerance, protein-losing enteropathy (PLE), atrioventricular valve (AVV) regurgitation, and other indications. The procedures included pacemaker insertion or revision (48 percent), inclusion of previously excluded hepatic veins (13 percent), revision to a lateral tunnel or extracardiac conduit pathway (11 percent), cardiac transplantation (7 percent), enlargement or creation of baffle fenestration (5 percent), isolated AVV repair or replacement (2 percent), and other procedures (14 percent). There were five early and five late deaths. Hospital mortality was greatest among patients undergoing cardiac transplantation (44 percent), who accounted for 80 percent of the early deaths. Most reinterventions can be performed with minimal morbidity and mortality. However, patients who require cardiac transplantation after a Fontan procedure fare poorly.[43]

For high-risk infants, some have advocated catheter-based hybrid approaches (stage I: ductal stenting and PA banding; stage II: septectomy, arch augmentation, and cavopulmonary anastomosis with or without pulmonary debanding and arterioplasty; stage III: catheter-based Fontan completion). One report of the hybrid stage I procedure in 14 high-risk neonates between 2003 and 2005 demonstrated promising results, with a 78.5-percent hospital survival rate. Eight patients underwent stage II procedures, with two operative deaths. These techniques may be limited in certain anatomic subsets, such as patients with aortic atresia in which preductal retrograde coarctation is a significant problem.[6]

The results from stage III palliation with Fontan circulation also continue to improve. The authors' group reviewed the outcomes of 332 patients: 281 with a lateral tunnel and 51 with an extracardiac Fontan procedure. There was a 93.4 percent hospital survival rate, and by questionnaire, 94.6 percent of guardians described their children's overall health as excellent or good and 5.4 percent reported it as fair or poor. School performance was described as above average in 30.2 percent, average in 39.9 percent, and below average in 29.8 percent. With regard to cardiac functional status, 34.2 percent responded that their children had no limitations to physical activity, 52.5 percent reported a slight limitation, 12.1 percent reported a significant limitation, and 1.2 percent reported a severe limitation. Although these data suggest that acceptable survival outcomes have been observed at intermediate follow-up of the Fontan operation and shed a positive light on the quality of life of this patient population.[44]

In comparing outcomes of extracardiac conduit and lateral tunnel Fontan connections, the results have been conflicting.

The Toronto group reported the results of 60 extracardiac conduit and 47 lateral tunnel total cavopulmonary connections performed between 1994 and 1998. Overall operative mortality was 5.6 percent and did not differ between groups. The lateral tunnel group had a significantly higher incidence of postoperative sinoatrial node dysfunction, supraventricular tachycardia, and need for temporary postoperative pacing. The median duration of ICU stay and the need for ventilatory support were longer in the lateral tunnel group. Holter analysis showed a higher incidence of atrial arrhythmias in the lateral tunnel group.[45]

However, other authors have not found support for one technique over the other. For example, the Charleston group found an incidence of sinus node dysfunction of 21 percent in the lateral tunnel group and 59 percent in the extracardiac group. No permanent pacemakers were placed in the lateral tunnel group, whereas three were placed in the extracardiac group.[46] Another report from the same unit demonstrated identical operative mortality and similar mean Fontan pressures, transpulmonary gradient, and common atrial pressure in the first 24 h after completion of the cavopulmonary connection. Duration of mechanical ventilation, ICU stay, chest tube drainage, and hospital stay did not differ. Again, extracardiac conduit patients had a higher incidence of sinus node dysfunction both in the postoperative period and at hospital discharge.[47] These techniques also appear equivalent in the situation of a failing Fontan, with no hospital deaths, no arrhythmias at hospital discharge, no differences in mean duration of intubation, inotropic support, ICU stay, hospital stay, or episodes of acute postoperative arrhythmias.[48]

## HYPOPLASTIC LEFT HEART SYNDROME BOARD REVIEW QUESTIONS (CHAPTER 76)

1. Which is the most common form of HLHS?
   A. Aortic stenosis with mitral stenosis
   B. Aortic atresia with mitral stenosis
   C. Aortic atresia with mitral atresia
   D. Aortic stenosis with mitral atresia
   E. Aortic atresia with interrupted aortic arch

2. Which is correct regarding epidemiology of HLHS?
   A. The syndrome is responsible for nearly 50 percent of cardiac deaths during the first week of life.
   B. There is a slight male predominance.
   C. Up to 20 percent will have a chromosomal abnormality.
   D. Williams syndrome is the most common associated syndrome lesion.
   E. Recurrence rate is less than 1 percent for one affected sibling.

3. Which is correct regarding stage I reconstruction for HLHS?
   A. DHCA is required for stage I techniques.
   B. The interatrial septum is carefully fenestrated to calibrate shunting.
   C. The aortotomy is carried under the arch just proximal to the ductus arteriosus.
   D. The proximal end of the Sano shunt is performed with the heart beating.
   E. The hybrid stage I repair is associated with reverse coarctation.

4. Which is correct regarding stage II reconstruction for HLHS?
   A. A Glenn shunt is preferred for patients eventually requiring a lateral tunnel operation.
   B. Use of a cavopulmonary anastomosis before 3 months of age is associated with increased hypoxia.
   C. The hemi-Fontan procedure sets the patient up for an extracardiac conduit.
   D. The SVC is anastomosed as far laterally as possible during the Glenn procedure.
   E. Partial bypass is required for the hemi-Fontan procedure.

5. Which is correct regarding outcomes after surgery for HLHS?
   A. Ten-year survival is 25 percent.
   B. Need for ECMO or VAD support prior to operation does not affect operative mortality.
   C. Home monitoring programs do not significantly reduce interstage attrition.
   D. Use of an RV–PA conduit may improve outcomes after stage I reconstruction.
   E. The most common reintervention is revision of a lateral tunnel or extracardiac conduit.

## ANSWERS

1. **Answer: C.** Aortic atresia with mitral atresia is the most common form, occurring in 40 percent of cases. Aortic stenosis with mitral stenosis and aortic atresia with mitral stenosis both have an incidence of about 30 percent. Aortic stenosis with mitral atresia and aortic atresia with interrupted aortic arch are both rare.

2. **Answer: B.** There is a slight male predominance. HLHS is responsible for nearly 25 percent of cardiac deaths during the first week of life. About 5 percent will have a chromosomal abnormality, with Turner syndrome being the most common. Recurrence rate is 2.2 percent for one affected sibling and 6 percent for two affected siblings.
3. **Answer: E.** The hybrid stage I repair requires stenting of the ductus arteriosus and can result in reverse coarcation by obstruction of the distal aortic arch. DHCA or antegrade cerebral perfusion are both suitable perfusion strategies for stage I techniques. The interatrial septum is completely excised. The aortotomy is carried past the ductus arteriosus to avoid recurrent coarctation. The proximal end of the Sano shunt is performed with the heart arrested.
4. **Answer: B.** Use of a cavopulmonary anastomosis before 3 months of age is associated with increased hypoxia and upper body congestion. A Glenn procedure (bidirectional cavopulmonary shunt) sets the patient up for eventual extracardiac conduit, whereas the hemi-Fontan procedure sets the patient up for eventual lateral tunnel completion Fontan. During the Glenn procedure, the SVC is anastomosed to the right PA as far medially as possible. DHCA is usually required to perform the hemi-Fontan operation.
5. **Answer: D.** The use of an RV–PA conduit may improve outcomes after stage I reconstruction compared to a traditional mBT shunt. Ten-year survival is about 40 percent. Need for ECMO or VAD support is a predictor of operative mortality. Home monitoring programs have provided significant benefit in reducing interstage attrition. The most common reintervention is pacemaker insertion or revision.

# Tricuspid Atresia and the Functionally Single Ventricle

*Carin A. van Doorn*
*Victor T. Tsang*
*Marc R. de Leval*

**KEY CONCEPTS**

- Epidemiology
  - Tricuspid atresia is the most common type of functionally single ventricle. Associated cardiac abnormalities are always present and may lead to obstruction of pulmonary or systemic outflow.
- Morphology and pathophysiology
  - The pulmonary and systemic circulations are in parallel. The degree of hypoxemia depends on pulmonary blood flow, which is determined by the associated cardiac abnormalities and the pulmonary vascular bed, both of which are subject to change over time.
- Diagnosis
  - Echocardiography provides detailed structural and functional information on the heart, particularly in infants. Cardiac catheterization, magnetic resonance imaging, and computed tomography may be necessary to gather additional information.
- Treatment
  - Without surgical treatment the majority of patients will die in infancy, either from severe cyanosis or, less commonly, congestive heart failure. The Fontan circulation is widely accepted as the definitive surgical palliation for patients with tricuspid atresia and other anomalies with functionally single ventricles. There are strict selection criteria for the Fontan operation. In particular, preserved ventricular and valvular function and an adequate pulmonary vascular bed are mandatory. Many patients require preliminary operations in infancy to balance pulmonary and systemic circulations. The surgical technique for the Fontan operation has evolved over time.
- Outcome
  - Operative mortality for suitable Fontan candidates in the current era is approximately 5 percent. Late attrition of the Fontan circulation is a serious clinical problem, and its mechanisms are poorly understood.

## INTRODUCTION

A wide variety of congenital cardiac lesions lack two well-developed ventricles; from a functional standpoint, they are characterized by a single ventricular chamber that supports both systemic and pulmonary circulations. It is well established that the definitive palliation for these univentricular hearts is the Fontan circulation, whereby the pulmonary and systemic blood flow are placed in series with the single ventricle connected to the systemic circulation. To achieve the Fontan state, many patients need preliminary procedures, either to reduce or to augment pulmonary blood flow.

## DEFINITIONS AND ANATOMIC CONSIDERATIONS

A truly morphologic univentricular heart is rare; more often there is an additional rudimentary chamber. The most common type of single ventricle is tricuspid atresia, with an incidence of 1 to 3 percent of all congenital heart lesions. In tricuspid atresia there is no direct communication between the right atrium and the right ventricle, and often a dimple or localized fibrous thickening is found at the expected site of the tricuspid valve. The right atrium is large and an interatrial communication is always present.

The right ventricle is hypoplastic and lacks an inflow portion, but its trabecular and outflow portions may be well developed. Tricuspid atresia is uniformly associated with other cardiac malformations. A ventricular septal defect (VSD) is usually present. The ventriculoarterial connection can be concordant or, less commonly, discordant (transposition of the great arteries); rarely, there is double-outlet right or left ventricle. Infundibular obstruction to pulmonary blood flow is often present, but this can also be observed at the level of the VSD (restrictive VSD) or the pulmonary valve, which may be atretic. In patients with transposition of the great arteries, there may be subaortic stenosis and/or coarctation. The associated cardiac malformations determine the balance between pulmonary and systemic blood flow. Other forms of univentricular hearts include left atrioventricular valve atresia, double-inlet right and left ventricle, hearts with a common atrioventricular valve and only one well-developed ventricle, hearts with heterotaxy syndrome and only one fully developed ventricle, and pulmonary atresia with an intact ventricular septum and hypoplastic right ventricle. In addition, some complex hearts with two well-formed ventricles cannot be septated and become candidates for a single-ventricle strategy as the only viable surgical option. Examples of the latter morphologic group are hearts with major straddling of the atrioventricular valves, or certain forms of double-outlet right ventricle, or transposition of the great arteries with remote VSD. Hypoplastic left heart syndrome, a common form of univentricular heart, is detailed in Chapter 76.

## HISTORICAL HIGHLIGHTS

With the advent of the Blalock–Taussig shunt in 1944,[1] palliation became possible for patients with single-ventricle physiology and cyanosis. Pulmonary artery banding was introduced in 1952 by Muller to alternatively reduce excessive pulmonary blood flow.[2] Following extensive laboratory work, Glenn showed that partial right heart bypass was possible in a patient with tricuspid atresia by anastomosing the superior vena cava (SVC) (or azygos vein) to the divided right pulmonary artery.[3] This procedure evolved to the bidirectional cavopulmonary shunt, in which the SVC is anastomosed end to side to the undivided pulmonary artery, thus shunting blood into both lungs.[4] In 1968, Fontan and Baudet performed the first total right heart bypass operation by establishing an atriopulmonary connection in a patient with tricuspid atresia.[5] The operation was based on the concept that the hypertrophied right atrium could replace the right ventricle as the driving force for the pulmonary circulation. In addition, separating the systemic and pulmonary circulations and placing them in series improved arterial oxygen saturation and reduced volume load on the single ventricle. Over the years, there have been several modifications of the Fontan procedure. It became apparent that the atrial "kick" was not essential to cardiac output, and the atriopulmonary connection has now been largely replaced by the more energy-efficient total cavopulmonary anastomosis.[6] In this palliative configuration, the SVC drains directly into the pulmonary artery and an intra-atrial tunnel or, more recently, an extracardiac conduit[7] is used to baffle the inferior vena cava (IVC) to the pulmonary artery. For patients with subaortic obstruction undergoing the Fontan procedure, Waldman described the concurrent use of a modified Damus–Kaye–Stansel procedure to achieve unobstructed systemic outflow.[8] Staging of Fontan palliation was introduced in an attempt to reduce the operative risk of the Fontan operation. Initial performance of a superior cavopulmonary shunt was followed at a later stage by completion of the total cavopulmonary connection.[9] Another modification in technique was the creation of a fenestration in the Fontan baffle to allow a right-to-left shunt to maintain systemic ventricular filling. This proved to be particularly important in patients with impaired pulmonary blood flow, albeit at the cost of variable degrees of cyanosis. The fenestration can be closed percutaneously.[10] Improved understanding of the Fontan physiology and evolution of the surgical techniques have extended the original indication of the Fontan operation from tricuspid atresia to many other forms of complex univentricular hearts.[11]

## PATHOPHYSIOLOGY

In tricuspid atresia, the systemic venous return crosses the interatrial communication to the left atrium, where it mixes with pulmonary venous blood. As a result, oxygen saturations in the ventricles, aorta, and pulmonary artery are virtually identical (Fig. 77-1). The presence of an unrestrictive atrial septal defect (ASD) is obligatory. Systemic arterial desaturation is always present but is worse when the pulmonary-to-systemic blood flow ratio is low (in case of associated pulmonary stenosis or restrictive VSD). In case of severe hypoxemia, metabolic acidosis will eventually develop. In tricuspid atresia with normally related great vessels, blood reaches the pulmonary artery indirectly through a VSD and hypoplastic right ventricle. Pulmonary blood flow may be unrestricted initially but usually diminishes over time due to restriction of the VSD or the development of infundibular stenosis. In tricuspid atresia with transposition of the great arteries, the left ventricle is connected directly to the pulmonary artery and, unless pulmonary stenosis is present, pulmonary blood flow is high and pulmonary vascular disease may develop. In this anatomic subgroup, the aorta receives blood indirectly via the VSD and the hypoplastic right ventricle. Progressive restriction of the VSD will produce the effect of developing subaortic stenosis. Similar issue may present after pulmonary artery banding. In patients with functionally single ventricles with other morphologic features, the pathophysiology will be determined by the balance between pulmonary and systemic blood flow, the effects of intracardiac mixing and streaming, and the presence of other cardiovascular pathology (such as abnormal pulmonary venous drainage or atrioventricular

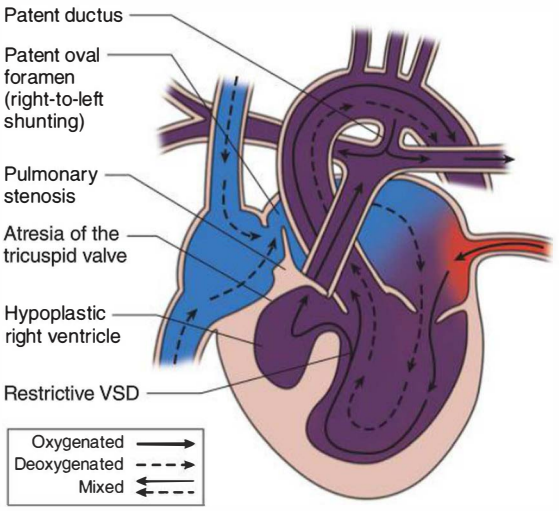

**FIGURE 77-1** Diagram illustrating the pathophysiology of tricuspid atresia. VSD, ventricular septal defect. (Reproduced with permission from Reitz BA, Yuh DD (eds). *Congenital Cardiac Surgery*. New York: McGraw-Hill, 2002:144. With permission.)

valve regurgitation). In most single-ventricle circulations, systemic ventricular dysfunction and failure can develop as the result of cyanosis and/or volume overload.

## NATURAL HISTORY

The natural history of single-ventricle circulations is predominantly related to the degree of pulmonary blood flow and any associated cardiac lesions. There may also be associated noncardiac abnormalities, which will have an independent impact on outcome. Early onset of cyanosis is a predictor of worst survival, leading to death in 90 percent of untreated cyanotic patients with tricuspid atresia in the first year of life.[12] Patients with unobstructed pulmonary blood flow also fare poorly, often dying in infancy from congestive heart failure or early onset of pulmonary vascular disease. This clinical course may be accelerated in the presence of left-sided obstruction, such a subaortic stenosis or coarctation. A small subset of patients has a balanced circulation with unobstructed systemic blood flow and adequate restriction to prevent pulmonary overcirculation. These patients have a more favorable prognosis, with a mean survival of 8 years.[13] Without surgical intervention, only 10 percent of infants will be alive by the age of 10 years.[14]

## CLINICAL PRESENTATION

The clinical features are determined by the degree of pulmonary blood flow and associated cardiac malformations (Fig. 77-2). Most patients with tricuspid atresia present with cyanosis in the first days of life. Some may have a duct-dependent pulmonary circulation and will become rapidly cyanotic as the ductus arteriosus closes after birth. In the majority of patients, cyanosis is progressive and due to increasing infundibular stenosis and/or restriction of the VSD. Hypoxic spells may occur and are characterized by cyanosis, dyspnea, and occasionally syncope. Clubbing may develop in older children. In a minority of patients, however, there is no obstruction to pulmonary blood flow, and these patients present with congestive heart failure from overcirculation. With falling pulmonary vascular resistance, symptoms will grow worse in the first weeks of life. In most univentricular hearts there is mixing of circulations, but streaming may occur, particularly in complex hearts, resulting in differential saturation in the great arteries.

## DIAGNOSTIC MODALITIES

Chest x-ray usually shows signs of low pulmonary blood flow, with reduced pulmonary vascular markings and diminutive hilar shadowing. In cases of high pulmonary blood flow (usually tricuspid atresia with discordant ventriculoarterial connection), there is pulmonary plethora and cardiomegaly. Electrocardiography in most patients will demonstrate left-axis deviation and, frequently, a tall (>2.5 mm) notched p-wave consistent with right atrial enlargement.

Echocardiography provides both detailed anatomic diagnosis and functional assessment. The echocardiogram will usually show a hyperechoic shelf at the expected site of the tricuspid valve, in association with reduced right ventricular dimensions. The following information is essential to allow proper surgical planning: size and course of the pulmonary arteries, relationship of the great vessels, degree of right ventricular outflow tract obstruction, size of the interatrial communication, size and position of the VSD, presence of patent ductus arteriosus, aortic coarctation or other structural cardiovascular abnormalities and, lastly, effectiveness of ventricular function. Particularly in infants (who typically have excellent echocardiographic windows), enough information can usually be acquired to proceed directly to operative intervention. Cardiac catheterization is not routinely performed but remains an important diagnostic adjunct if there is doubt about the size and distribution of the pulmonary arterial supply and a need for direct pressure measurements. In addition, catheter interventions can be performed to supplement or sometimes avert initial surgical intervention. Magnetic resonance imaging and computed tomography are being utilized with increasing frequency to investigate patients with congenital heart disease, allowing for three-dimensional reconstruction of the cardiovascular structures and noninvasive assessment of hemodynamic function. When available, magnetic resonance imaging should serve as the initial screening procedure for preFontan assessment (branch pulmonary artery size and flow, ventricular function, cardiac index, atrioventricular valve function, and residual outflow obstruction) prior to any further diagnostic or interventional catheterization.

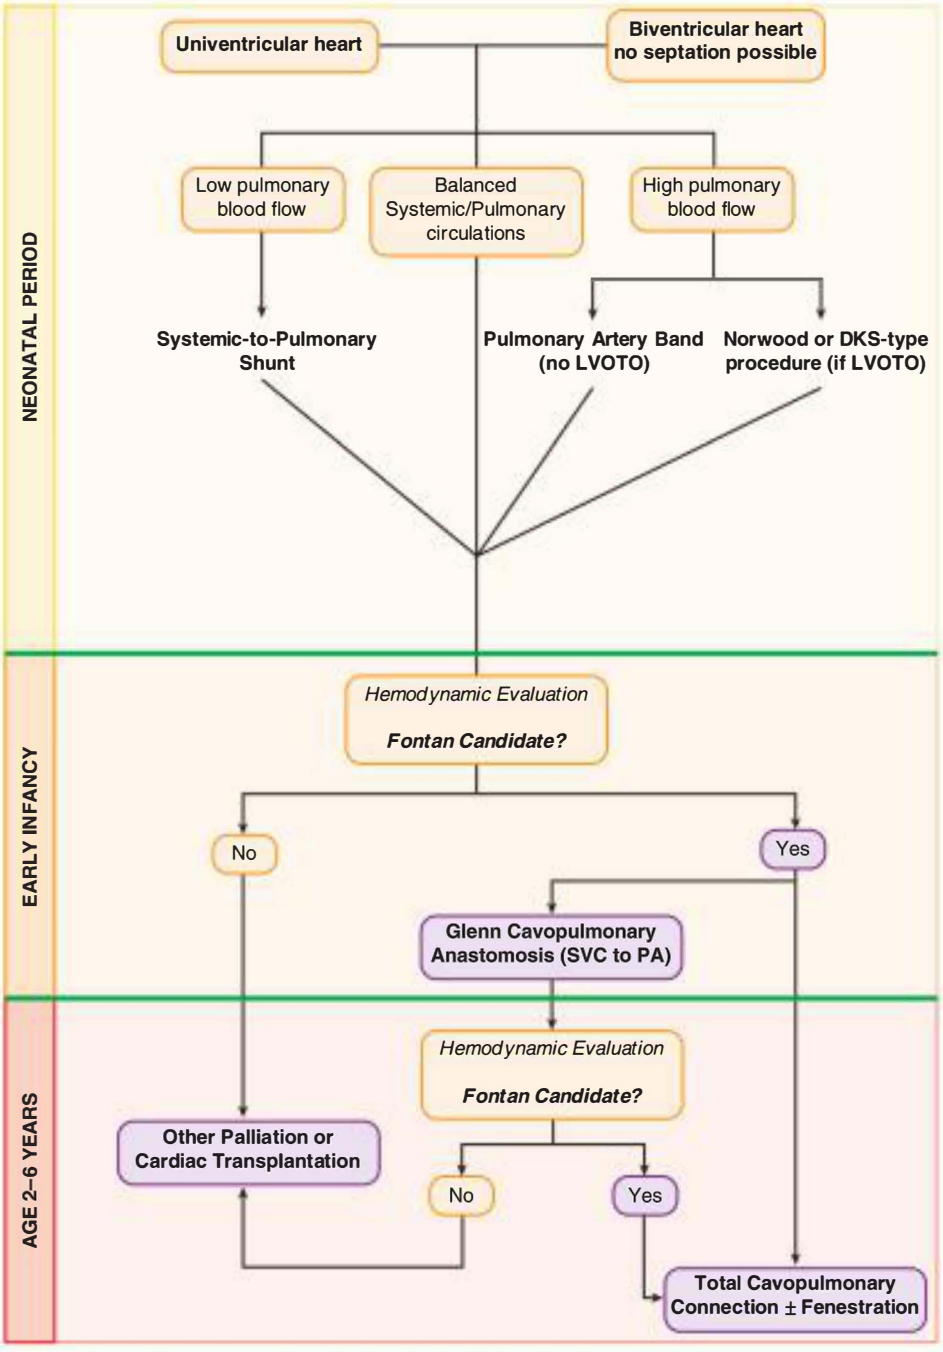

**FIGURE 77-2** Clinical decision-making flowchart for pediatric patients with functionally univentricular hearts.

## SELECTION CRITERIA FOR THE FONTAN PROCEDURE

The initial selection criteria for the procedure, described by Fontan and colleagues for patients with tricuspid atresia, were very strict and known as the "ten commandments" (Table 77-1).[15] With increasing experience, these criteria have been relaxed and, at the same time, the indication for the operation has been extended to many forms of complex single ventricle. However, owing to the unique physiology associated with the Fontan procedure, appropriate patient selection remains of paramount importance.

**TABLE 77-1: The "Ten Commandments" for Selection of Patients with Tricuspid Atresia for the Fontan Procedure**

1. Minimum age 4 years
2. Sinus rhythm
3. Normal caval drainage
4. Right atrium of normal volume
5. Mean pulmonary artery pressure ≤15 mm Hg
6. Pulmonary arterial resistance <4 U/m²
7. Ratio of pulmonary artery diameter to aorta diameter ≥0.75
8. Normal ventricular function (ejection fraction >0.6)
9. Competent left atrioventricular valve
10. No impairing effects of previous shunts

Data from Choussat A, Fontan F, Besse P, et al. Selection criteria for Fontan's procedure. In: Anderson RH, Shinebourne EA (eds). *Paediatric Cardiology.* Edinburgh: Churchill Livingstone, 1978:559–566. With permission.

The minimal age of patients undergoing the Fontan operation has been progressively lowered in an attempt to try to minimize the deleterious effects of long-standing cyanosis and volume overload. The optimal and minimal ages are not known, but successful Fontan operations have been performed in patients as young as 7 months who presented with increasing cyanosis and suitable hemodynamics.[16] It remains to be seen whether a very early Fontan operation has a better long-term outcome, particularly in patients with well-balanced circulations. Preoperative sinus rhythm, normal caval drainage, and normal right atrial volume are not absolute requirements, but unobstructed pulmonary venous drainage is obligatory. The pulmonary vasculature remains an important selection criterion for the Fontan procedure. Mean pulmonary arterial pressure (<15 mm Hg) and pulmonary arteriolar resistance (<4 U/m²) should be low and any pulmonary distortion related to previous shunts should be corrected. Adequate size of the pulmonary arteries is also important. There have been various attempts to standardize pulmonary artery measurements, such as the McGoon ratio[17,*] and the Nakata index,[18,†] but the usefulness of these indices has been questioned, as they do not account for the compliance of the pulmonary vascular bed and they have been established for a biventricular circulation. Adequate ventricular function is also crucial for a successful Fontan procedure. Ventricular impairment, however, is not always an absolute contraindication if it can be related to volume overload in the presence of an aortopulmonary shunt that will be taken down at the time of second-stage palliation. The same is true for mild or moderate atrioventricular valve regurgitation in the setting of a volume-loaded heart. More recently, ventricular hypertrophy has also been recognized as an important risk factor for Fontan failure.[19] Predisposing conditions for ventricular hypertrophy, such as subaortic obstruction or coarctation, should be corrected as soon as possible. In the absence of uniform selection criteria, most centers will use a combination of the above criteria and grade patients as being at low, intermediate, or high risk for the Fontan procedure.

*The McGoon ratio is obtained from the sum of the diameters of the immediately prebranching portions of the left and right pulmonary arteries divided by the diameter of the descending aorta just above the diaphragm.

†The Nakata index is derived from the sum of the diameters of the left and right pulmonary arteries (measured just before the origin of the upper-lobe branches) divided by the body-surface area.

## MEDICAL THERAPY

Medical therapy in the management of the functionally single ventricle is limited to supportive measures. Neonates with severe hypoxemia, in whom pulmonary blood flow is dependent on a patent ductus arteriosus, benefit from prostaglandin $E_1$ infusion until surgical intervention can be undertaken. The same strategy is utilized in patients with associated aortic coarctation and duct-dependent systemic circulation. In those with congestive heart failure, treatment with diuretics is indicated.

## SURGICAL THERAPY

### Preliminary Procedures in Preparation for the Fontan Circulation

The goals of preliminary surgical procedures leading up to the Fontan operation are as follows:

1. Improvement of clinical symptoms
2. Optimization of the pulmonary vascular bed and of ventricular performance
3. Provision of anatomic setup for the Fontan procedure

In the majority of patients with single-ventricle circulation, pulmonary blood flow is restricted; in some it is excessive, and very few have naturally balanced circulations. Within the first year of life, therefore, most patients will require palliative procedures (Chapter 62), either to increase pulmonary blood flow or restrict it. The choice of procedure is guided by the underlying anatomy and pulmonary vascular resistance, both of which are subject to change over time. For augmentation of pulmonary blood flow, a systemic-to-pulmonary artery shunt is usually placed. However, in the subset of patients with transposition of the great arteries with aortic coarctation, a Norwood-type procedure is the best option to relief the obstruction to systemic blood flow at the same time (see Chapter 76). In those with unrestricted pulmonary blood flow, banding of the main pulmonary artery can be used; however, patients with transposition of the great arteries who undergo this procedure need close postoperative monitoring because of the risk for development of subaortic stenosis. In these patients, a Norwood procedure may be considered. It should always be remembered that improper preliminary procedures can result in the loss of Fontan candidacy.

## Bidirectional Cavopulmonary Shunt

The connection from the SVC to the pulmonary artery (Fig. 77-3) can be performed (when no preliminary shunting or PA banding is needed) during the Fontan operation or as the first of two procedures of a staged total cavopulmonary connection. The advantages of a venous-to-pulmonary artery shunt over an arterial shunt are that the venous blood that enters the pulmonary artery is much more desaturated; therefore a higher take up of oxygen per milliliter of blood is possible. In addition, systemic venous blood is diverted to the lungs, thus reducing volume load on the single ventricle. There is no universal agreement on selection criteria for a cavopulmonary shunt, but it is generally accepted that these are less rigorous than those for the Fontan operation. It remains open to discussion whether any additional source of pulmonary blood flow (such as a patent ductus arteriosus, patent right ventricular outflow tract, or systemic-to-pulmonary artery shunt) should be taken down at the time of the cavopulmonary shunt. Any adverse anatomic features for the Fontan circulation should, if possible, be corrected at the time of operation (e.g., atrial septectomy, systemic AV-valve repair). The creation of a cavopulmonary shunt requires complete occlusion of the SVC during the anastomosis. To avoid dangerous levels of upper body venous hypertension, the operation is usually performed on cardiopulmonary bypass. This has the added advantage that the patient's oxygenation will not be compromised if any systemic-to-pulmonary artery shunts are taken down and that, in addition, other cardiac anomalies can be corrected during the operation. An alternative method to achieve decompression of the venous system is the use of a temporary cavoatrial shunt, thus avoiding the deleterious effects of cardiopulmonary bypass. This shunt can be inserted either between the SVC and right atrium or, if pulmonary blood flow is a concern, between the SVC and pulmonary artery. The hemi-Fontan modification of the cavopulmonary shunt involves patch augmentation of the central pulmonary arteries and an anastomosis between the superior cavoatrial junction and the pulmonary artery. This operation has been particularly popular in patients with hypoplastic left heart syndrome in whom, following first-stage Norwood palliation, pulmonary distortion and hypoplasia are common.[20] The hemi-Fontan operation is described in Chapter 76.

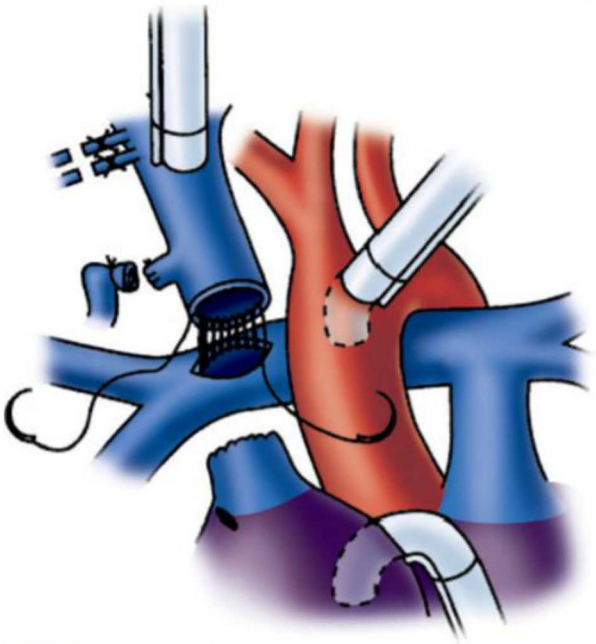

**FIGURE 77-3** Surgical technique for bidirectional cavopulmonary anastomosis (Glenn shunt). The superior vena cava (SVC) and branch pulmonary arteries are fully mobilized. The azygos vein and small venous branches near the innominate vein–SVC junction are ligated to prevent runoff into the inferior vena cava (IVC). If there is IVC interruption with azygos continuation, the azygos vein must be preserved. Cardiopulmonary bypass is instituted with two cannulas draining the right atrium and SVC–innominate vein junction and an aortic return line. The aortopulmonary shunt is subsequently taken down (not seen in the diagram). The SVC is divided and the cardiac end is oversewn. The SVC is anastomosed end to side to the upper margin of the right pulmonary artery. Additional sources of pulmonary blood supply, such as forward flow over a stenosed pulmonary outflow tract or left-sided arterial pulmonary shunt, can be left in place according to institutional preference.

A controversial point in the surgical management plan for the cavopulmonary shunt is whether to leave an additional source of pulmonary blood flow in place (such as an existing aortopulmonary shunt or forward flow over a banded pulmonary artery) with the cavopulmonary shunt. Proponents argue that this adds some pulsatility to pulmonary blood flow, which is more physiologic to the pulmonary vascular bed; those disfavoring this approach are concerned about the increased volume load on the single ventricle.

Complications associated with a cavopulmonary shunt include preferential perfusion of the lower parts of the lung and the formation of pulmonary arteriovenous fistulas.[21] Communications between the (higher pressure) SVC territory and lower body veins, left atrium, and pulmonary veins may also be present, the latter promoting right-to-left shunting and increasing cyanosis.[22] Furthermore, aortopulmonary collateral vessels may impose an increased volume load on the heart. With somatic growth of the child, the relative contribution of SVC return to total venous return decreases, and an additional source of pulmonary blood flow is needed. In suitable patients, total cavopulmonary connection should now be completed. If the patient is not a Fontan candidate, another option may be to add a small arterial shunt to increase net pulmonary blood flow.

## COMPLETION OF TOTAL CAVOPULMONARY CONNECTION

The original atriopulmonary Fontan operation has now largely been replaced by a total cavopulmonary connection. The IVC is connected to the pulmonary artery either

by means of an intra-atrial baffle (Fig. 77-4) or with the use of an extracardiac polytetrafluoroethylene conduit. The latter procedure (Fig. 77-5) can be performed without cross-clamping the aorta and, if a temporary shunt between the IVC and right atrium is used, also without the use of cardiopulmonary bypass. With advances in all aspects of patient management, some centers currently consider fenestration during extracardiac Fontan completion as an exception rather a rule. With this selective approach, there are no survival disadvantages, and the potential risk of hypoxia, systemic embolism, and late instrumentation can be avoided.[23]

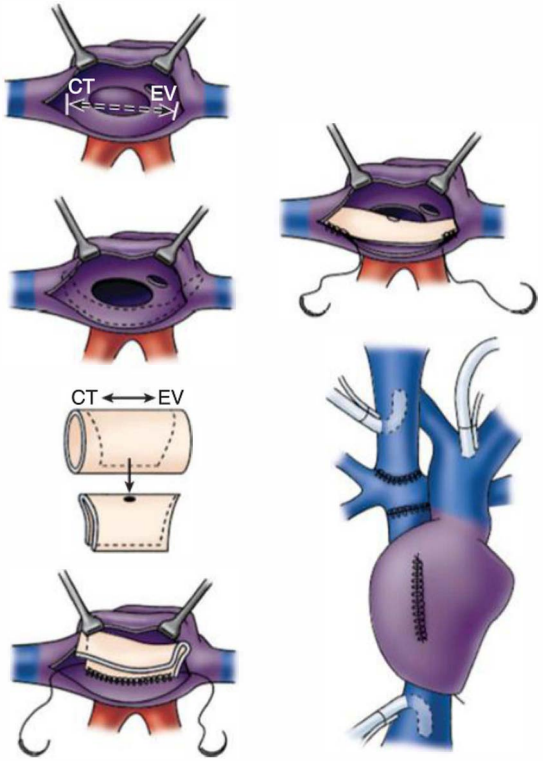

**FIGURE 77-4** Surgical technique for intracardiac Fontan. The beginning of the operation may involve performing a bidirectional cavopulmonary anastomosis (see Fig. 77-3), or this may already be in place. Bicaval venous cannulation and aortic return are utilized to institute cardiopulmonary bypass at moderate hypothermia. The right atrium is opened along the crest of the septum (top left) and the size of the intra-atrial baffle is measured between the eustachian valve (EV) and the crista terminalis (CT). A polytetrafluoroethylene conduit at least 16 mm in diameter is opened longitudinally and, if required, a 4-mm fenestration is performed. The prosthetic baffle is sewn halfway around the junction of the inferior vena cava with the right atrium, along the posterior wall of the atrial septum, crista terminalis, and halfway around the junction with the superior vena cava (SVC) (bottom left and top right). Care is taken to avoid injury to the sinus node. The cardiac end of the transected SVC is anastomosed end to side to the undersurface of the right pulmonary artery (bottom right).

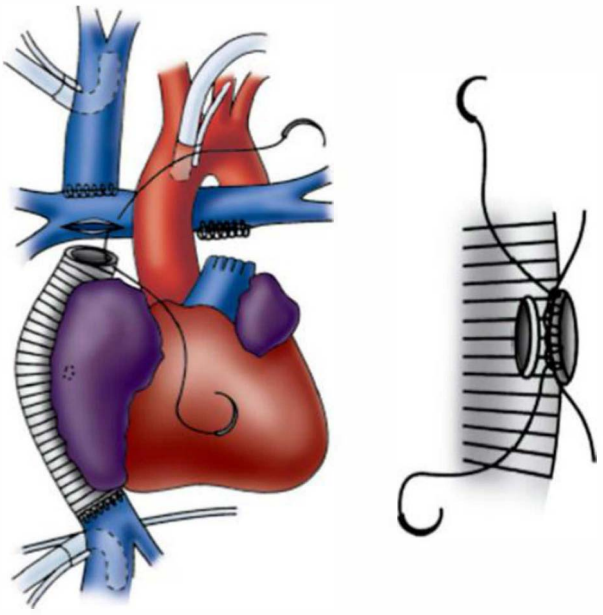

**FIGURE 77-5** Surgical technique for extracardiac Fontan. Cannulation for cardiopulmonary bypass is as described in Figure 77-4. The inferior cavopulmonary junction is transected the cardiac end oversewn. A polytetrafluoroethylene conduit of at least 16 mm in diameter (22-mm diameter in adults) with a tapered end is anastomosed end to end to the transected inferior vena cava. The conduit is gently curved around the right atrium, and the tapered top end of the prosthesis is anastomosed end to side to the underside of the pulmonary arteries. If a fenestration is required, a 4-mm hole is cut in the prosthesis and a larger opening is made in the opposite right atrial wall with side-biting clamps. The two orifices are then anastamosed with a fine suture line away from the fenestration (right).

## OUTCOMES

### Early Mortality and Morbidity

Morbidity and mortality from the various preliminary procedures performed for various structural abnormalities with functionally single ventricle are reported in Chapter 62. The operative mortality for the lateral tunnel Fontan and extracardiac Fontan has decreased steadily and is currently less than 2 percent in best centers.[24–27]

However, in patients with the syndrome of a single ventricle and heterotaxy, mortality is two to three times higher owing to the multiple associated-cardiovascular-abnormalities.[24] When hemodynamic appears stable, early extubation soon after surgery is the preferred pathway. Occasionally, a low cardiac output in the immediate postoperative period can lead to a vicious cycle, resulting in multiple organ failure and death unless early takedown of the IVC connection or fenestration is performed. Such a low-output state can be triggered by various factors, including ventricular dysfunction, subaortic stenosis, raised pulmonary vascular resistance, cardiac arrhythmias, and suboptimal technical procedures.

Investigations should be undertaken promptly. Pleural effusions requiring prolonged chest tube drainage are a common early occurrence after the Fontan operation, and early catheterisation may be indicated.

## LATE RESULTS

The Fontan state is associated with a premature decline in functional status and survival compared with the normal population. In 1990, Fontan and colleagues reported that, even if the operation was performed under perfect conditions, predicted long-term survival was 86, 81, and 73 percent at 5, 10, and 15 years, respectively.[28] In a recent series following patients who had undergone the lateral tunnel Fontan, long-term survival was 93 percent at 5 years and 91 percent at 10 years. For the more recently introduced extracardiac-conduit Fontan, survival up to 8 years is similar.[26] The reasons for the late attrition after the Fontan operation are poorly understood, but chronic elevation of the systemic venous pressure probably plays a major role.

The distended atrium in the atriopulmonary Fontan is prone to dysrhythmias, especially because of the presence of multiple suture lines. The incidence of this has been much reduced in the lateral tunnel Fontan, with reported freedom from supraventricular tachyarrhythmias of 96 and 91 percent at 5 and 10 years, respectively, and freedom from new bradyarrhythmias of 88 and 79 percent at the same follow-up interval.[25] Risk factors for arrhythmias are related to cardiac morphologic features, such as heterotaxy syndrome and atrioventricular valve abnormalities.[25] Five-year follow-up results for the extracardiac Fontan are similar.[29]

Pulmonary arteriovenous fistulas occur both following the cavopulmonary shunt and the Fontan operation. They can produce significant right-to-left shunting with resultant hypoxemia and cyanosis. Their etiology is unclear, but exclusion of the hepatic effluent from the pulmonary circuit may be a factor; resolution has been reported by redirecting hepatic venous blood to the pulmonary arteries.[30]

Thromboembolism occurs both early and late after the Fontan operation and consists of pathway thrombosis as well as pulmonary and/or cerebral emboli. Although the reported incidence ranges from 3 to 16 percent for venous thrombosis[31,32] and from 3 to 19 percent for stroke,[33,34] many events are probably unrecognized. The etiology is likely to be multifactorial and includes suboptimal flow patterns, arrhythmias, thrombogenicity of vascular conduits, hypercoagulable states, and liver dysfunction. Prophylactic long-term anticoagulation remains a contentious issue but is utilized routinely in many centers.

Protein-losing enteropathy (PLE) is a debilitating, poorly understood complication that involves loss of protein from the gastrointestinal tract. It can occur any time after the Fontan operation, with a reported incidence of up to 15 percent and a mortality of 50 percent at 5 years following initial diagnosis.[35,36] Clinical symptoms are related to the degree of nonselective protein loss and include ascites, effusion, peripheral edema, immunodeficiency, and coagulopathy. An elevated fecal $\alpha_1$-antitrypsin level is diagnostic.[37] Medical treatment is often disappointing. High-dose cortico steroids (1–2 mg/kg/day for a minimum of 2–3 weeks)[38] and unfractionated heparin (5000 U/m$^2$/day for several weeks)[39] may benefit some patients. Optimization of the hemodynamics through revision of the Fontan pathways, creation of a fenestration, pacing, or cardiac transplantation has been successful in other cases. In refractory cases, takedown of the Fontan circuit or cardiac transplantation have been performed with regression of PLE.

Pathway problems involving baffle leaks and localized stenoses have been increasingly managed by catheter interventions. In the recently introduced extracardiac conduit Fontan, lack of growth of the tube prosthesis is a potential drawback, but this has not been a problem when conduits between 18 and 20 mm in diameter were used.[29] Conversely, oversizing of the conduit has been complicated by poor hemodynamic performance and conduit thrombosis.[40]

Ventricular dysfunction is common and is multifactorial in origin. The Fontan state itself is associated with a reduction in ventricular preload (suboptimal systemic and pulmonary venous return) as well as an increase in afterload (a single ventricle with the pulmonary and systemic resistance in series), but in the absence of the compensatory increase in contractility seen in normal hearts.[41] Other adverse working conditions include volume overload, subaortic stenosis, atrioventricular valve regurgitation, atrial arrhythmias, and coronary sinus hypertension. In addition, the myocardium in some congenitally malformed hearts may be intrinsically abnormal[42] or the anatomic and structural characteristics may be inadequate to support the systemic circulation. Reduced exercise capacity has been demonstrated in Fontan patients with a morphological right ventricle.[43]

## MANAGEMENT OF THE LATE FAILING FONTAN CIRCULATION

Hemodynamic failure of the Fontan circulation currently occurs predominantly in patients who received an atriopulmonary connection. In those patients who have structural problems of the Fontan pathways or refractory atrial arrhythmias, Fontan conversion to a total cavopulmonary connection with concomitant arrhythmia surgery has been shown to improve exercise tolerance with low incidence of recurrent arrhythmias.[44] Patients with end-stage ventricular failure or other Fontan-related problems refractory to medical treatment should be considered for transplantation. However, pretransplant evaluation of the pulmonary vascular bed in the Fontan circulation is difficult because of the inability to reliably measure pulmonary blood flow, while low pulmonary arterial pressure and transpulmonary gradient may not be predictive of absence of pulmonary vascular disease. The transplant operation itself can be technically challenging because of multiple previous operations and the need for

extensive vascular reconstruction. In small series, operative mortality for transplantation after staged Fontan palliation ranges from 7 to 67 percent,[45,46] with high mortality among potential recipients awaiting a suitable donor allograft.

## FOUR DECADES OF FONTAN PALLIATION

The introduction of Fontan procedure in 1968 has transformed the surgical management of many cardiac lesions with a functionally single ventricle. It was timely that the outcomes and the clinical problems associated with this unique circulation were thoughtfully reviewed in a recent article by deLeval and Deanfield.[11] Many of the achievements and limitations with future challenges were highlighted.

## TRICUSPID ATRESIA AND THE FUNCTIONALLY SINGLE VENTRICLE BOARD REVIEW QUESTIONS (CHAPTER 77)

1. Which is correct regarding morphology of tricuspid atresia?
   A. The least common type of single ventricle is tricuspid atresia.
   B. The right atrium is small.
   C. The right ventricle is hypoplastic and lacks an outflow portion.
   D. A VSD is usually present.
   E. The ventriculoarterial connection is usually discordant.

2. Which is correct regarding clinical features of tricuspid atresia?
   A. Most patients present with cyanosis in the first day of life.
   B. In most patients, the cyanosis is progressive due to delayed closure of the patent ductus arteriosus.
   C. There is no obstruction to pulmonary blood flow in most patients.
   D. Symptoms may improve as pulmonary vascular resistance increases over the first few months of life.
   E. Electrocardiography demonstrates right-axis deviation and small p-waves.

3. Which is not a criterion for the Fontan procedure?
   A. Age over 1 year
   B. Unobstructed pulmonary venous drainage
   C. Adequately sized pulmonary arteries
   D. Adequate ventricular function
   E. Only mild or moderate atrioventricular valve insufficiency

4. Which is correct regarding bidirectional cavopulmonary shunting?
   A. The venous blood that enters the pulmonary artery is less desaturated.
   B. Systemic venous blood is diverted to the lungs, reducing the volume load on the single ventricle.
   C. Creation of the shunt does not require occlusion of the SVC.
   D. Bidirectional cavopulmonary shunts reduce the formation of pulmonary arteriovenous malformations.
   E. Aortopulmonary collateral vessels reduce the volume load on the heart.

5. Which is true regarding outcomes after Fontan procedure?
   A. Survival at 10 years after the extracardiac Fontan procedure is 80 percent.
   B. Incidence of atrial arrhythmias is reduced after the lateral tunnel procedure.
   C. Arteriovenous malformations are eliminated after Fontan completion.
   D. Thromboembolism rates are less than 10 percent.
   E. Ventricular dysfunction is almost always due to atrioventricular valve regurgitation.

## ANSWERS

1. **Answer: D.** A VSD is usually present in tricuspid atresia. Tricuspid atresia is the most common type of single ventricle. The right atrium is usually large, and the right ventricle is small, lacking an inlet portion. The ventriculoarterial connection is usually concordant.
2. **Answer: A.** Most patients present with cyanosis on the first day of life due to closure of the patent ductus arteriosus. There is obstruction to pulmonary blood flow in the majority of patients. Symptoms may worsen as pulmonary vascular resistance decreases over the first few weeks of life. Electrocardiography demonstrates left-axis deviation and large p-waves consistent with right atrial enlargement.
3. **Answer: A.** Suitable patients under 1 year of age can safely undergo the Fontan operation. Unobstructed pulmonary venous drainage, adequately sized pulmonary arteries, adequate ventricular function, and no more than moderate atrioventricular valve insufficiency are all important criteria for successful Fontan conversion.
4. **Answer: B.** Systemic venous blood is diverted to the lungs, reducing the volume load on the single ventricle. This venous blood is more desaturated than with a systemic–pulmonary shunt. Creation of the shunt requires occlusion of the SVC. Bidirectional cavopulmonary shunts are associated with the formation of pulmonary arteriovenous malformations. Aortopulmonary collateral vessels may increase the volume load on the heart.
5. **Answer: B.** The incidence of atrial arrhythmias is reduced after the lateral tunnel procedure. Survival at 10 years after the extracardiac Fontan procedure is 90 percent. Arteriovenous malformations are not eliminated after Fontan completion. Thromboembolism rates range from 3 to 20 percent. Ventricular dysfunction is multifactorial.

# Surgery for Left Ventricular Outflow Tract Obstruction in Children

*Tara Karamlou*
*Lester C. Permut*
*Marco Ricci*
*Gordon A. Cohen*

## KEY CONCEPTS

- Epidemiology
  - Left ventricular outflow tract obstruction (LVOTO) occurs in 2.8 of 10,000 live births, accounting for 3 to 6 percent of congenital heart defects.
- Morphology
  - LVOTO is valvar in 50 percent, subvalvar in 25 percent, and supravalvar in 10 percent of cases. Multilevel obstruction is present in 15 percent of cases.
- Pathophysiology
  - Obstruction at any level causes increased left ventricular systolic pressure and wall stress and consequent left ventricular hypertrophy. Left ventricular hypertrophy produces subendocardial ischemia and diastolic dysfunction. Eventually, myocardial fibrosis occurs with associated left ventricular systolic dysfunction. Low cardiac output, pulmonary edema, and ventricular arrhythmias may occur late and are associated with increased mortality.
- Clinical features:
  - Neonates with critical valvar aortic stenosis (AS) present with low cardiac output and shock, requiring emergency treatment. Other forms of LVOTO are often asymptomatic and may be detected by the presence of a heart murmur or abnormalities on ECG. Chest pain, dyspnea, and palpitations occur with increased activity as the degree of obstruction worsens. Symptoms at rest occur with long-standing LVOTO.
- Diagnosis
  - Diagnostic evaluation is performed in children with a characteristic systolic ejection murmur. Echocardiography allows diagnosis and determines the level(s) of obstruction. The left ventricular outflow tract gradient can be estimated with the use of Doppler flow velocity, and ventricular systolic and diastolic function can be assessed. Diagnostic cardiac catheterization is rarely necessary.
- Treatment
  - Neonates with critical valvar AS and morphology amenable to biventricular repair respond well to percutaneous transcatheter balloon valvotomy. Aortic valve replacement is required in older children. Enlargement of a small annulus may be achieved with the use of Konno aortoventriculoplasty. Options for valve replacement include a bioprosthetic or mechanical prosthesis, or an autograft (Ross procedure), but all have significant disadvantages in the pediatric population. Discrete subaortic membrane is resected via aortotomy, but diffuse tunnel-like narrowing requires a modified Konno procedure. A variety of aortoplasty techniques are available for patients with supravalvar AS.
- Outcomes
  - Excellent outcomes, with operative mortality of less than 5 percent, are achieved in most patients. Reoperation to upsize valves is expected in pediatric patients with somatic growth after aortic valve replacement or for structural valve deterioration. Discrete subaortic membrane recurs in approximately 15 to 20 percent of patients despite successful initial repair, and is dependent on the preoperative gradient.

## INTRODUCTION

Left ventricular outflow tract obstruction (LVOTO) is a relatively common form of congenital heart disease; it occurs in 2.8 per 10,000 births and accounts for 3 to 6 percent of congenital heart defects.[1] The levels of obstruction are classified anatomically as valvar (50 percent), subvalvar (25 percent), and supravalvar (10 percent). Multiple levels of obstruction are present in about 15 percent of cases.[2] LVOTO may be associated with other congenital heart defects, including atrioventricular canal defect, double-outlet right ventricle (RV), and some forms of functionally single ventricle. This chapter focuses on isolated congenital LVOTO in functionally biventricular hearts. Aortic arch interruption and coarctation are specifically discussed in Chapter 79.

## SURGICAL ANATOMY OF THE LEFT VENTRICULAR OUTFLOW TRACT

The left ventricular outflow tract is positioned centrally in the heart in close anatomic relation to other important cardiac structures (Fig. 78-1). Below the level of the aortic valve, the outflow tract is bordered anteriorly and to the left by the infundibular septum. Posteriorly, it is bordered by the anterior leaflet of the mitral valve and by the central fibrous body. The membranous septum is positioned anteriorly and to the right, beneath the junction of the right coronary and noncoronary cusps of the aortic valve. This relationship is surgically important, as the bundle of His courses beneath the membranous septum on the left ventricular aspect and may be injured in the course of resection or suture placement, resulting in complete heart block.

The normal aortic valve consists of three thin leaflets of equal size that are attached to the aortic wall in a semilunar fashion. The so-called aortic annulus, therefore, is not a circular ring but a scalloped coronet.[3] The free edge of each leaflet has an area of central thickening termed the nodulus of Arantius. The leaflet edges coapt in diastole and open freely in systole, creating an unobstructed triangular orifice for the ejection of blood from the left ventricle to the aorta. Leaflets are designated in accordance with the adjacent coronary artery ostia as left, right, and noncoronary cusps.

The proximal ascending aorta constitutes the distal left ventricular outflow tract. Immediately above the ventriculoarterial junction, the aorta enlarges to form the sinuses of Valsalva. These sinuses, like their corresponding valve leaflets, are named for the coronary artery ostia that arise from them. They are important for normal aortic valve function and coronary artery blood flow.[4] The sinotubular junction refers to the normal area of aortic narrowing at the junction between the sinuses of Valsalva and the tubular portion of the ascending aorta. The uppermost point of aortic valve leaflet attachment occurs at the sinotubular junction.

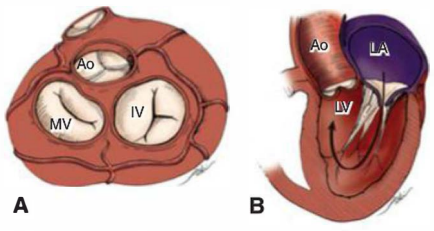

**FIGURE 78-1** Anatomy of the left ventricular outflow tract. **A.** Cranial view. The aortic valve is centrally positioned between the mitral and tricuspid valves. **B.** Schematic left-sided view: The noncoronary aortic cusp is in fibrous continuity with the anterior leaflet of the mitral valve. ## PATHOPHYSIOLOGY OF LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Regardless of the etiology, obstruction to flow through the left ventricular outflow tract results in increased left ventricular systolic pressure and wall stress. Left ventricular hypertrophy develops as a compensatory mechanism that maintains normal wall stress and stroke volume in accordance with Laplace's law. However, increased ventricular wall mass increases myocardial oxygen demand while limiting diastolic coronary blood flow. Oxygen demand eventually exceeds supply, resulting in myocardial ischemia.[5]

Left ventricular systolic function is initially normal or hyperdynamic in the early stages of obstruction. With progressive left ventricular hypertrophy, decreased wall compliance restricts ventricular filling and produces diastolic dysfunction. A decreased preload reduces stroke volume and cardiac output. Left ventricular end-diastolic and left atrial pressures rise, resulting in left atrial hypertrophy. Patients with long-standing obstruction develop myocardial fibrosis, areas of ischemic injury, and decreased ventricular systolic function. Low cardiac output, pulmonary edema, and ventricular arrhythmias ensue, associated with an increasing risk of sudden death.

Relief of LVOTO ideally is achieved before the development of systolic dysfunction. Early relief of obstruction leads to regression of ventricular hypertrophy and normalization of cardiac function. In the later stages, some components of ventricular dysfunction are likely to be irreversible despite relief of obstruction. Surgical repair in these patients is associated with higher risk and poorer outcomes.

### Valvar Aortic Stenosis

#### PATHOLOGY

Valvar aortic stenosis (AS) in children is most commonly congenital in etiology. The leaflets are thickened and dysplastic, with variable degrees of commissural fusion (Fig. 78-2). The valve is typically bicuspid in morphology but may be

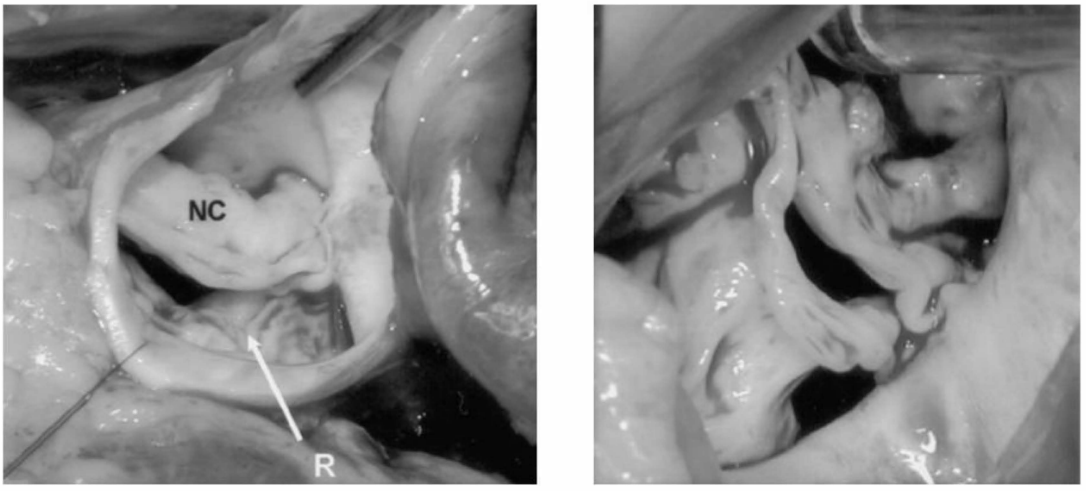

**FIGURE 78-2** Stenotic bicuspid aortic valve. Left: The leaflets are asymmetric, with a larger leaflet resulting from the fusion between the left and right coronary cusps at the raphe (R), poorly coapting against the thickened noncoronary leaflet (NC). Right: Severe calcific stenosis of the bicuspid aortic valve. (Image courtesy of Dr. Duke Cameron, Division of Cardiac Surgery, Johns Hopkins University Hospital.)

tricuspid or even unicuspid. Fusion of the right and left cusps is associated most frequently with stenosis.[6] Obstruction results from decreased leaflet mobility and a reduction in effective orifice size. Small annular size also may be present, further impeding left ventricular ejection.

## CLINICAL PRESENTATION

Neonates with critical AS develop symptoms soon after birth. After closure of the ductus arteriosus, severe outflow obstruction results in pulmonary congestion and poor peripheral perfusion. Dyspnea, tachypnea, and rales are present on pulmonary examination. A systolic ejection murmur may be present, but it may be difficult to hear when cardiac output is reduced severely. The distal extremities have cold, clammy skin with poor capillary refill and thready, rapid pulses. The differential diagnosis includes other causes of shock, including sepsis and other forms of congenital heart disease. Prompt diagnosis and institution of therapy are necessary to prevent rapid deterioration and death.

Older children present less acutely, often with the finding of an asymptomatic heart murmur on routine physical examination. Difficulty feeding in infants and decreased exercise tolerance in older children may be observed as the severity of obstruction increases. Later symptoms include exertional angina, congestive heart failure, and syncope. Physical findings are generally limited to the cardiovascular examination: a harsh systolic ejection murmur at the right upper sternal border radiating to the neck, $S_4$ gallop, and poor upstroke of the carotid pulse. An ejection click may indicate the presence of a bicuspid valve.

## DIAGNOSIS

Chest x-ray is usually nondiagnostic. In neonates with critical stenosis, cardiomegaly and pulmonary congestion are present. Findings in older children generally are limited to moderate left ventricular enlargement, left atrial enlargement, and prominence of the aortic knob.

The electrocardiogram shows left ventricular hypertrophy. Serial findings of increasing QRS voltage and the development of a strain pattern suggest worsening obstruction.

Echocardiography is the principal diagnostic method for the evaluation of LVOTO. Two-dimensional echocardiography allows assessment of aortic valve morphology including leaflet number, degree of thickening, and mobility. Doming of the leaflets is typical (Fig. 78-3). Dimensions of

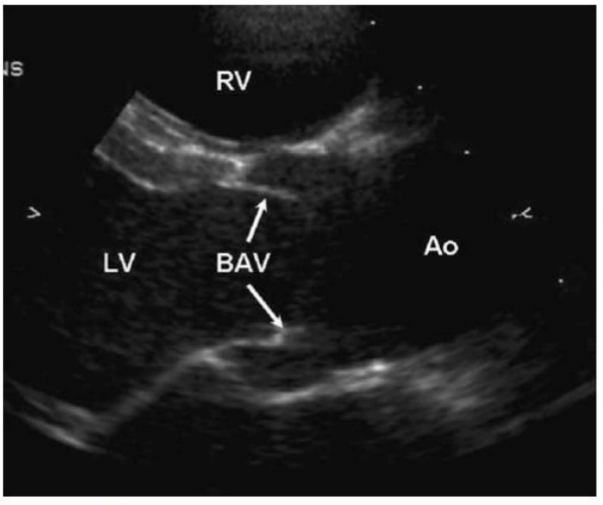

**FIGURE 78-3** Two-dimensional echocardiogram in a patient with congenital aortic stenosis. Long-axis view of bicuspid valve. The leaflets are doming in systole. Ao, aorta; BAV, bicuspid aortic valve; LV, left ventricle; RV, right ventricle. (Image courtesy of Dr. William Ravekes, Division of Pediatric Cardiology, Johns Hopkins Hospital.)

the subvalvar area, annulus, effective valve orifice, and aortic root are measured accurately. Left ventricular cavity size and the presence and severity of left ventricular hypertrophy can be assessed. Indexes of systolic and diastolic function can be calculated. Color Doppler imaging accurately identifies the level of obstruction, allowing a distinction between valvar, subvalvar, and supravalvar stenosis. Doppler measurement of blood flow velocity across the valve provides an estimate of the peak pressure gradient. Progression of disease and timing of intervention, therefore, can be determined in a noninvasive fashion in most cases.

With accurate echocardiographic assessment, cardiac catheterization is rarely required in the diagnostic evaluation of AS. It may be indicated to confirm the diagnosis or assess the severity of obstruction when the clinical and echocardiographic findings are equivocal. Direct simultaneous measurement of left ventricular pressure and aortic pressure is the most accurate method for assessing the outflow tract gradient. However, identification of the precise level of obstruction may not be possible. Elevation of left ventricular end-diastolic pressure indicates impaired diastolic function. Left ventriculography allows assessment of ventricular systolic function and may outline the valve leaflets, providing some assessment of morphology.

## TREATMENT

***Neonatal Critical Aortic Stenosis.*** Critical AS diagnosed in the newborn period constitutes a medical emergency. A neonatal presentation indicates severe outflow obstruction that requires urgent intervention. Initial stabilization includes endotracheal intubation and inotropic support. Prostaglandin infusion will establish or maintain patency of the ductus arteriosus and improve systemic perfusion. Emergency aortic valvotomy previously was the treatment of choice, performed soon after resuscitation. In the current era, percutaneous transcatheter balloon aortic valvotomy has supplanted surgical valvotomy in most centers. The procedure is performed in the catheterization laboratory, with the advantages of rapid relief of obstruction and avoidance of cardiopulmonary bypass and aortic cross-clamping. Risk factors for failure include a small aortic annulus, a bicuspid aortic valve, poor left ventricular function, and limited operator experience.[7,8] Outcomes are generally similar to those for open valvotomy. Hospital mortality for either procedure ranges between 0 and 20 percent.[9,10] Mortality is higher in patients with bicuspid valve morphology. Significant aortic regurgitation is more likely after balloon valvotomy, and is associated with an increased risk of early death.[11] Earlier reports suggested that residual stenosis was more common after surgical valvotomy,[9] though this has not borne out in recent studies. Miyamoto et al. reported an 85 percent freedom from reintervention at 5 years following surgical valvotomy among 34 neonates.[12] Zain and colleagues similarly found that neonates undergoing balloon valvotomy had a higher reintervention rate than those having surgical valvotomy despite a more modest immediate gradient reduction following surgical valvotomy.[13] Regardless of the technique, neonatal aortic valvotomy is considered a palliative procedure for most patients, with 41 percent undergoing reintervention within 10 years.[9,14]

In a small subset of neonates with critical AS and small left ventricular size, it may be difficult to determine whether a biventricular approach with aortic valvotomy/replacement or a single-ventricle approach with the Norwood procedure is more appropriate.[15] Several studies have attempted to identify preoperative predictors for suitability of single ventricle versus biventricular repair in this challenging population.[15] Hammon et al.[16] proposed an angiographically derived 20 mL/m$^2$ threshold for end-diastolic volume for successful biventricular repair. Rhodes and associates[17] identified criteria, including body surface area, indexed aortic root dimension, ratio of left ventricle to heart length, and indexed mitral valve area, as predictors of successful valvotomy. However, the Rhodes score was developed using a small, retrospective group of 65 infants with valvar AS who were pre-selected for biventricular repair. The score has recently been revalidated by Colan et al.,[18] but still has shown poor discrimination when applied to neonates with multiple levels of left heart obstruction or whose primary pathology is other than critical AS. The most robust clinical tool for triaging patients to a single or biventricular pathway, termed the "Critical Aortic Stenosis calculator," was developed by the Congenital Heart Surgeons' Society (CHSS). The calculator was derived from a prospective multi-institutional cohort of 320 patients with critical AS or atresia. Multivariable linear regression analysis identified independent factors associated with survival after biventricular repair versus single ventricle palliation.[19] The derived regression equation requires the following values: age at entry, aortic valve *z*-score, grade of endocardial fibroelastosis, diameter of ascending aorta, presence of moderate or severe tricuspid regurgitation, and *z*-score of left ventricular length. A positive number favors the Norwood approach, a negative number favors biventricular repair, and the magnitude of the number represents the degree of the predicted survival benefit. Individual patient data can be entered and the relative risk of either approach can be estimated by using the website of the Congenital Heart Surgeons Society (www.chssdc.org). An updated analysis of the same CHSS cohort by Hickey et al.[20] allowed refinement of the CHSS prediction algorithm, with substitution of two variables (mid-aortic arch diameter and minimum LVOT diameter) as surrogates for patient age, and the addition of the *z*-score of the mitral valve annulus.

***Neonates with Multilevel Left Ventricular Outflow Tract Obstruction.*** Neonates with multiple levels of LVOTO represent a complex group. Surgical options must be tailored to the particular anatomic considerations (Fig. 78-4). Neonates undergoing single ventricle palliation can be managed with a staged approach, consisting of a Norwood or modified Norwood operation. Hybrid palliation, with implantation of a ductal stent with concomitant bilateral pulmonary arterial (PA) banding, is another recently developed option. This

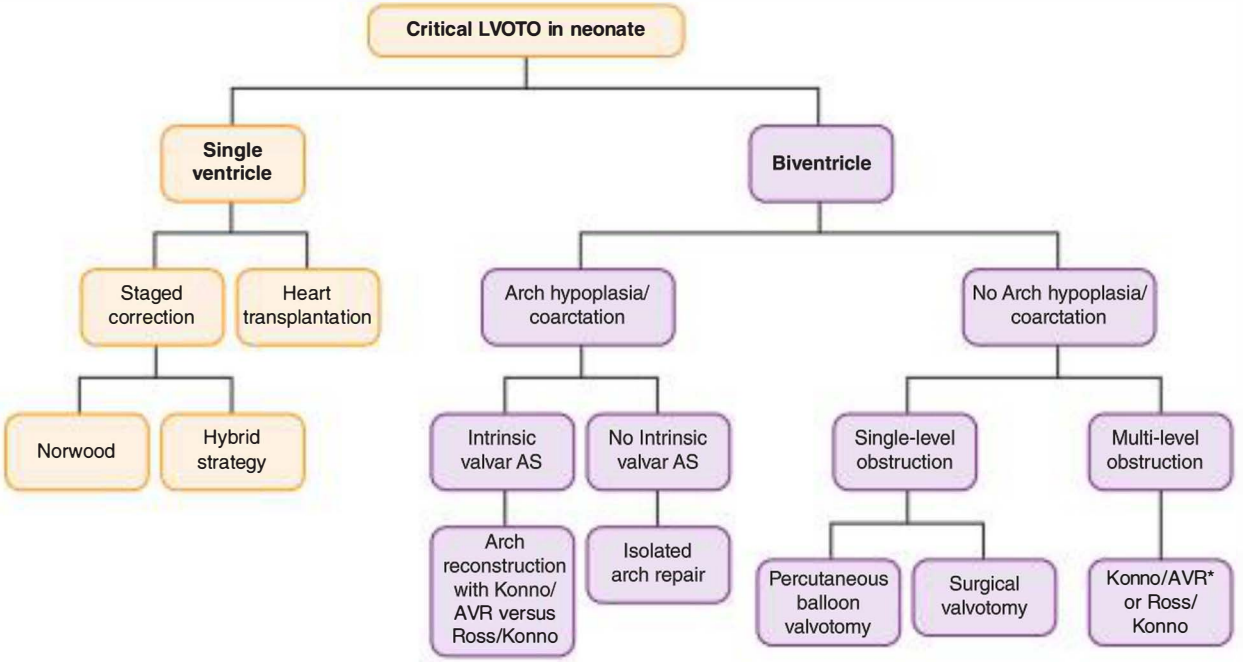

**FIGURE 78-4** Treatment algorithm for neonates and infants with critical left ventricular outflow tract obstruction.

strategy, however, is generally reserved for marginal candidates with contraindications to standard Norwood-type palliation or as a bridge to heart transplantation. Orthotopic heart transplantation is an attractive strategy for infants with severe atrioventricular valve regurgitation, visceral heterotaxy, or poor systemic ventricular function.

Neonates undergoing biventricular repair have several potential options depending upon the associated intracardiac and arch pathology. Infants with combined valvar AS and aortic arch obstruction can be managed with standard patch aortoplasty concomitant with either a neonatal Ross operation or a mechanical aortic valve replacement with an annular enlargement (Konno aortoventriculoplasty). Our institutional preference has been to manage these patients with aortic valve replacement and Konno root augmentation, as results with the neonatal Ross operation have been poor, especially in neonates with associated mitral valve abnormalities.[15,21–23] The presence of a ventricular septal defect adds an additional level of complexity, with options including those discussed above, arch repair with closure of the ventricular septal defect, or a Yasui reconstruction.

***Valvar Aortic Stenosis in Older Children.*** The objectives of surgical treatment of AS are relief of symptoms and reduction of the risk of sudden death. Sudden death is related directly to the severity of obstruction and correlates with the peak systolic gradient, though it is reported to be less than 1 percent.[24] Stenosis is considered severe when the mean echocardiographic gradient is equal to or greater than 40 mm Hg, moderate when it is between 25 and 40 mm Hg, and mild when it is <25 mm Hg.[24] Surgery is indicated in any symptomatic patient regardless of severity, and in asymptomatic patients with severe stenosis. Surgery is not recommended for asymptomatic patients with mild stenosis. There is controversy about the management of asymptomatic patients with moderate stenosis. Surgical management should be considered on an individual basis. The authors generally recommend surgery in patients who demonstrate reduced left ventricular function, a strain pattern on electrocardiography or abnormal exercise testing.

The two options for surgical management of AS are valvotomy and aortic valve replacement. Valve replacement in children poses unique challenges that are not seen in the adult population. The smallest mechanical and bioprosthetic valves available (17-19 mm) are too large for the annular size of smaller children. Even when replacement is feasible, unless an "adult-size" valve is used, somatic growth eventually results in recurrent outflow obstruction because the prosthesis size is fixed. Re-replacement with an appropriately sized valve may be limited by restricted annular growth from the original prosthesis. These limitations may necessitate concomitant annular enlargement, such as in a Konno procedure. Posterior enlargement procedures such as the Nicks or Manougian operations are often insufficient in children.[25,26]

The choices of prosthetic valves for children are more limited than are those for adults. Bioprostheses do not require anticoagulation, but calcific degeneration occurs at an accelerated rate compared with adults, limiting their use in children.[27] Mechanical prostheses maintain their structural integrity and generally have excellent freedom from reintervention or re-replacement,[28–30] but require anticoagulation

with warfarin. Anticoagulation can be achieved safely in children, but issues of compliance, inconsistent diet, and potential for traumatic injury increase the risk of bleeding and thromboembolic complications in this patient population. A recent paper by Alsoufi and colleagues[31] demonstrated that the use of either homograft or bioprosthetic valves in children was associated with an increased risk of valve-related reoperation (82 percent at 15 years) compared to both mechanical valve implantation and the Ross operation. However, long-term survival was excellent (86 percent at 15 years) in patients having homograft or bioprosthetic valve replacement, underscoring the fact that these valve types can be useful in female patients or those in whom anticoagulation cannot be utilized.

Allograft replacement of the aortic root became popular in the early 1990s. Small valves with excellent early hemodynamic performance were readily available, and it was hoped that degeneration would not occur. Subsequent reports, however, demonstrated severe accelerated degeneration that required early reoperation in younger children.[32] Severe calcification and inflammatory reaction of surrounding tissues complicate allograft removal and place adjacent structures, including mitral valve, the bundle of His and the coronary arteries at risk during reoperation.

Pulmonary autografting and reconstruction of the RV outflow tract with an allograft (the Ross procedure) are often the best choice for aortic valve replacement in small children. The autograft has growth potential, does not develop calcific degeneration, and does not require anticoagulation. There are, however, a number of important limitations. The aortic and pulmonary annular sizes must be similar; stretching of the autograft to fit a dilated aortic root will result in neoaortic insufficiency. The operation is technically challenging, requiring longer periods of cardiopulmonary bypass and aortic cross-clamping compared with other, simpler techniques for valve replacement. Allograft reconstruction of the RV outflow tract invariably necessitates eventual reoperation for conduit stenosis from somatic growth or calcific degeneration. Finally, it has been recognized that the pulmonary autograft develops important dilation over time out of proportion to somatic growth, and that this dilation can result in progressive neoaortic insufficiency.[33,34] The propensity for neoaortic dilation was initially thought to be limited to those with aortopathy associated with a bicuspid aortic valve. However, data from Pasquali et al.[33] and others[34] demonstrated that, using serial echocardiographic data, freedom from neoaortic root intervention was 88 percent at 6 years, freedom from moderate neoaortic regurgitation was 60 percent, and freedom from neoaortic root size $Z$-score more than 4 was only 3 percent. Interestingly, several recent papers[33,34] reported that autograft dilation was not associated with the development of neoaortic insufficiency, which was the main reason for reintervention.

In summary, there is no ideal substitute for aortic valve replacement in children with valvar AS. Aortic valvotomy is, whenever feasible, the procedure of choice in this population. Although often not definitive, adequate palliation is usually achieved. Small residual gradients and mild aortic insufficiency are acceptable. Valvotomy can defer the need for valve replacement significantly, allowing for insertion of a larger prosthesis at a later time and reduction of the total number of re-replacements required over a patient's lifetime.

**Aortic Valvotomy.** Surgical aortic valvotomy is usually performed via a median sternotomy. A single right atrial cannula provides venous drainage, and the aortic cannula is placed as distally as possible. Some surgeons advocate closed valvotomy that is performed by passing dilators of increasing size (usually up to 1 mm larger than the preoperative echocardiographic aortic annulus diameter) through the aortic valve; the dilators are introduced through a purse string in the left ventricular apex. This technique can be performed through a left thoracotomy without the need for cardiopulmonary bypass.[35] The authors believe that open valvotomy with direct visualization of the aortic valve allows more precise leaflet separation, resulting in better relief of gradient and a decreased risk of significant aortic insufficiency.

The aorta is clamped, and cardioplegia is delivered via the aortic root. A transverse aortotomy is made just above the sinotubular junction, with care taken to avoid injury to the right coronary artery and the aortic valve leaflets. The valve is inspected carefully. Fused commissures are opened precisely with a scalpel (Fig. 78-5). The incisions are not extended to the aortic wall, since this may result in loss of support and aortic insufficiency. Excessive fibrous tissue, if present, is excised from the leaflets. Fibrous attachments between the base of the leaflets and the aortic wall are divided to maximize leaflet mobility. Despite these steps, the effective orifice may be inadequate, particularly in smaller bicuspid valves. Ilbawi and colleagues[36] described a technique of extended valvotomy for these patients. Circumferential incisions are made above the true commissures and raphes (Fig. 78-6). They reported a low incidence of aortic insufficiency and significantly lower gradients compared with standard

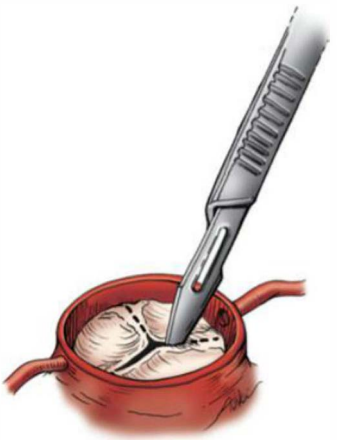

FIGURE 78-5 Open aortic valvotomy. The incision is performed toward the commissural post of the nonfused leaflets. (Reproduced with permission from Shizuka N. Aoki.)

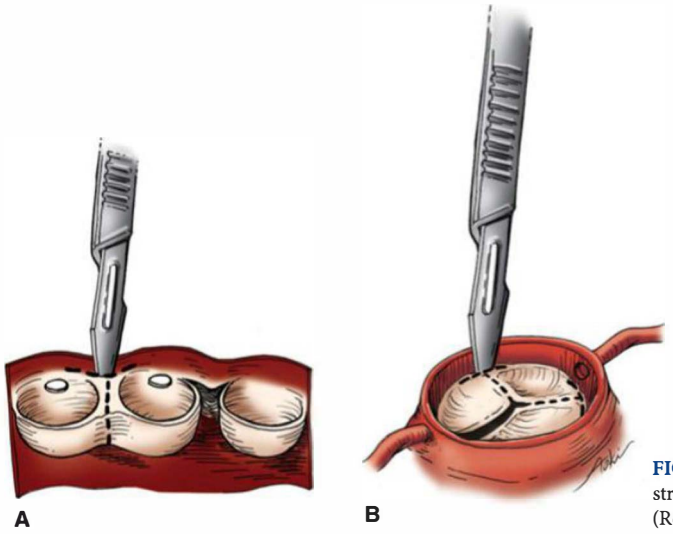

FIGURE 78-6 Extended aortic valvotomy. **A.** Lateral view demonstrating incisions at true commissures and raphe. **B.** Cranial view. (Reproduced with permission from Shizuka N. Aoki.)

valvotomy. The aortotomy is closed precisely to avoid supravalvar narrowing, and the cross-clamp is removed. The patient is weaned from cardiopulmonary bypass with mild inotropic support (dopamine 5 μg/kg/min and milrinone 0.5 μg/kg/min). The adequacy of repair is assessed by transesophageal echocardiography and direct measurement of pressure in the left ventricle and ascending aorta. Modified ultrafiltration is performed before decannulation.

Early mortality in older infants and children undergoing aortic valvotomy is reported currently to be less than 2 percent,[2,7] and late mortality is rare. Reintervention for progressive regurgitation or restenosis may be required, but this generally occurs later than in neonates. Reoperation rate in children over 1 year of age at the time of the initial valvotomy is 2 percent at 10 years but increases thereafter by 3.3 percent per year.[37]

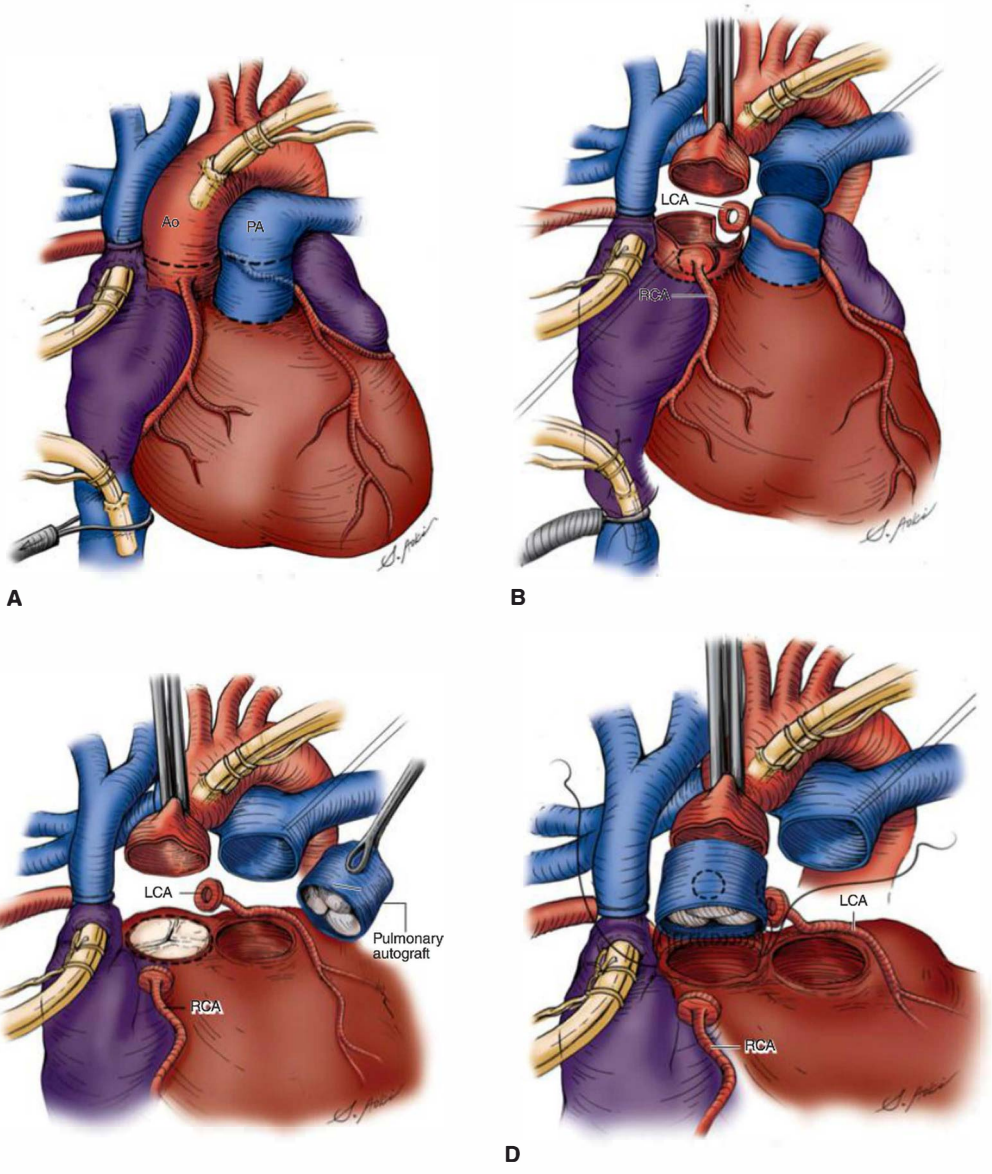
**Aortic Valve Replacement.** Aortic valve replacement is required when valvotomy is not sufficient to reduce the transvalvar gradient adequately, or in patients with greater than mild aortic insufficiency. In larger children with adequate annular size, simple replacement of the valve is performed as it is in adults. Prosthesis selection should be individualized. The authors generally avoid porcine and bovine bioprostheses as well as allograft implantation because of the rapid degeneration and early failure observed in children. The remaining options, therefore, are limited to mechanical prosthesis and pulmonary autograft.

Aortic valve replacement with a mechanical prosthesis is performed via a median sternotomy. A single right atrial or two-stage venous cannula provides venous drainage, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. After aortotomy, additional cardioplegia is delivered every 30 min through a retrograde coronary sinus catheter or by direct coronary ostial perfusion. A left ventricular vent is placed through the left atrial appendage or the right superior pulmonary vein.

An oblique aortotomy is made and is extended into the noncoronary sinus of Valsalva. The aortic valve leaflets are excised. Interrupted pledgeted mattress sutures are placed circumferentially around the annulus. In smaller patients, intra-annular placement may be preferable to avoid coronary ostial obstruction by the sewing ring. The sutures are passed through the sewing ring, and the valve is parachuted into place. After the sutures are tied, the prosthetic leaflets are assessed carefully to ensure unhindered mobility. The aortotomy is closed, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass on mild inotropic support. Transesophageal echocardiography is used to assess prosthetic function. Modified ultrafiltration is performed before decannulation.

Hospital mortality after mechanical aortic valve replacement in children is less than 5 percent. Early complications include permanent heart block in 3 percent and acute endocarditis in 2 percent of these patients. Late complications relate primarily to anticoagulation. In reports of long-term follow-up, valve thrombosis occurs in up to 2 percent of patients. This sometimes can be managed pharmacologically with thrombolytic agents but frequently requires urgent surgical thrombectomy or valve replacement. Embolic events are reported in 2 percent, and significant bleeding episodes occur at a rate of 0.15 percent/patient year.[38,39] Freedom from reintervention or re-replacement is approximately 86 percent at 20 years, but is increased in younger patients having smaller prostheses.[28–31]

**Ross Procedure.** Ross[40] reported aortic valve replacement with a pulmonary autograft and allograft reconstruction of the RV outflow tract in 1967 (Fig. 78-7). In the absence of significant size discrepancy or connective tissue disease, the Ross procedure is the preferred technique for aortic valve



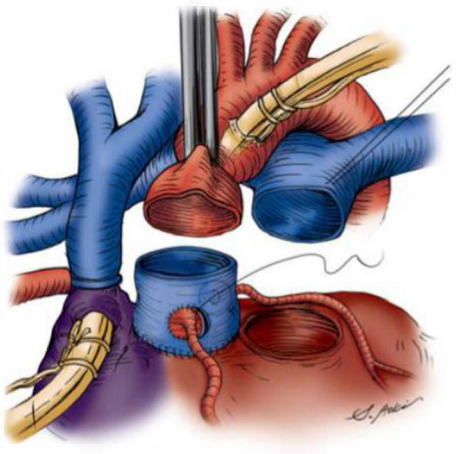


**FIGURE 78-7** Ross procedure. **A.** Dotted lines indicate incisions in the aorta, pulmonary trunk, and right ventricular infundibulum. **B.** The aorta and pulmonary artery are transected, and the coronary buttons are excised from the sinuses of Valsalva. **C.** Removal of the pulmonary autograft. **D.** The proximal anastomosis of the pulmonary autograft is begun posteriorly.

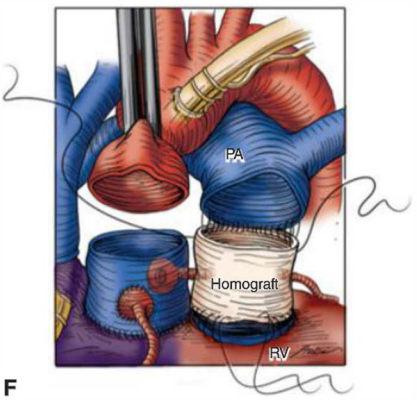
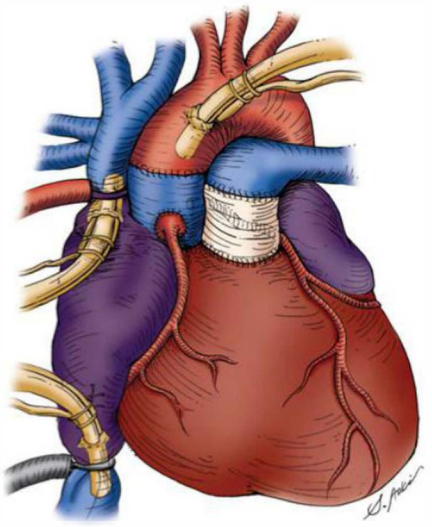


replacement in small children. In larger children, it frequently is preferred over mechanical prosthesis to avoid the need for anticoagulation.

The approach is via a median sternotomy. The venae cavae are cannulated individually, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. Cardioplegia may also be delivered in a retrograde fashion with a coronary sinus catheter or by direct coronary ostial perfusion after an aortotomy. Additional cardioplegia is delivered every 30 min during the cross-clamp period. A left ventricular vent is placed through the left atrial appendage or the right superior pulmonary vein.



The aorta and the pulmonary trunk are separated, and the pulmonary artery is opened transversely just proximal to the bifurcation. The pulmonary valve is inspected to identify any pathology that would preclude its use as an aortic valve substitute. Transection of the pulmonary trunk is then completed. A right-angle clamp is passed carefully through the leaflets into the RV outflow tract, and a site for proximal transection is identified in the infundibular free wall approximately 5 mm below the level of the valve.

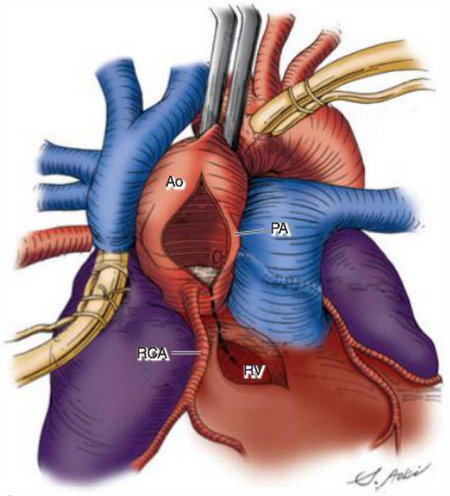
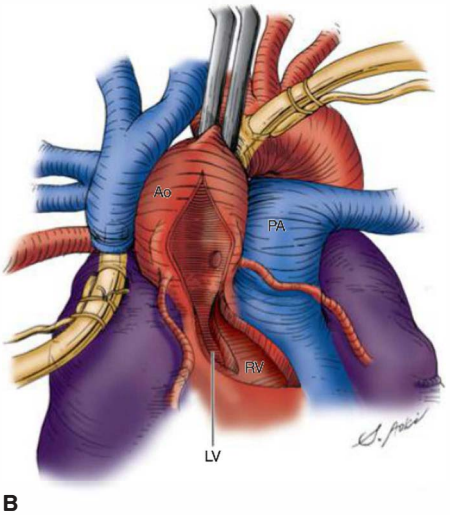
**FIGURE 78-7** (*Continued*) **E.** The proximal autograft anastomosis is completed, and the coronary buttons are sutured to the autograft sinuses of Valsalva. **F.** A homograft restores continuity of the right ventricular outflow tract. **G.** The autograft is anastomosed distally to the ascending aorta. Ao, aorta; LAD, left anterior descending coronary artery; LCA, left coronary artery; PA, pulmonary artery; RCA, right coronary artery; RV, right ventricle. (Reproduced with permission from Shizuka N. Aoki.)



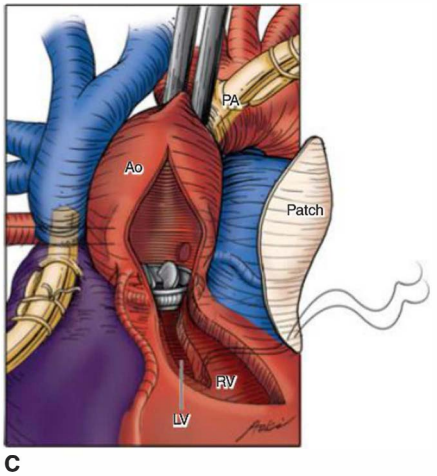
A transverse infundibular incision is made and carried to the infundibular septum at each end. The infundibular septum is scored with a scalpel blade. A plane can be developed between the subconal muscle and the underlying interventricular septum. Dissection in this plane completes the harvest, and the autograft is stored in normal saline solution before implantation. The resulting posterior raw surface is cauterized. In their practice, the authors also apply a thin layer of biological sealant to ensure hemostasis. In dissecting the autograft, care must be taken at the leftward extent of the septal dissection to avoid injury to the first septal perforating branch of the left anterior descending coronary artery. The PA is sized, and an appropriate allograft is thawed and prepared for reconstruction of the RV outflow tract.

The aorta is transected just above the sinotubular junction. The aortic valve leaflets are excised, and the left and right coronary arteries are excised with a generous button of aortic wall. The autograft is oriented by alignment of the commissures. The proximal anastomosis is then constructed. Interrupted simple braided sutures are used for smaller patients, although a continuous technique with polypropylene sutures can be used in larger children and teenagers. The coronary buttons are anastomosed to incisions in the respective autograft sinuses of Valsalva. The distal aortic anastomosis is constructed with a running polypropylene suture. Air is evacuated from the left side of the heart, and the aortic clamp is removed. Continuity between the RV and the PA is restored by interposing the previously thawed allograft in the reperfused, beating heart. The patient is weaned from cardiopulmonary bypass with mild inotropic support. Transesophageal echocardiography is used to assess autograft and allograft function as well as left ventricular wall motion. Modified ultrafiltration is performed before decannulation in children with an operative weight below 20 kg.



The results of the Ross procedure are reasonable in carefully selected pediatric patients. Early mortality is less than 6 percent, occurring primarily in infants under 5 months of age.[41–44] However, patients with concomitant mitral valve disease or aortic arch hypoplasia, even when judged to have adequate biventricular physiology, fare poorly with the Ross operation. A recent paper by Shinkawa and colleagues from the University of Michigan reported a 36 percent early mortality in this subgroup.[22] Similarly, Hickey and colleagues[23] reported a 31 percent early mortality rate in infants younger than 3 months, and an actuarial 1-year survival less than 50 percent for neonates. Complications occur infrequently and include bleeding, arrhythmia, heart block, and stroke.[43,44] Actuarial survival for all patients is 84 percent at 1 year and 77 percent at 5 years.[22] Aortic root dilatation is common late after the Ross procedure in children as noted above and warrants careful echocardiographic follow-up.[33,34,45,46]

**Konno Aortoventriculoplasty.** Annular enlargement is required in children with small aortic annular size requiring aortic valve replacement. Nicks and colleagues[47] and Manougian and Seybold-Epting[48] described techniques for posterior annular enlargement that have been used successfully in adults. However, the resulting increase in annular size is generally inadequate to allow insertion of even a small prosthetic valve in small children. Konno and coworkers[49] described a technique of anterior enlargement that more effectively increases annular size and relieves coexistent subvalvar stenosis in pediatric patients (Fig. 78-8).



The approach is via a median sternotomy. The venae cavae are cannulated individually, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. Additional cardioplegia is delivered every 30 min during the cross-clamp period. A left ventricular vent

The incision is to the left of the origin of the right coronary artery. **B.** The aortic leaflets are excised. An incision is made through the annulus and extended into the infundibular septum. **C.** The aortic valve prosthesis is sutured to the annulus posteriorly. The lower portion of a diamond-shaped patch is sutured to the septum, enlarging the annulus and subvalvar area.

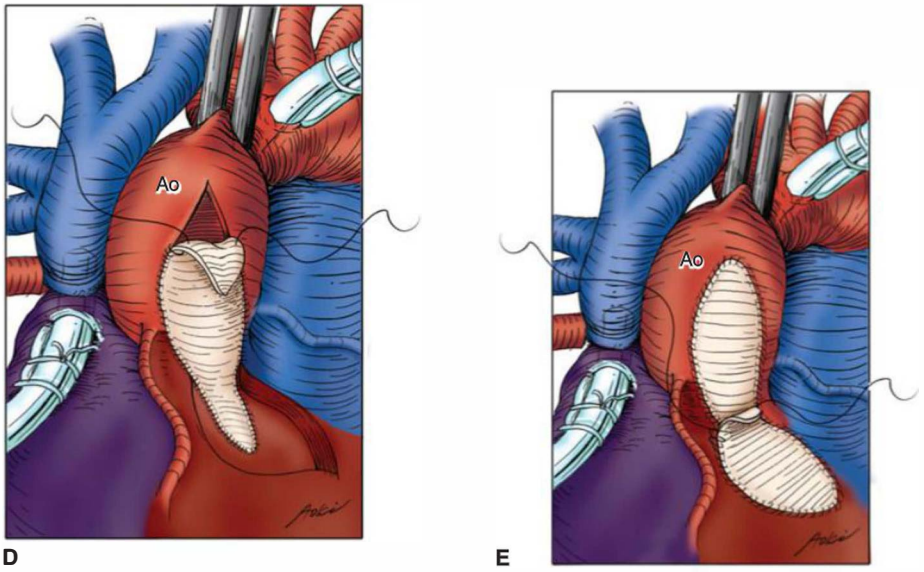

**FIGURE 78-8** (*Continued*) **D.** The prosthetic valve is sutured to the patch anteriorly, and the upper portion of the patch closes the aortotomy. **E.** The right ventriculotomy is closed with a patch of bovine pericardium. is placed through the left atrial appendage or the right superior pulmonary vein.

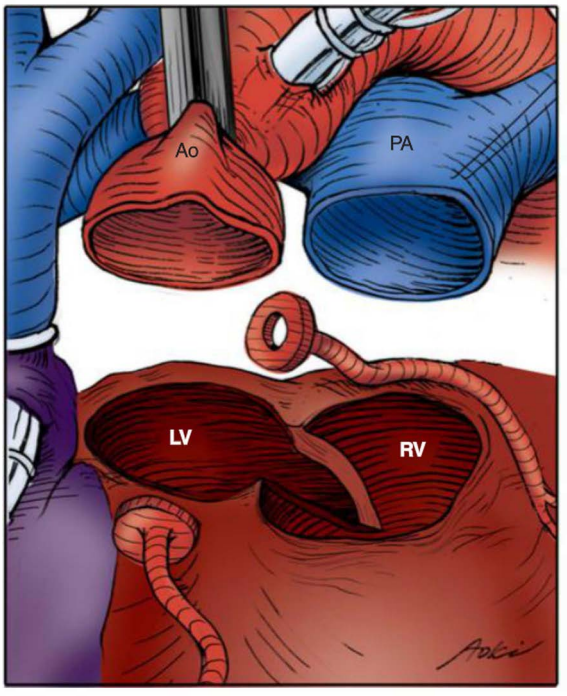
A vertical aortotomy is made and is carried onto the RV outflow tract well to the left of the origin of the right coronary artery. Care is taken to avoid injury to the pulmonary valve. The aortic valve leaflets are excised, allowing visualization of the left and RV aspects of the infundibular septum. An incision is made across the aortic annulus into the infundibular septum. Injury to the conduction tissue is avoided by placing this incision to the left of the papillary muscle of the conus (muscle of Lancisi). A diamond-shaped patch of Dacron is fashioned, and the inferior portion is sutured to the edges of the septal incision with interrupted pledgeted mattress sutures. An appropriately sized prosthetic valve is then inserted as was described for aortic valve replacement. Anteriorly, the valve sutures are passed through the prosthetic patch. The superior portion of the patch is used to close the ascending aorta. The RV free wall is enlarged with a patch of bovine pericardium. Air is evacuated from the left side of the heart, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass with mild inotropic support. Transesophageal echocardiography is used to assess prosthetic function, patch leaks, and left ventricular wall motion.



A modification of this technique can be used for annular enlargement in conjunction with the Ross procedure. A Ross–Konno is an ideal procedure in infants or children under 2 years of age, whose size precludes implantation of at least a 21-mm prosthesis or larger. The pulmonary autograft is harvested with a triangular portion of RV free wall that is used as the septal patch (Fig. 78-9).

In light of the complex form of LVOTO seen in pediatric patients who require the Konno or the Ross–Konno procedure, early and late results are quite good. On average, the annulus is enlarged to twice the original size, often allowing insertion of an adult-sized prosthesis (23 or 25 mm) in most patients over 3 years of age.[26,50] Operative mortality for the Konno procedure with prosthetic valve replacement is between 5 and 15 percent. Ten-year actuarial survival is 92 percent.[26] Ten-year freedom from reoperation with a mechanical prosthesis is 80 to 89 percent. The linearized rate of reoperation is approximately 3.9 percent/year, and is increased among patients undergoing a Konno operation to correct aortic valve pathology in conjunction with annular hypoplasia.[25] An important and often underappreciated complication of the Konno procedure (with or without concomitant Ross operation) is pulmonary regurgitation, which occurs at a cumulative incidence of 10 percent at 16 years postoperatively.[25] Operative mortality for the Ross-Konno procedure is 0 to 7 percent even in children under one year of age.[41,51,52] Postoperative complications include bleeding, arrhythmia, heart block, and left ventricular dysfunction. No permanent effects on ventricular function are present at long-term follow-up.[53]

## Subvalvar Aortic Stenosis

Subaortic stenosis in children results from either a discrete fibrous membrane or, less commonly, diffuse, fibromuscular tunnel-like stenosis. The discrete subaortic membrane is probably an acquired lesion that rarely is seen in infants, albeit with "anatomic precursors." An abnormal septal angle

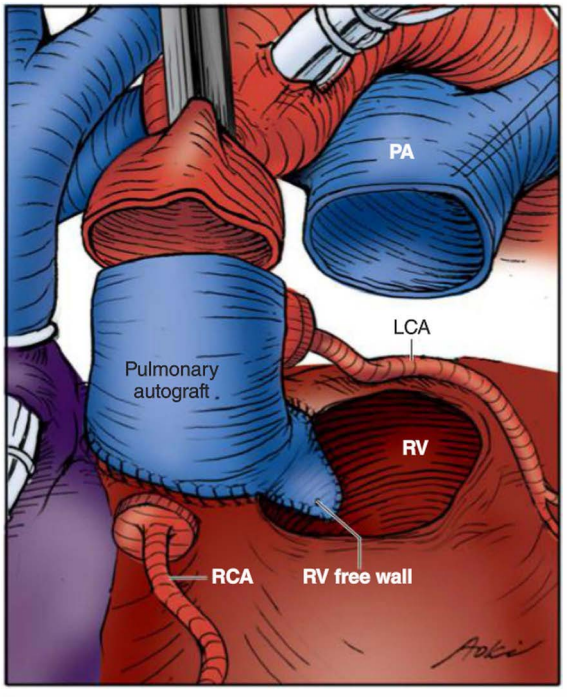


**FIGURE 78-9** Ross–Konno procedure. **A.** The aorta and autograft are prepared as illustrated in Figure 70-6A–C. An incision is made across the aortic annulus and extended into the septum. **B.** The annulus and subvalvar area are enlarged. **C.** The autograft is harvested with a triangular portion of right ventricular free wall that is used for septal closure. LV, left ventricle; RV, right ventricle. (Reproduced with permission from Shizuka N. Aoki.)

between the muscular and conal septum may be an important causative factor, but a definitive etiology has not been established. Turbulence within a small or elongated aortic root causes thickening of the endocardium. A ring of fibrous tissue results that is adherent to the septum anteriorly, extending posteriorly to the right and left fibrous trigones and to the anterior mitral leaflet.[54] Associated subaortic anomalies are present in 31 percent of these patients, including anomalous septal insertion of the mitral valve, accessory mitral valve tissue, anomalous papillary muscles, and anomalous muscular bands.[55] In addition to outflow obstruction, aortic insufficiency develops in more than 50 percent of these patients from turbulence-induced leaflet deformity or direct attachment of the membrane to the aortic leaflets.[56]

Tunnel-like subaortic stenosis is a congenital lesion in which the subaortic region is diffusely hypoplastic. Thickened septal myocardium and endocardial fibrosis contribute to outflow tract obstruction.

## SIGNS AND SYMPTOMS

Patients with discrete subaortic stenosis usually present after infancy when an asymptomatic murmur is detected on physical examination. Early symptoms include feeding intolerance and easy fatigability. Chest pain, syncope, and congestive heart failure may develop with worsening obstruction. A systolic ejection murmur without an ejection click is heard on auscultation. A diastolic decrescendo murmur may be heard at the left lower sternal border when a discrete subaortic membrane is associated with aortic insufficiency. Tunnel-like fibromuscular stenosis often presents in infancy but is otherwise indistinguishable from a discrete membrane on the basis of signs and symptoms.

## DIAGNOSIS

Chest x-ray is usually nondiagnostic. Findings generally are limited to moderate left ventricular enlargement, left atrial enlargement, and prominence of the aortic knob.

The electrocardiogram shows left ventricular hypertrophy. Serial findings of increasing QRS voltage and the development of a strain pattern suggest worsening obstruction.

Two-dimensional echocardiography is the primary imaging modality for diagnosing subaortic stenosis and distinguishing a discrete fibrous membrane from the diffuse fibromuscular type of obstruction. A discrete membrane is usually detected below the aortic valve, extending from the anterior mitral leaflet to the septum (Fig. 78-10). Diffuse fibromuscular stenosis is identified as a long hypoplastic outflow tract (Fig. 78-11). A color Doppler flow study reveals the level of obstruction below the aortic valve leaflets and will detect the presence of aortic insufficiency. Doppler measurement of blood flow velocity in the outflow tract provides an estimate of the peak pressure gradient. Progression of disease and timing of intervention, therefore, can be determined in a noninvasive fashion.

AV, aortic valve; LA, left atrium; LV, left ventricle; RV, right ventricle; SAM, subaortic membrane. (Image courtesy of Dr. William Ravekes, Division of Pediatric Cardiology, Johns Hopkins Hospital.)

With accurate echocardiographic assessment, cardiac catheterization is rarely required in the diagnostic evaluation of subaortic stenosis. It may be indicated to assess the severity of obstruction when the clinical and echocardiographic findings are equivocal.

## TREATMENT

***Discrete Fibrous Subaortic Stenosis.*** Surgical excision of a discrete fibrous subaortic membrane is indicated for relief of symptoms, for severe obstruction (mean gradient greater than 30 mm Hg), and when moderate to severe aortic insufficiency is present.[57–59] Asymptomatic patients with mean gradients less than 30 mm Hg and without significant aortic insufficiency do not require surgery but should be followed

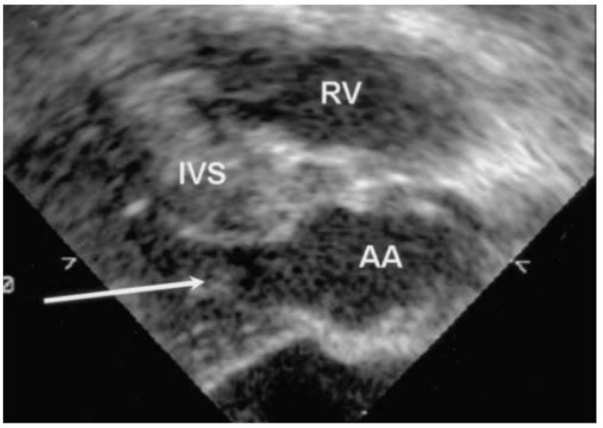

**FIGURE 78-11** Two-dimensional transesophageal echocardiogram of diffuse fibromuscular tunnel-like subaortic stenosis. The arrow points to the subaortic stenotic left ventricular outlet. AA, ascending aorta; IVS, interventricular septum; RV, right ventricle. (Image courtesy of Dr. William Ravekes, Division of Pediatric Cardiology, Johns Hopkins Hospital.)

with serial echocardiograms to detect progression. There is controversy about asymptomatic patients with moderate obstruction and mild aortic insufficiency. Some centers advocate prophylactic excision in all cases, citing the low risk of surgery and the benefit of preventing aortic insufficiency.[60] However, clinically important progression is not universal, and factors determining at-risk substrates are debated.[57] Furthermore, the efficacy of early surgery is controversial because of the variable outcomes in patients undergoing early surgical intervention coupled with a high postoperative prevalence of both recurrent stenosis and aortic regurgitation even after successful relief of subaortic obstruction.[61] Patients with a mean echocardiographic gradient greater than 30 mm Hg, close proximity of the membrane to the aortic valve, and membrane extension to the mitral valve are at higher risk for progressive obstruction and should undergo surgical repair.[62] Older age and a gradient above 30 mm Hg are independent risk factors for progressive aortic insufficiency and are indications for repair.[57,63]

The surgical approach is via a median sternotomy. A single right atrial or a two-stage venous cannula provides venous drainage, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. An oblique aortotomy is made and is extended into the noncoronary sinus of Valsalva. The aortic valve leaflets are gently retracted, allowing visualization of the membrane in the left ventricular outflow tract.

The membrane is grasped anteriorly with a skin hook or a traction suture. A radial incision is made into the membrane, initiated just to the left side of an imaginary line descending from the right coronary ostium, extending just into the underlying septal myocardium. The membrane is then excised circumferentially in a counterclockwise direction by blunt dissection. Care is taken to avoid injury to the anterior leaflet of the mitral valve and the aortic valve leaflets. Resection of additional septal muscle is performed to ensure complete excision of the membrane. Yacoub and colleagues[54] advocate the additional resection of fibrous tissue in the left and right fibrous trigones.

The aortotomy is closed, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass. Transesophageal echocardiography is used to assess relief of obstruction and aortic insufficiency. Mortality after resection of discrete subaortic membrane approaches zero in most series. Permanent heart block and iatrogenic ventricular septal defect occur in fewer than 5 percent of these patients. Reoperation for recurrent obstruction is required in 15 to 20 percent of patients at 5 years.[60,64,65] Multiple studies have suggested that the risk of recurrent obstruction is increased in patients with higher LVOT gradients following initial resection, thus advocating for aggressive pursuit of any residual LVOT gradient documented by intraoperative echocardiographic or direct pressure measurements.[57,60] Aortic insufficiency progresses in 25 percent of patients at 10-year follow-up, and is more likely in patients with a higher mean postoperative echocardiographic gradient and in patients whose preoperative mean echocoardiographic gradient exceeded 30 mm Hg.

The indications for excision of recurrent discrete subaortic stenosis are the same as those for the initial operation. Re-resection with more aggressive septal myectomy is the authors' procedure of choice. In the case of a second recurrence, a modified Konno procedure is performed as described below for the treatment of tunnel-like stenosis.

***Diffuse Fibromuscular Subaortic Stenosis.*** Indications for surgery in patients with tunnel-like subaortic stenosis are the same as those for patients with a discrete subaortic membrane, but relief of the obstruction is technically more challenging. Furthermore, results following surgical treatment are less favorable in this subgroup of patients compared to those obtained following resection of discrete subvalvar stenosis.[66] Resection of fibromuscular tissue from the septum may be possible, but this is often inadequate because of the long circumferential narrowing of the outflow tract. Conal enlargement with a modified Konno procedure is the preferred approach in these patients (Fig. 78-12).[67]

The modified Konno procedure is performed via a median sternotomy incision. The venae cavae are cannulated individually, and the ascending aorta is cannulated distally. The aorta is clamped and cardioplegia is infused in the aortic root. A transverse aortotomy is made just above the sinotubular junction. The subaortic area is inspected through the retracted aortic valve leaflets. A transverse incision is made in the RV infundibulum, allowing visualization of the infundibular septum. A right-angle clamp is passed through the aortic annulus, and a safe site for septal incision is identified. A full-thickness longitudinal septal incision is made through the right ventriculotomy, and subaortic fibromuscular tissue is resected. The resulting ventricular septal defect is closed with a Dacron or Gore-Tex patch. The right ventriculotomy is closed with a bovine pericardial patch, and the patient is weaned from cardiopulmonary bypass. Early mortality was 0 in several large series of patients who underwent a modified Konno procedure. Excellent relief of obstruction is obtained, with no permanent heart block and no hemodynamically significant residual ventricular septal defects. More long-term follow-up is required, but freedom from reoperation at 3 years has been found to be 95 to 100 percent.[68,69]

Placement of a left ventricular apicoaortic valved conduit has been described for patients with severe outflow tract obstruction considered not amenable to conventional repair.[70] The authors believe that nearly all patients can be treated more definitively with resection and a modified Konno procedure.

## Supravalvar Aortic Stenosis

Supravalvar AS is the least common form of LVOTO. The underlying biochemical mechanism is abnormal elastin synthesis that is related to mutations in the chromosome region 7q11.23. This may occur in association with Williams

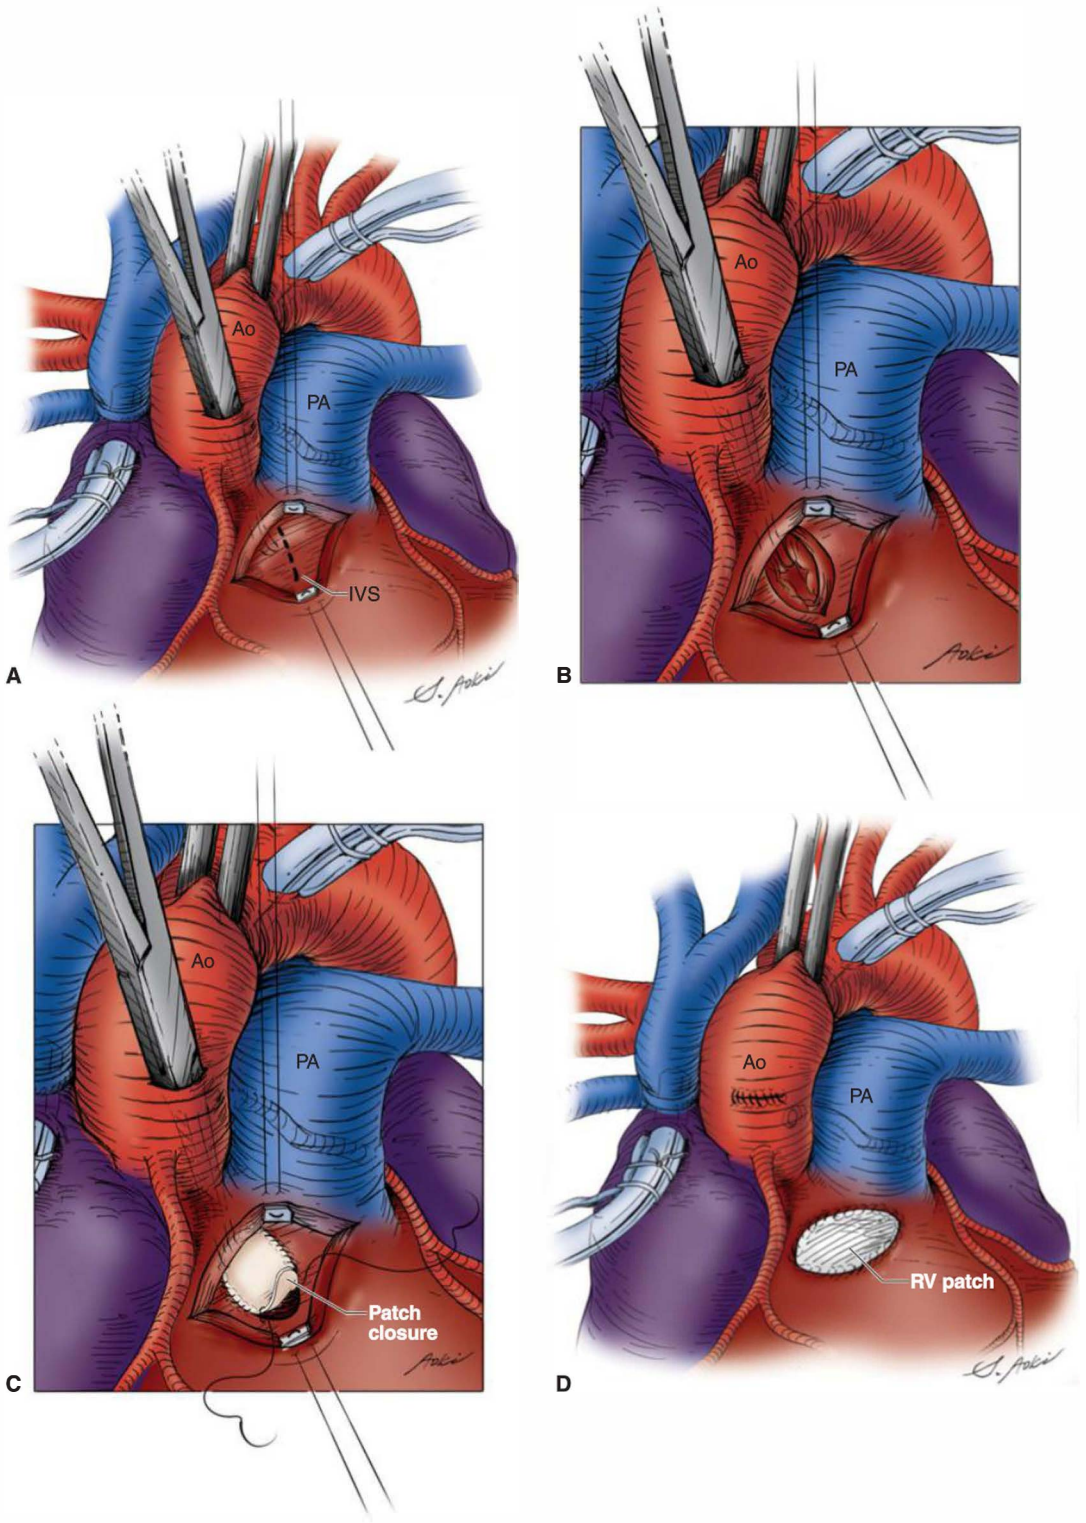

**FIGURE 78-12** Modified Konno procedure. **A.** Transverse incisions are made in the aorta and right ventricular infundibulum. A right-angle clamp is passed through the aortic valve leaflets to identify the site of septal incision. **B.** The septum is incised longitudinally, and fibromuscular tissue is resected. **C.** The ventricular septal defect is closed with a synthetic patch. **D.** The right ventricular incision is closed with a bovine pericardial patch. Ao, aorta; IVS, interventricular septum; PA, pulmonary artery; RV, right ventricle. (Reproduced with permission from Shizuka N. Aoki.)

syndrome, as an autosomal dominant familial trait, or as a sporadic finding.[71]

The pathologic lesion in supravalvar stenosis is a thickening of the aortic wall that results from collagen deposition and smooth muscle hypertrophy in the media as well as hyperplasia and fibrosis of the intima.[72] The narrowing is localized to the sinotubular junction in 85 percent of cases, with either an hourglass or a discrete membranous morphology. Diffuse hypoplasia is present in 15 percent of cases and involves the entire ascending aorta, occasionally extending to the transverse arch and the descending aorta.[73]

Although the site of stenosis may be localized, it is important to recognize that the pathologic process involves the entire aortic root.[74,75] Distortion of the aortic valve and sinuses of Valsalva may occur, including leaflet adherence to the stenotic ridge at the sinotubular junction. Concomitant valvar or subvalvar stenosis is present in 20 to 40 percent of these patients.[73,76,77] Central and peripheral PA stenosis may also occur in association with supravalvar AS.

Coronary ostial stenosis, most commonly involving the left coronary artery, occurs in 25 percent of these patients.[49] Three mechanisms have been identified: (1) thickening of the ostial wall may occur as part of the generalized aortopathy, (2) adherence of the aortic valve cusp to the sinotubular junction may isolate the ostium from the lumen of the aorta, and (3) diffuse narrowing of the left main coronary artery may represent a form of premature atherosclerosis that results from the abnormally high sinus of Valsalva pressures.[78] Ischemic lesions are found in 80 percent of autopsy specimens.[79]

## SIGNS AND SYMPTOMS

Patients with supravalvar AS typically present in the first year of life, although cardiovascular findings are present in less than one-third of these newborns.[80] Symptoms include feeding or exercise intolerance, angina, and syncope. About 10 percent of patients are asymptomatic.[76]

Patients with Williams syndrome may be identified by the presence of dysmorphic "elfin" facies, mental retardation, poor growth, urogenital anomalies, and hypercalcemia. Cardiovascular findings include a systolic ejection murmur with radiation to the neck and poor carotid pulse upstroke.

## DIAGNOSIS

As with other causes of LVOTO, chest x-ray findings are nonspecific. Mild-to-moderate left ventricular and left atrial enlargement may be present.

The electrocardiogram shows left ventricular hypertrophy. ST-segment and T-wave abnormalities consistent with ischemia may be seen in patients with coronary artery involvement. Two-dimensional echocardiography is the usual method of diagnosis in patients with supravalvar AS. Decreased aortic caliber, increased wall thickness, and abnormal leaflet mobility are identified. Localized stenosis can be distinguished from the more diffuse pattern, and the extent of distal involvement can be assessed. Coronary ostial involvement as well as concomitant subaortic stenosis can also be detected. In contrast to valvar and subvalvar stenosis, echocardiographic measurement of peak gradients in supravalvar stenosis correlates poorly with catheter-measured gradients. Echocardiography is, therefore, less helpful in assessing the severity of obstruction and the timing of surgical intervention.[81]

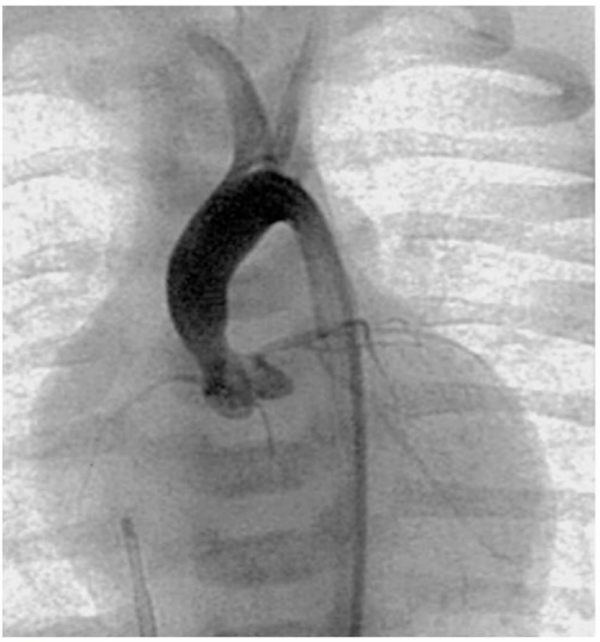

**FIGURE 78-13** Aortogram of supravalvar aortic stenosis. The typical hourglass appearance of the ascending aorta is demonstrated. (Courtesy of Dr. Richard Ringel, Division of Pediatric Cardiology, The Johns Hopkins Hospital.)

Cardiac catheterization is performed routinely to assess patients with supravalvar stenosis when surgical repair is being considered. It is the only method for accurate measurement of the peak systolic gradient. Aortography distinguishes the localized type from diffuse hypoplasia and accurately defines the distal extent of narrowing (Fig. 78-13). Coronary ostial stenosis can also be detected; this is helpful in planning the surgical procedure.

## TREATMENT

Surgical repair of supravalvar AS is indicated in symptomatic patients as well as in asymptomatic patients with a peak catheter-measured systolic gradient greater than 50 mm Hg or an aortic annulus *Z*-score less than –3. The goals of repair are to relieve outflow obstruction and restore normal geometry to the aortic valve and sinuses of Valsalva. Expectant management of asymptomatic patients with lower LVOT gradients is acceptable since lesion regression has been documented in an important proportion of these patients coupled with a similar overall survival in patients treated with and without operative intervention.[82]

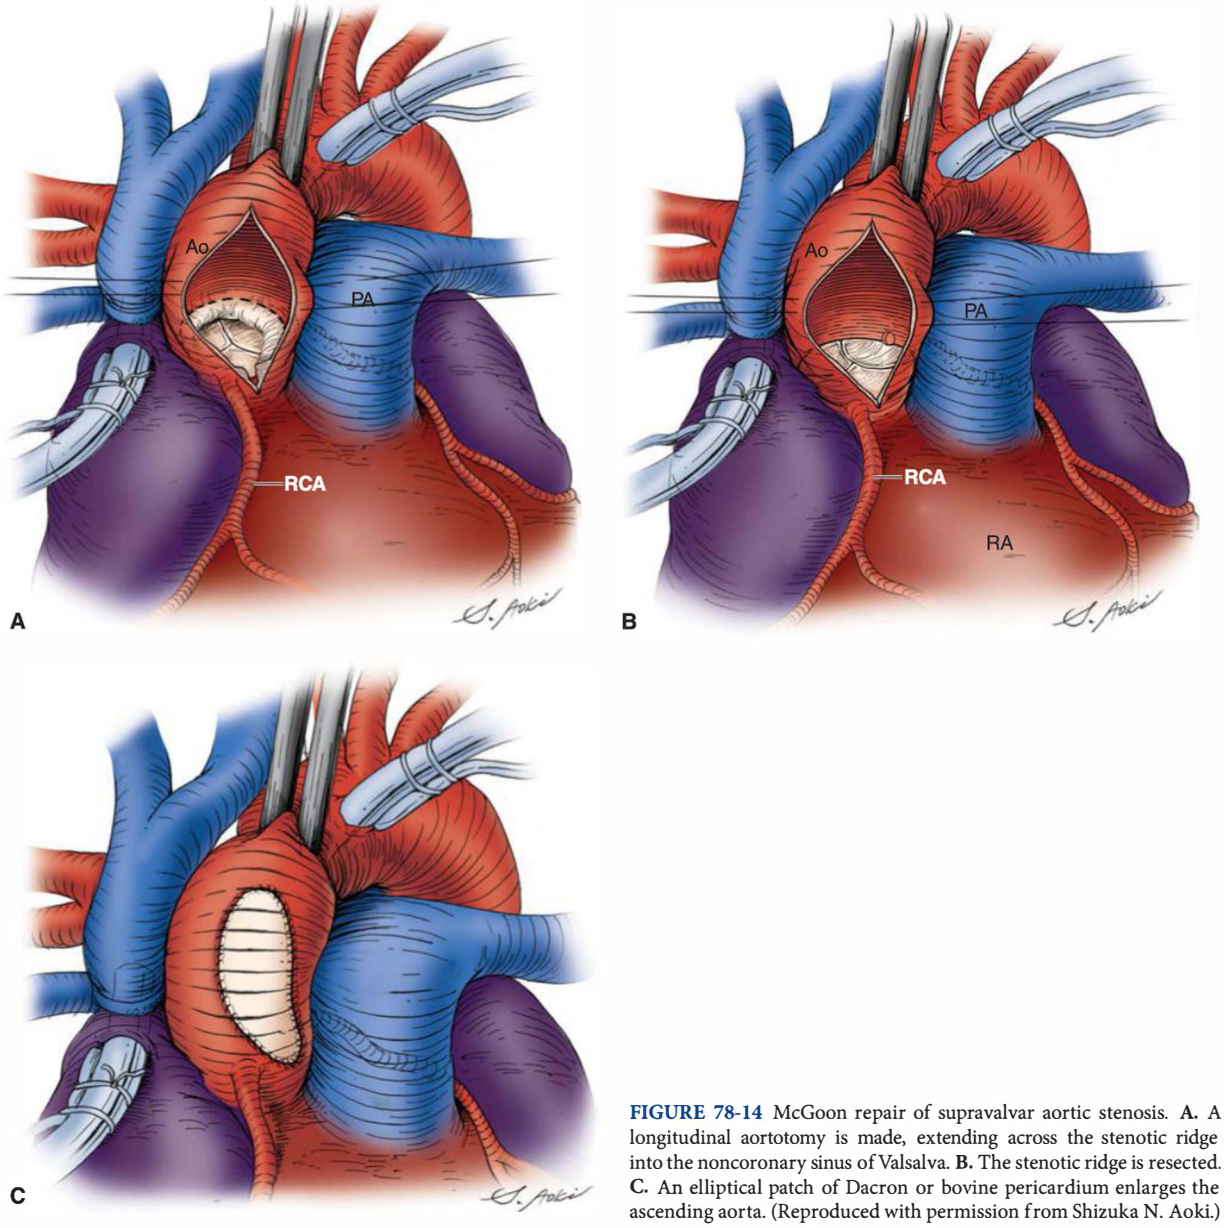

**FIGURE 78-14** McGoon repair of supravalvar aortic stenosis. **A.** A longitudinal aortotomy is made, extending across the stenotic ridge into the noncoronary sinus of Valsalva. **B.** The stenotic ridge is resected. **C.** An elliptical patch of Dacron or bovine pericardium enlarges the ascending aorta. (Reproduced with permission from Shizuka N. Aoki.)

The approach is via a median sternotomy. A single right-atrial cannula provides venous drainage, and the aortic cannula is placed as distally as possible. The aorta is clamped, and cardioplegia is delivered via the aortic root. Surgical repair techniques have evolved considerably since the first description by McGoon[83] in 1961, mainly in an effort to obviate distortion of the aortic root and sinuses and restore a more normal geometric configuration. McGoon and colleagues first performed a longitudinal aortotomy, beginning above the area of narrowing and extending into the noncoronary sinus of Valsalva (Fig. 78-14). The stenotic ridge is excised, and a diamond-shaped patch of bovine pericardium, Dacron, or Gore-Tex is used to augment the ascending aorta. With the recognition that distortion of the aortic valve and sinuses of Valsalva may contribute to outflow obstruction, techniques were developed to maintain greater symmetry of the sinuses. Doty and associates[84] described an inverted Y-incision into the noncoronary and right coronary sinuses of Valsalva (Fig. 78-15). The incision in the right sinus is placed well to the left of the origin of the right coronary artery. A pantaloon-shaped patch enlarges both the ascending aorta and the sinuses. Brom[85] advocated augmentation of all three sinuses (Fig. 78-16). The aorta is transected at the area of narrowing. Incisions are made into each sinus of Valsalva. The sinuses

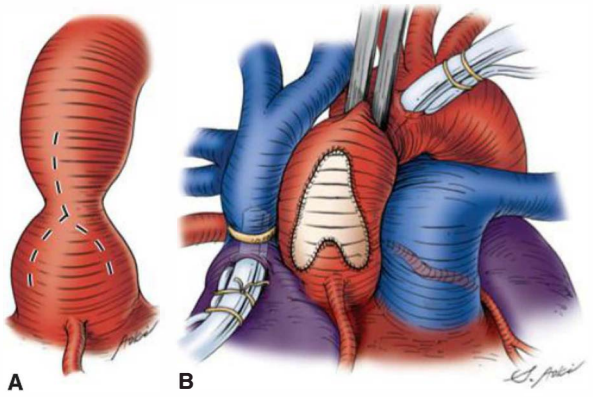

FIGURE 78-15 Doty repair of supravalvar aortic stenosis. **A.** An inverted Y-incision is made into the noncoronary and right sinuses of Valsalva. **B.** The aorta is augmented with a pantaloon-shaped patch. (Reproduced with permission from Shizuka N. Aoki.)

are augmented with triangular patches, and the augmented root is reanastomosed to the ascending aorta. To match in size the aortic root with the ascending aorta, and additional patch on the anterior aspect of the latter might be required. Myers and Waldhausen[86] described an innovative technique to achieve three-sinus augmentation using autologous tissue, termed the slide aortoplasty (Fig. 78-17). The aorta is transected at the area of narrowing, and incisions are made in the sinuses as with Brom's technique. Three incisions are made in the ascending aorta opposite the aortic valve commissures, and the aorta is reapproximated. Variations of this technique include excision of the stenotic segment[87] and the use of an autologous ring of PA to enlarge the sinuses.[88]

Regardless of the technique utilized, the coronary ostia should be inspected carefully to identify any obstruction that may be present. Treatment is based on the mechanism of obstruction. When ostial wall thickening is present, a Brom repair is used, with extension of the left coronary sinus incision into the left main coronary artery. Patch repair of the sinus is continued onto the coronary artery, with resultant coronary ostioplasty.[78,89] Coronary obstruction from leaflet adherence to the stenotic ridge is relieved by careful separation of the fused leaflet and resection of residual tissue around the ostium. Diffuse narrowing of the left main coronary artery requires coronary artery bypass. A saphenous vein graft may be preferable since progressive arteriopathy may involve the subclavian artery and limit internal mammary artery flow.[78]

Patients with diffuse hypoplasia pose a greater surgical challenge. A combination of the techniques discussed above must be tailored to the specific findings that are encountered.[90,91] Involvement of the transverse arch and descending aorta requires extensive augmentation using deep hypothermic circulatory arrest or low-flow bypass with continuous cerebral perfusion.[90–92]

It is difficult to assess the results of surgery for supravalvar AS because of the variability of pathologic findings, the diversity of the techniques employed, and the relatively small

number of patients in each reported series.[93–97] Regardless of the technique, aortoplasty for localized obstruction achieves a long-term reduction of peak gradient from 90 mm Hg to 10 to 30 mm Hg with an early mortality of less than 2 percent.[73,77,93] No consistent differences in short- or long-term outcome were noted between techniques augmenting one, two, or all three sinuses of Valsalva, though Kaushal and colleagues[73,94,95] and Metton and colleagues[96] reported superior outcomes (less aortic insufficiency or stenosis, and reduced reoperation rate) with the Brom technique. Freedom from reoperation at 10 years is 70 to 85 percent, and 10-year actuarial survival is 90 to 95 percent.[76,77,94–96] Reoperation and late death most commonly are related to progressive valve dysfunction, not recurrence of supravalvar stenosis.[73,76,77] Surgery for diffuse supravalvar stenosis is less successful. Early mortality is greater than 10 percent, and rates of reoperation and late death also are increased.[98] Poor aortic growth persists in both the localized and the diffuse forms despite successful relief of obstruction, and so long-term serial monitoring is required.[99]

## SUMMARY

LVOTO is a common form of congenital heart disease that affects the aortic valve, the subvalvar region, and the supravalvar region. Severe stenosis results in left ventricular hypertrophy, cardiac failure, and sudden death. Early diagnosis (primarily by two-dimensional echocardiography) allows assessment of the level and severity of obstruction so that an appropriate plan of management can be designed. Surgery is indicated in symptomatic patients and in asymptomatic patients with moderate-to-severe obstruction or significant aortic regurgitation. Surgical techniques are available to relieve obstruction at all levels. The development of a replacement valve that has growth potential, resists degeneration, and does not require anticoagulation will improve outcomes and quality of life in this group of patients.

## SURGERY FOR LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION IN CHILDREN BOARD REVIEW QUESTIONS (CHAPTER 78)

1. Regarding isolated severe tricuspid valvar aortic stenosis in a 16-year-old male who weighs 110 kg, all listed options would be acceptable surgical therapies EXCEPT:
   A. Replacement of the aortic valve with a mechanical prosthesis
   B. Repair of the aortic valve using surgical valvotomy of the fused right and noncoronary commissures
   C. Ross operation
   D. Replacement of the aortic valve with a bioprosthetic valve

2. A neonate presents with severe acidosis and hypotension. Echocardiogram demonstrates a bicuspid aortic valve with severe stenosis (gradient 70 mm Hg). The most appropriate next step in management is:
   A. Immediate transcatheter balloon valvotomy to relieve aortic obstruction and restore systemic perfusion
   B. Institution of prostaglandin, appropriate inotropic support, and further evaluation of the adequacy of the left-sided structures
   C. Cannulation for venoarterial support with ECMO
   D. Institution of prostaglandin and urgent surgical valvotomy

3. Surgical intervention for discrete aortic valvar stenosis is indicated when:
   A. The echocardiographic mean gradient is >40 mm Hg.
   B. The echocardiographic mean gradient is >25 mm Hg.
   C. There is left ventricular hypertrophy.
   D. There is concomitant aortic valvar insufficiency and stenosis.

4. The Ross operation has the following advantage compared to valve replacement with a bioprosthetic valve:
   A. The autograft possesses growth potential
   B. Absence of need for long-term anticoagulation
   C. Shorter cross-clamp and cardiopulmonary bypass time
   D. Reduced need for further intervention

5. A 100-kg 18-year-old active male is undergoing aortic valve replacement. During the operation, the aortic annulus is sized to 19 mm using calibrated sizers. The most reasonable next step is to:
   A. Implant a 19-mm prosthesis and separate from cardiopulmonary bypass
   B. Perform a posterior annular enlarging procedure and re-size the annulus
   C. Recannulate both vena cavae and perform a Konno aortoventriculoplasty
   D. Implant a 21-mm prosthesis in the supra-annular position

## ANSWERS

1. **Answer: B.** Repair of the aortic valve in isolated valvar stenosis, in the setting of a nonbicuspid valve, is unlikely to be successful. Aortic valvotomy can be tried as an initial strategy in the setting of discrete stenosis involving commissural fusion, but this patient has a trileaflet valve. All of the other listed interventions would be acceptable alternatives. Use of newer generation bioprosthetic valves have shown improved durability, and have made replacement a viable option even in young patients.

2. **Answer: B.** Although the neonate is in shock from severe aortic valvar stenosis, and likely would benefit from relief of the left ventricular outflow tract obstruction (whether surgically or using transcatheter methods), the adequacy of the left-sided structures to support the systemic circulation must be evaluated further with echocardiography. There are multiple predictive algorithms which have been published to assist with the decision making in neonatal critical aortic stenosis, including the "Critical Aortic Stenosis calculator" from the Congenital Heart Surgeons' Society, and the Rhodes' score. The initial management includes institution of prostaglandin to maintain ductal patency, support with inotropes, and resuscitation until the evaluation has been accomplished. ECMO may be required should initial stabilization be unsuccessful, but primary cannulation is not indicated.

3. **Answer: A.** Surgery is indicated when the mean echocardiographic gradient exceeds 40 mm Hg (severe stenosis), evidence of myocardial strain, ischemia on exercise testing, or in the presence of symptoms.

4. **Answer: A.** The bioprosthetic valve does not, obviously, possess growth potential. The Ross operation is technically more demanding and requires a longer cross-clamp and cardiopulmonary bypass time. Unfortunately, patients will require further intervention to replace the RV–PA conduit following a Ross operation, and may also require root replacement to relieve neoaortic dilation and associated neoaortic insufficiency. Newer generation bioprosthetic valves have improved durability compared to older valves, and therefore it is unlikely that patients will require a greater number of interventions to replace a bioprosthetic valve than those undergoing repeat RV–PA conduit interventions. Neither scenario, a Ross operation or a bioprosthetic valve, will require postoperative anticoagulation in the long term.

5. **Answer: B.** This patient is at significant risk for extreme patient–prosthesis mismatch if a 19-mm prosthesis is utilized. The best next step is to perform a posterior annular enlarging procedure such as the Manougian or Nicks procedure and resize the annulus. If the annular area can be enlarged sufficiently to accommodate an appropriately sized prosthesis for the patient's body surface area, this is the appropriate next step. Although a Konno procedure would certainly allow placement of an adequately sized prosthesis, it requires recannulation of both vena cavae and excessive intracardiac manipulation that may not be necessary in this case. Should the initial posterior enlarging procedures prove inadequate, a Konno procedure would be the appropriate next step.

# Coarctation of the Aorta and Interrupted Aortic Arch

*Mark D. Rodefeld*

## KEY CONCEPTS

- **Coarctation of the aorta (CoA)**
  - Introduction
    - CoA is defined as a hemodynamically significant narrowing of the aorta. It occurs in about 4 in 10,000 births and accounts for more than 5 percent of congenital heart defects.
  - Clinical features
    - CoA presents as a spectrum of disease, ranging from neonatal ductal dependence to newly diagnosed, previously unrecognized, long-standing hypertension in an adult. One-third of neonates have an isolated CoA, one-third a ventricular septal defect (VSD), and one-third have complex congenital heart disease. A bicuspid aortic valve is present in 50 percent. Up to 80 percent of neonates with hypoplastic left heart syndrome have a CoA.
  - Diagnosis
    - Echocardiography is the diagnostic modality of choice in neonates. In older patients, computed tomography, magnetic resonance imaging and angiography are employed.
  - Treatment
    - Surgical treatment is preferred, with several techniques available. The choice of procedure depends on the anatomy of the aorta and associated anomalies. Native CoA balloon angioplasty is possible but has decreased long-term success in neonates; its use is perhaps of better application in desperately ill neonates and older children and recoarctation. Endovascular stents have emerged as a possible alternative to surgery, but long-term data are not available.
  - Results
    - Surgical repair of isolated CoA in the neonatal period can be accomplished with minimal morbidity and mortality, whereas the results of repair of CoA in association with complex congenital heart disease vary according to the dominant cardiac pathology and patient-related variables. Recoarctation occurs in up to 30 percent of patients corrected in the neonatal period, with a similar incidence despite the different techniques utilized. Late hypertension is common in patients operated later in life and is partly responsible for the slightly decreased long-term survival of this patient population.
- **Interrupted aortic arch (IAA)**
  - Morphology
    - In this condition there is anatomic lack of continuity in the aortic arch, classified according to the site of occurrence into type A (distal to left subclavian), type B (between the left common carotid and subclavian), and type C (just distal to the innominate artery). Type B is most common and is associated with thymic agenesis and 22q11 microdeletion. The prevalence of IAA is 0.003 per 1000 live births. A VSD is nearly always present. Bicuspid aortic valve is found in 50 percent of infants, with left ventricular outflow tract obstruction (LVOTO) often seen because of hypoplasia of the aortic root or posterior malalignment of the infundibular septum.
  - Clinical features
    - In newborns not prenatally diagnosed, presentation is rapid because of ductal closure and resulting visceral hypoperfusion and shock. Peripheral pulses vary according to the site of interruption and there is variable pulmonary overcirculation. Median time of death if untreated is between 4 and 10 days from birth, with 75 percent mortality within 1 year.
  - Diagnosis
    - Echocardiography is the diagnostic modality of choice in neonates. In more complex anomalies, computed tomography, magnetic resonance imaging, and angiography are employed.
  - Treatment
    - Surgical treatment follows a brief period of stabilization with prostaglandin ($PGE_1$) infusion

and restoration of ductal patency. Single-stage repair of aortic arch interruption and coexisting cardiac anomalies is then undertaken. Alternatively, a staged approach with initial arch repair and banding of the pulmonary artery followed by delayed correction of intracardiac anomalies can be considered.

- Results
  - In the current era, operative mortality following operative repair of an IAA is less than 10 percent. Five-year survival is reported at greater than 70 percent. Reintervention rates (surgical and percutaneous) for arch obstruction at 3-year follow-up range between 15 and 30 percent.

## COARCTATION OF THE AORTA

The term *coarctation* derives from the Latin *coarctare,* to compress. Coarctation of the aorta (CoA) is defined as a congenital narrowing of the aorta that is hemodynamically significant. CoA occurs in more than 4 in 10,000 live births and accounts for more than 5 percent of anomalies in children born with congenital heart defects.[1] Although isolated coarctation is more common in males, coarctation associated with other cardiac lesions occurs with equal frequency in males and females.

CoA can occur along the entire length of the aorta, but is most commonly located proximal to the junction of the ductus arteriosus and the descending aorta (Fig. 79-1). A posterior protuberance of the media, often augmented by ductal tissue, typically creates a "shelf" that protrudes into the aortic lumen. Externally, the aorta may be visibly narrowed, but often to a lesser extent than observed within the lumen. In addition, the aortic isthmus, defined as the segment between the left subclavian artery and the ductus arteriosus, is frequently hypoplastic. In some patients, hypoplasia may involve the entire transverse aortic arch. There are numerous classification systems, all of which are essentially descriptive.

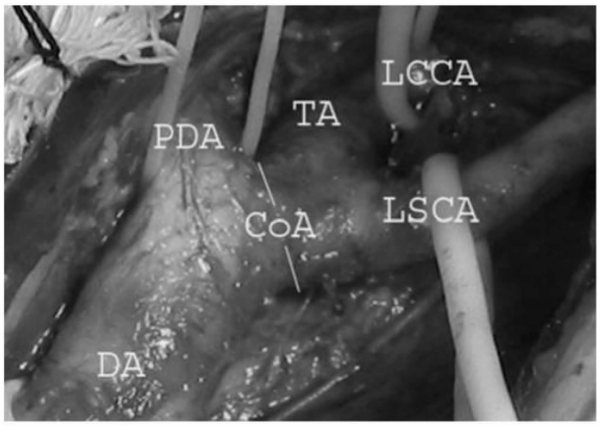

**FIGURE 79-1** Surgical photograph of aortic coarctation in an infant as seen through a left thoracotomy (operating surgeon's view). CoA, coarctation of aorta; DA, descending aorta; LCCA, left common carotid artery; LSCA, left subclavian artery; PDA, patent ductus arteriosus; TA, transverse arch.

The first description of aortic coarctation is credited to Paris in 1791, whereas the first published report of repair by resection and end-to-end anastomosis was by Crafoord in 1944.[2,3] Gross independently described a nearly identical repair in 1945 and was the first to describe the technique of interposition grafting.[4,5] Effective augmentation of the narrowed aortic segment with patch aortoplasty was described by Vossschulte in 1957, while Waldhausen introduced the subclavian flap aortoplasty in 1966.[6,7]

### Etiology

The etiology of aortic coarctation is unknown. Coarctation may be associated with genetic anomalies including Turner syndrome (45X,O) and Noonan syndrome; to date, however, no specific or reproducible molecular abnormality has been identified. In the fetal circulation, right-to-left flow through the ductus arteriosus results in decreased flow across the aortic isthmus with respect to either the ascending or descending aorta. Following postnatal ductal closure, the normal aorta presumably expands and grows in response to increased flow and pressure. This concept is corroborated by an increased incidence of CoA in patients with lesions associated with diminished aortic flow, such as aortic stenosis, ventricular septal defect (VSD), and mitral valve pathology. Furthermore, coarctation is rarely seen in lesions that result in increased aortic flow, such as tetralogy of Fallot.

It has been well recognized that the presence of ductal tissue within the aorta may contribute to this process. The muscular wall of the ductus arteriosus is exquisitely sensitive to changes in neonatal hemodynamics and to pharmacologic agents such as prostaglandin ($PGE_1$) and nonsteroidal anti-inflammatory agents. In some patients, ductal tissue extends well into the adjacent aortic wall and, during ductal contraction, may contribute to the development of coarctation. These findings have been confirmed in histologic studies.[8] Additional biochemical factors have been identified in patients with CoA. The aortic isthmus and, in some, the transverse arch exhibit a higher fraction of elastin lamellae and a lower fraction of α-actin-positive cells. These findings may account for decreased aortic growth.[9]

## Clinical Features

Clinical presentation is determined by the location and degree of aortic narrowing as well as the presence of associated intra- or extracardiac anomalies. Although neonates may appear normal at birth, they develop evidence of aortic obstruction with ductal closure. Manifestations include poor feeding, irritability, and tachypnea. A persistent systolic precordial murmur in the setting of weak or absent femoral pulses should raise the suspicion of aortic coarctation. Other presenting signs include differential oxygen saturations between upper and lower extremities and pulmonary overcirculation from left to right shunting across the patent foramen ovale. In the most severe form, with ductal closure over the first days to weeks of life, the sudden increase in afterload on the nonhypertrophied left ventricle results in a marked decrease in left-sided stroke volume and ejection fraction. Cardiomegaly results from an acute increase in right ventricular end-diastolic volume consequent to increased left-to-right shunting through the patent foramen ovale.[10] Poor perfusion and listlessness may occur. Femoral pulses are not palpable and metabolic acidosis ensues. If CoA is left untreated, end-organ damage (including renal failure and necrotizing enterocolitis) will ultimately result in death.

Infants who undergo more gradual closure of the ductus may develop arterial collaterals, allowing for a less catastrophic presentation. In such cases, the most common finding is usually failure to thrive. These children often have difficulty with feedings and diaphoresis. Physiologically, these infants have compensated for the increase in afterload and present with left ventricular hypertrophy. Older children and adults not diagnosed in infancy (presumably due to less severe disease) commonly present with unexplained hypertension or during the workup of a murmur. Lower extremity pulses are delayed or absent, exercise tolerance may be diminished, and claudication may be a chief complaint. Other symptoms include manifestations of upper body hypertension such as headache, epistaxis, visual field disturbances, and stroke.

## Associated Anomalies

In one report, 82 percent of all coarctations were isolated, 11 percent were associated with a VSD, and complex anatomy was observed in 7 percent.[11] CoA is associated with a bicuspid aortic valve in approximately 50 percent of patients.[12] Since CoA creates a pressure load on the left heart, a patent foramen ovale with a left-to-right shunt is often present. Aortic coarctation occurs in less than 10 percent of patients with transposition of the great vessels and in up to 50 percent of patients with the Taussig–Bing Anomaly (see Chapter 71).[13,14] In these patients, conal malalignment may produce subaortic obstruction with decreased antegrade flow through the transverse arch and isthmus. Hypoplastic left heart syndrome has an 80 percent incidence of CoA.[15] Coarctation is also associated with other forms of functional single ventricle, including tricuspid atresia with transposition of the great arteries and double-inlet left ventricle. Shone complex is characterized by a parachute mitral valve, supra-annular mitral ring, subaortic stenosis, and CoA. These patients present with a spectrum of disease, the most severe of which requires single ventricle palliation.

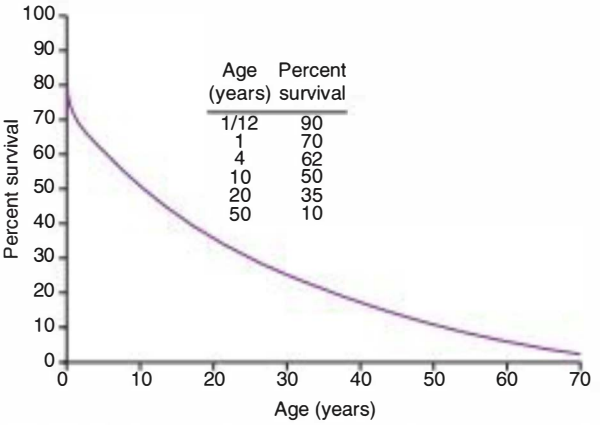

**FIGURE 79-2** Survival of patients with surgically untreated isolated coarctation of the aorta. (From Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). Coarctation of the aorta and interrupted aortic arch. In: *Kirklin/Barratt-Boyes: Cardiac Surgery,* 3rd ed. Philadelphia: Churchill-Livingstone, 2003:1328. With permission.)

## Natural History

Unrecognized CoA is rare in the current era. Untreated coarctation leads to premature death due to complications of unrelenting hypertension, with its attendant effects on the coronary and cerebral circulation. These effects include coronary artery disease, cerebrovascular accidents (both aneurysmal and atherosclerotic), congestive heart failure, and aortic rupture. In addition (particularly in patients with bicuspid aortic valves) bacterial endocarditis can occur. The survival of untreated patients with isolated CoA is depicted in Figure 79-2.

## Diagnostic Modalities

The principal method of diagnosis early in life is echocardiography. In the neonate and infant, the presence of a large thymus allows for excellent visualization of the arch structures (Fig. 79-3). Surface echocardiography provides specific anatomic information including location, length (diffuse versus discrete narrowing), and dimension of the coarctation segment. Severity of obstruction can be assessed quantitatively by measurement of Doppler flow velocity and qualitatively by evaluation of abdominal aortic pulsatility and diastolic flow. The presence of left ventricular hypertrophy also suggests increased severity. In addition, echocardiography allows for the detection of associated intracardiac lesions

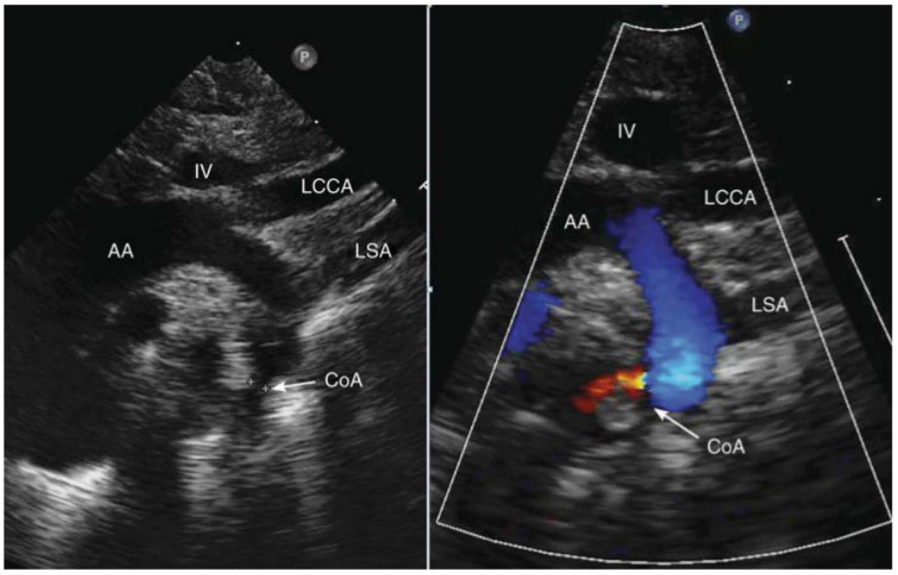

**FIGURE 79-3** Echocardiographic findings in aortic coarctation, with Doppler color imaging (right panel). AA, ascending aorta; CoA (with a rrow), coarctation of aorta; IV, innominate (left brachiocephalic) vein; LCCA, left common carotid artery; LSA, left subclavian artery. The innominate artery is not visible as off-axis in the two frames (Image used with permission of William Ravekes, MD, Johns Hopkins University.)

and transverse arch hypoplasia. In the presence of a patent ductus arteriosus, the ability of echocardiography to diagnose CoA may be limited. As thymic regression ensues, the interposition of lung tissue between the arch and the chest wall obscures echocardiographic details, making echocardiography less useful in older children and adults. In this particular age group, the use of cross-sectional imaging, such as thin-slice computed tomography and magnetic resonance imaging, provides excellent structural detail of the aortic arch and its branches. In addition, as these modalities provide imaging of the entire chest and abdomen, the detection of important collateral arteries is feasible.

Angiography (traditionally viewed as the "gold standard" for aortic evaluation) is now rarely used for diagnosis, as it is invasive and exposes the patient to a nephrotoxic contrast load (Fig. 79-4). However, angiography may be considered with the objective of delineating unclear anatomy and when percutaneous intervention is contemplated.

## Medical Therapy

The role of medical therapy in the treatment of hemodynamically significant CoA is limited to temporizing measures while the timing and method of surgical repair are being considered. The mainstay of medical therapy in neonates is intravenous PGE1 infusion. This maintains patency of the ductus arteriosus, allowing for resuscitation and restoration of end-organ perfusion in compromised infants. Side-effects of $PGE_1$ include generalized edema, hypotension and apnea, sometimes requiring preoperative mechanical ventilation.

In patients who have undergone repair and in those in whom the diagnosis is made later in life, the surveillance and treatment of hypertension is paramount.

## Catheter-Based Intervention

Successful primary treatment of aortic coarctation by balloon angioplasty has been reported but requires further investigation to define its overall efficacy, safety, and long-term durability. The main limitations of balloon angioplasty, particularly in the neonate, are early recurrence of coarctation, aneurysm formation, and access-related injury to the femoral artery. In a recent retrospective review, nearly 60 percent of neonates undergoing primary balloon angioplasty required subsequent surgical repair, and 13 percent developed saccular aneurysms. In the surgical repair group, 18 percent developed recoarctation responsive to balloon dilatation, and no patients developed aneurysms.[16] Balloon angioplasty has a limited role in critically ill neonates who are poor surgical candidates because of severe left ventricular dysfunction or intercurrent illness, allowing for palliation until surgical correction can be safely undertaken. Balloon angioplasty is nevertheless the treatment of choice for recurrent coarctation following neonatal surgical repair, with a greater than 90 percent success rate at relieving the gradient and a 16 percent incidence of restenosis requiring reintervention.[17]

Endovascular stents provide durable relief of aortic coarctation in older children and adults. Stents have a significant advantage over simple angioplasty in that they prevent elastic recoil of the aortic wall, reducing the likelihood of dissection during the procedure. Stent placement in younger children, however, is generally not preferable. Smaller stents cannot undergo serial dilation to keep pace with somatic growth, resulting in the eventual need for a technically difficult surgical repair. Larger stents may allow serial dilatation, but the size of the femoral artery often precludes stent placement in smaller patients. As with surgical intervention, persistent hypertension despite successful relief of obstruction requires diligent surveillance and treatment. In a review of endovascular treatment of CoA in adolescents and adults (1-year follow-up), all patients had persistent resolution of their aortic gradient, with a 13 percent incidence of small aneurysms.[18] Although long-term data are not yet available, midterm results appear to compare favorably with surgical repair.

## Surgical Therapy

Surgical correction is indicated for all symptomatic neonates and infants, as well as older children and adults who are not candidates for transcatheter therapy. Operation should be considered in asymptomatic patients for an upper-to-lower extremity mean blood pressure gradient in excess of 20 mm Hg that is associated with upper extremity hypertension and a greater than 50 percent reduction in luminal diameter in the coarctation segment. A low gradient in the presence of robust collateral development does not exclude severe obstruction and should not be considered a contraindication to surgery.

Following induction of general anesthesia, a right radial arterial line is inserted and the patient is placed in the right lateral decubitus position (for left-sided descending aorta). A left posterolateral thoracotomy through the fourth intercostal space provides ideal exposure for most repairs. Alternatively, a muscle-sparing extrapleural approach can provide adequate exposure with comparable results.[19] In cases requiring associated intracardiac repair or complex transverse arch reconstruction, median sternotomy and cardiopulmonary bypass with circulatory arrest may be utilized; a description of these more complex techniques is beyond the scope of this discussion. Following thoracotomy, the lung is retracted anteroinferiorly and the pleura overlying the aorta and left subclavian artery is incised longitudinally. If present, a supreme intercostal vein and any crossing lymphatics are ligated and divided to prevent the occurrence of a chylothorax. Care is taken to preserve the left vagus nerve and the recurrent laryngeal nerve as it passes around the ligamentum arteriosum or PDA. The pleural edges are suspended by sutures to aid in exposure and retraction of the lung (Fig. 79-5). For all methods of reconstruction, dissection and control of the proximal aortic arch, left common carotid and subclavian arteries, descending aorta, ductus

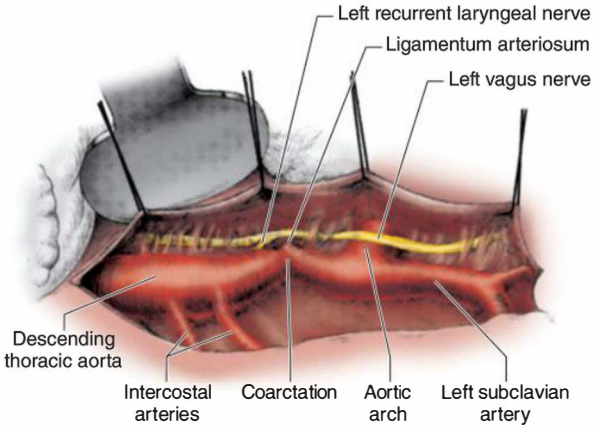

**FIGURE 79-5** Surgical anatomy of a coarctation of the aorta. (From Khonsari S, Sintek CF. *Cardiac Surgery: Safeguards and Pitfalls in Operative Technique,* 3rd ed. Philadelphia: Lippincott, Williams & Wilkins, 2003:188. With permission.)

arteriosus, and intercostal arteries is essential for safe repair. Although it is preferable to preserve the intercostal arteries when possible, several pairs may be sacrificed to obtain a tension-free anastomosis.

## RESECTION WITH END-TO-END ANASTOMOSIS

The ductus arteriosus is ligated and divided. The proximal aorta is clamped obliquely across the left subclavian artery and transverse aortic arch. The distal aorta is clamped well below the planned resection and anastomotic site. In young patients, the left common carotid artery may be safely occluded by the proximal clamp, but the innominate artery must remain patent to preserve cardiac output and cerebral blood flow. This is confirmed by an adequate waveform on the right radial artery pressure monitor and maintained cerebral infrared spectroscopy data (NIRS). In older patients, occlusion of the left common carotid artery may be inadvisable. Care is taken to ensure that the clamps do not distort the area of reconstruction or compress the innominate artery. Intercostal arteries that backbleed into the field should be controlled by temporary clips or snares. The coarctation segment is completely resected, including all ductal tissue macroscopically visible within the aorta. The aorta is then reapproximated in a running fashion using 7-0 suture in neonates and small infants (Fig. 79-6). Interrupted suture placement or the use of absorbable suture material has not been shown to improve results. Generally, a clamp time of less than 30 minutes is felt to be safe. Mild hypothermia is employed by many groups to reduce the risk of spinal cord ischemia.

The primary advantage of resection and end-to-end anastomosis is the complete excision of all abnormal aortic tissue. However, adequate mobilization is required to create a tension-free anastomosis. Mobilization of the distal aorta risks injury to fragile intercostal and collateral vessels in older children and adults. Other techniques of repair may therefore be more appropriate in this age group.

Extended resection with end-to-end anastomosis is necessary in the presence of severe transverse arch hypoplasia. The proximal clamp is placed to the level of the innominate artery and ascending aorta. After the coarctation segment is resected, the underside of the aortic arch is spatulated and anastomosed to the appropriately beveled descending aorta (Fig. 79-7). This results in a larger effective anastomotic

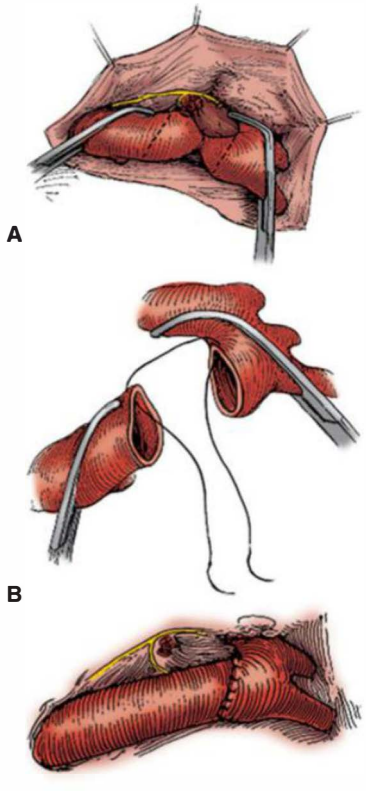

**FIGURE 79-6** Resection of aortic coarctation segment with end-to-end anastomosis. **A.** Proximal and distal control of the aorta is obtained and the ductus is ligated. **B.** The coarctation is resected. The aorta is reapproximated using fine polypropylene suture. **C.** Completed aortic reconstruction. (Reprinted with permission from Shen I, Ungerleider RM. Coarctation of the aorta. orifice area. Extensive proximal and distal mobilization is necessary to allow tension-free approximation.

### SUBCLAVIAN FLAP AORTOPLASTY

Full mobilization of the left subclavian artery is required for this repair. The left subclavian artery is ligated at the level of its first branch, taking care to preserve all distal branches, as they provide the collateral circulation to the left arm. Some surgeons additionally ligate the vertebral artery to prevent late subclavian steal syndrome. The ductus is ligated and a longitudinal aortotomy is begun distal to the area of coarctation. The incision is extended proximally across the coarctation site and into the left subclavian artery, ending just proximal to the previously placed ligature. The left subclavian artery is only then transected and the resulting subclavian flap is turned inferiorly and sutured to the edges of the descending aorta (Fig. 79-8). A "reverse" subclavian flap may be used less commonly for discrete coarctation proximal to the left subclavian artery or distal transverse arch hypoplasia (Fig. 79-9). A reverse subclavian flap aortoplasty can also be combined with an end-to-end anastomosis to address distal arch and isthmic hypoplasia in the setting of coarctation.

The advantages of subclavian flap aortoplasty include ease of repair and the avoidance of extensive aortic mobilization. Adequate length and caliber of the subclavian artery should be ascertained when considering this technique. Subclavian flap aortoplasty is generally avoided beyond infancy because of concern with upper extremity perfusion.

### PATCH AORTOPLASTY

Following clamp placement, the aorta is incised longitudinally across the coarctation, from the left subclavian artery origin to the level of the first intercostal artery (Fig. 79-10). The coarctation ridge is typically not excised, and an oval patch of prosthetic material is fashioned and sutured to the aortotomy margin using continuous suture technique. Care is taken to ensure that the widest portion of the patch overlies the coarctation ridge.

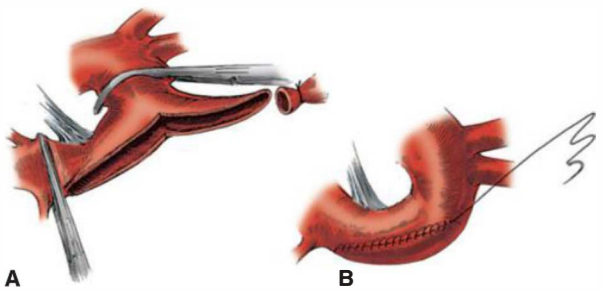

**FIGURE 79-8** Subclavian flap aortoplasty. **A.** The transverse arch and descending aorta are clamped. An aortotomy extends from the descending aorta across the coarctation into the left subclavian artery. **B.** The left subclavian artery is sewn over the isthmus of the aorta using a continuous 7-0 polypropylene suture. (From Aortic coarctation. In: Casteneda AR, Jonas RA, Mayer JE, Hanley FL (eds). *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Elsevier, 1994:347. With permission.)

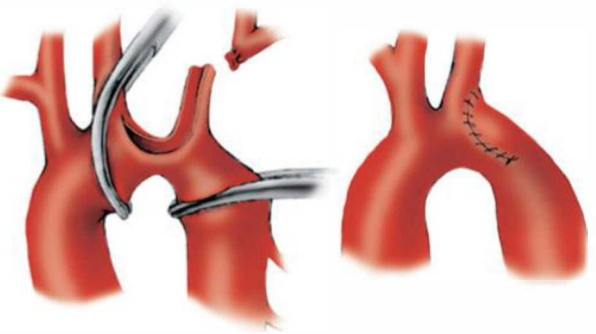

**FIGURE 79-9** Reverse subclavian flap aortoplasty. The left subclavian artery is divided at its first branch (left). An incision is made on the medial aspect of the subclavian artery extending across the superior transverse arch to the origin of the left common carotid artery. The subclavian artery flap is turned medially to augment the transverse aortic arch (right). (From Khonsari S, Sintek CF. *Cardiac Surgery: Safeguards and Pitfalls in Operative Technique*, 3rd ed. Philadelphia: Lippincott, Williams & Wilkins, 2003:188. With permission.)

The advantage of this technique is that it is relatively expedient and can be performed with minimal dissection of collaterals, particularly in the older patient in whom mobilization and a tension-free anastomosis might not be easily achieved. Furthermore, the patch can cover a relatively long coarctation segment and can be made sufficiently redundant to limit the risk of recoarctation. The recoarctation rate is very low, particularly in children above 1 year of age.

The main disadvantage of patch aortoplasty is aneurysmal dilatation in the aortic wall opposite the patch. Rates of aneurysm formation varied widely but in some series have occurred in over 50 percent of patients.[20] It is now recognized that this complication was largely related to the use of Dacron as the patch material in earlier series. The noncompliant quality of Dacron generated excessive tension in the aortic wall opposite the patch.[21] This was accentuated in patients in whom the coarctation ridge was excised. Currently, polytetrafluoroethylene is the prosthetic material of choice for patch aortoplasty. A recent series reported no true aneurysm formation in 125 patients between the ages of 4 days and 17 years.[22]

In older children and adults, where somatic outgrowth is not a concern, interposition grafting can be performed with a technique similar to that described for thoracic aortic aneurysms.

## Management of Associated Anomalies

In patients with complex associated lesions (e.g., transposition of the great arteries, double-outlet right ventricle), the approach and timing of coarctation repair is usually dictated by the management of the more complex anatomy.

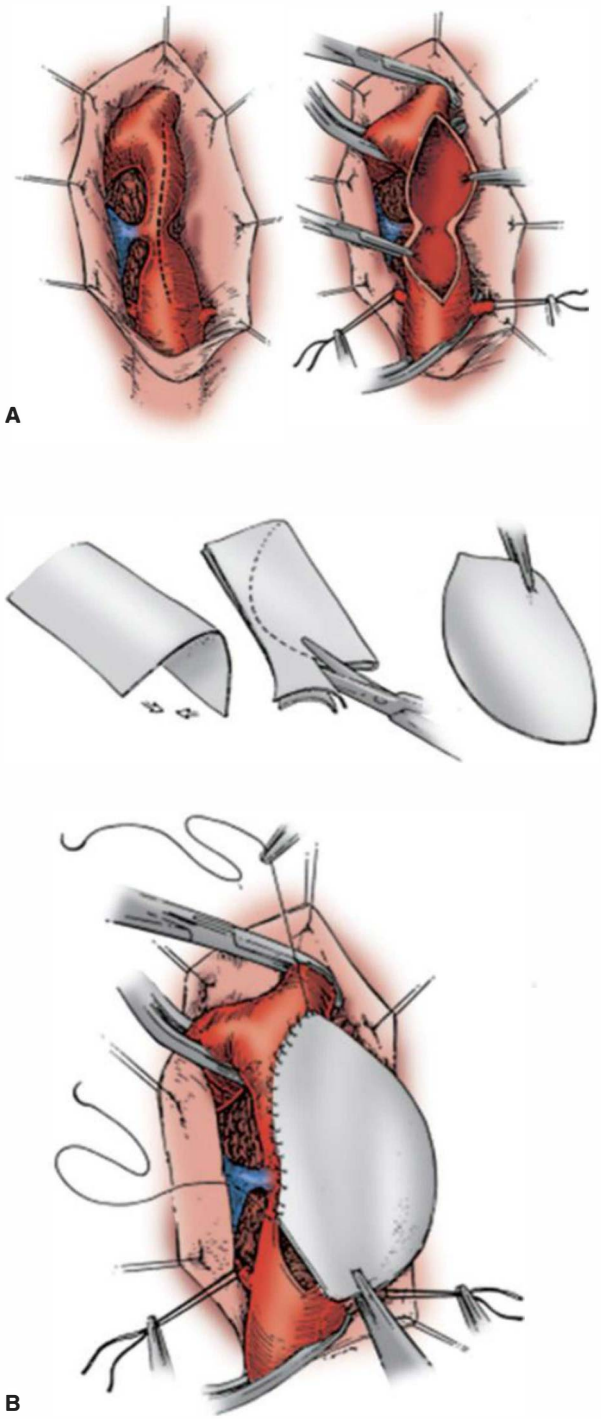

**FIGURE 79-10** Patch aortoplasty. **A.** The aorta is incised longitudinally (dotted) line after obtaining proximal, distal and branch control. The coarctation ridge is left in situ. **B.** An oval patch of polytetrafluoroethylene is fashioned and sutured in place using a continuous suture, ensuring substantial redundancy to allow for growth. (From Backer CL, Paape K, Zales VR, et al. Coarctation of the aorta: Repair with polytetrafluoroethylene patch aortoplasty. *Circulation* 1995;92:132. With permission.)

This typically entails repair via median sternotomy with hypothermic circulatory arrest or low-flow continuous cerebral perfusion. Coarctation repair is performed by patch aortoplasty or resection and extended end-to-end anastomosis.

The management of CoA associated with a VSD remains controversial. Patients with VSDs that are likely to cause congestive heart failure, unlikely to close spontaneously, and have favorable anatomy, may benefit from a single-stage repair of both VSD and coarctation via median sternotomy. Gaynor and colleagues advocate simultaneous repair for all infants with aortic coarctation, moderate-to-large VSDs, and aortic arch hypoplasia.[23] In their retrospective series, median survival at 16 months was 96 percent (actuarial 3-year survival), with actuarial freedom from all reintervention of 71 percent at 1 year and 59 percent at 2 years. Alternatively, some centers advocate pulmonary artery banding at the time of coarctation repair via left thoracotomy. Closure of the VSD and removal of the pulmonary artery band is performed via median sternotomy at 4 to 6 months of age. A multi-institutional study reported a 97-percent 2-year survival in patients undergoing two-stage repair. In this group of 34 patients, 38 percent had undergone subsequent VSD closure and 9 percent had expired, leaving 53 percent free from further surgery at 2-year follow-up.[24] New technologies, such as absorbable pulmonary artery bands and catheter-guided septal occluders, may increase the potential benefits of a two-staged approach.

## Postoperative Management and Early Complications

In the absence of complex congenital heart disease, postoperative management focuses on pain control and pulmonary toilet, as would be expected after any thoracotomy. In neonates, careful monitoring is essential, particularly as this group has a higher incidence of apnea and lobar collapse. Arterial hypertension following repair is common and independent of pain control. So-called paradoxical hypertension can persist for days to weeks following repair and may be related to increased catecholamine levels in a sensitive vascular bed coupled with an overstimulated renin-angiotensin axis. Age-appropriate antihypertensive agents are used carefully in order to avoid hypotension. Five to ten percent of older patients will report abdominal discomfort for a few days following coarctation repair ("postcoarctectomy syndrome"). This is mild in most cases but in some may require a period of bowel rest and nasogastric decompression. The most malignant form of this process can lead to necrotizing mesenteric arteritis requiring bowel resection. Aggressive management of hypertension appears beneficial. Chylothorax may occur secondary to lymphatic leak from mediastinal dissection. Tube thoracostomy drainage should be carefully monitored for chylous characteristics, and clinically significant late pleural effusions should be evaluated by thoracentesis.

Conservative management predominates. Rarely, reoperation for ligation of lymphatics is required. The most feared complication of coarctation repair is paraplegia, with an incidence of up to 0.5 percent in some series.[25] A number of contributing factors have been identified, including cross-clamp time (greater than 30 min), division of arterial collaterals during dissection, and intraoperative hypotension, among others. The recognition of these factors has resulted in a decreased incidence of paraplegia in the modern era. Preventive measures may include somatosensory evoked potential monitoring, especially in older patients presenting with coarctation.

## Operative Mortality

The development of modern neonatal intensive care has shown a positive impact on the results of surgery for aortic coarctation. Most patients arrive in the operating room in stable condition and are closely monitored in the immediate postoperative period. Although early and late morbidity may occur, perioperative mortality remains rare. Serfontein and Kron reported neonatal mortality of 1.2 percent, and this was directly related to the presence of preoperative instability.[26] In older patients the operation is even safer unless CoA is accompanied by significant associated anomalies.

## Long-Term Results

The development of long-term complications is not rare.[27] Table 79-1 summarizes key long-term sequelae, their incidence, and considerations regarding their etiology.

### HYPERTENSION

Hypertension is frequently reversed immediately following repair. Unfortunately, there is a significant incidence of late postoperative hypertension independent of recurrent coarctation, which may account for many of the long-term sequelae in these patients. The etiology of hypertension is multifactorial. At least some component is a result of renin overactivity, as renal perfusion is limited by the coarctation. Other contributing factors include deranged baroreceptor and endothelial function and abnormal arterial wall stiffness in the upper extremities.[28] The result is a poorly defined vasculopathic state associated with persistent hypertension throughout life. The roles of prenatal hemodynamics and delayed early treatment are also unknown.

### RECURRENT COARCTATION

Recurrence of aortic coarctation is a process largely limited to repairs performed in the neonate. The overall recurrence rate depends on the original morphology, patient's age and weight at repair, associated anomalies, type of repair used, and vigilance of postoperative surveillance. Most centers use the same criteria for recurrence as with initial diagnosis: a pressure gradient across the lesion of greater than 20 mm Hg. The recurrence rate in neonates weighing less than 2 kg may be as high as 44 percent,[29] but it is between 15 and 20 percent overall.[16,30] There is a 2 percent recurrence rate following coarctation repair in adults.[31]

### ANEURYSM FORMATION

As discussed above, the development of aneurysms following patch repair with a polyester prosthetic patch has been

**TABLE 79-1: Risk Factors for Complications Following Repair of Coarctation of the Aorta**

| Complication | Prevalence (%) | Cause of Death (%) | Risk Factors |
|---|---|---|---|

well described. In addition, pseudoaneurysm formation along suture lines has been reported. These can become further complicated if they are mycotic.

### LATE MORTALITY

The true incidence of long-term mortality directly related to CoA is difficult to determine. Heterogeneity of patient groups, loss to follow-up, and the underdetection of hypertension-related deaths preclude simple analysis. In the perioperative period, mortality is less than 3 percent, and is more than likely independent of technique of repair.[23,32] More important to the survival of these patients is the presence or absence of complex congenital heart disease. Late mortality appears to be related to the sequelae of uncontrolled hypertension, such as congestive heart failure, cerebrovascular events, and aortic dissection or rupture.[26]

## Conclusions

Aortic coarctation presents in a diverse population, ranging from critically ill neonates with complex congenital anatomy to adults with newly diagnosed refractory hypertension. The efficacy of surgical therapy is well established, with several acceptable techniques for resection and repair being available. The presence of associated congenital anomalies is the largest risk factor for both prognosis and mortality. Catheter-based interventions may be appropriate in some older patients, but surgical repair remains the treatment of choice for the majority of patients with aortic coarctation.

# INTERRUPTED AORTIC ARCH

Interrupted aortic arch (IAA) describes a congenital cardiovascular malformation involving an anatomic lack of continuity between the proximal and distal components of this vascular structure. Unlike coarctation, it is a complete disruption of the aorta. It is frequently associated with presence of a VSD and a spectrum of hypoplasia of left-sided heart structures secondary to limited left heart outflow in fetal life. In addition, there is an association with microdeletion of the q11 segment of chromosome 22, which may involve issues of developmental delay and cognitive sequelae.

IAA comprises 1 to 4 percent of autopsy cases of congenital heart disease and represents 1.3 percent of infants presenting with congenital cardiovascular disease. The estimated prevalence is 0.003 per 1000 births.[33] Untreated, this uncommon anomaly has a median age at death between 4 and 10 days, with a 75 percent mortality within 1 month.[34] Death occurs with closure of the ductus arteriosus. If the ductus remains open longer, survival is possible; however, mortality is then 90 percent by 1 year.[35]

This malformation was first described by Steidele in 1778.[36] Surgical intervention was first described by Merrill in 1955, where a direct anastomosis was performed in a patient with short segment IAA.[37] An associated VSD was not closed at the time of repair. By 1959, Celoria and Patton had collected 28 cases that were classified according to site of obstruction.[38] Villalobos and colleagues as well as Blake and colleagues each reported a successful case during the early 1960s, in which they employed a prosthetic graft for repair.[39,40] Sirak and colleagues were the first to describe the use of "turned down" arch vessels in the reconstruction as well as the first neonate to survive this repair.[41] Barratt-Boyes and coworkers in 1970 performed the first simultaneous repair of aortic arch interruption and VSD closure.[42] This procedure was performed using deep hypothermic circulatory arrest via thoracotomy and median sternotomy. The first simultaneous IAA and VSD repair via the anterior approach and without use of a prosthetic graft was reported by Trusler in 1975.[43] The treatment of IAA was revolutionized with the introduction of $PGE_1$ in 1976 by Elliot and colleagues.[44]

## Embryology

The aortic arch is described anatomically as having proximal and distal components. In early fetal development, there are six aortic arches. These connect with the right and left dorsal aortas distally (descending aorta) and with the conotruncus proximally (proximal aorta). Arches I to III subsequently regress to become facial and skull vessels.[45]

In normal embryogenesis, the proximal aortic arch originates from the left horn of the aortic sac to develop the portion between the innominate and left carotid arteries. The distal arch (between the left carotid and left subclavian arteries) is derived from the left fourth aortic arch. The aorta between the left subclavian artery and the ductus arteriosus is derived from the confluence of the dorsal aorta and the left sixth arch. The site of interruption is associated morphologically with a specific abnormality in the development of these aortic arches.[45]

## Morphology and Classification

Celoria and Patton introduced a classification system for IAA in 1959 (Fig. 79-11).[38] Type A interruption was described as occurring distal to the left subclavian artery. In this subset, the interruption yields a duct-dependent environment for lower-body perfusion. This form of IAA has also been described as "aortic atresia" and classically presents with a fibrous cord with no luminal continuity spanning the interruption. The length of interruption may vary and can approach up to 3 cm in some cases. Type B interruption occurs between the left common carotid artery and the left subclavian artery. It is the most common type of IAA, with an approximate incidence of 60 to 70 percent.[46] It is important to note that type B IAA can be associated with an aberrant right subclavian artery originating from the distal descending thoracic aorta. This associated anomaly is correlated with the nomenclature of

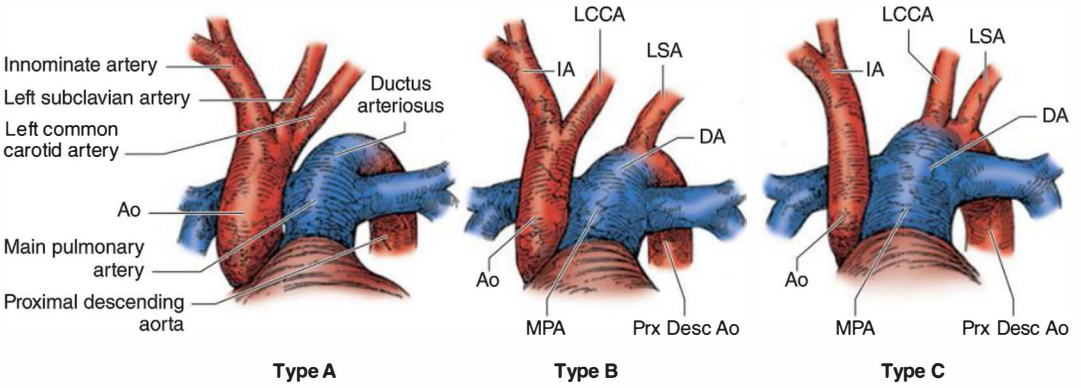

**FIGURE 79-11** Celoria and Patton morphologic classification of aortic arch interruption, according to the site of anatomic discontinuity along the arch. (From Jonas RA. Interrupted aortic arch. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery,* 3rd ed. Philadelphia: Mosby, 2003:345–359. With permission.)

type $B_1$ versus type $B_2$ IAA. Type B IAA is also the specific subtype associated with DiGeorge syndrome and 22q11 microdeletion. Type C interruption is found between the innominate artery and left common carotid artery. It is the rarest form, comprising less than 5 percent of IAAs.[47]

## Associated Cardiac Anomalies

Anomalies of the brachiocephalic vessels are relatively common. As mentioned, an aberrant right subclavian artery originating as a fourth brachiocephalic branch from the descending thoracic aorta is common in type B but may also be found in type A IAA. Other abnormal origins of the right subclavian artery include a cervical takeoff from the right common carotid artery or from a right-sided ductus, which itself is originating from the right pulmonary artery.[48]

The aortic valve is bicuspid in approximately 30 to 50 percent of patients with IAA, as is the case with aortic coarctation. Subaortic stenosis may be present or may develop later, especially in cases involving type B IAA and an aberrant origin of the right subclavian artery. This is due to the increased flow via the ductus arteriosus during fetal development and less flow via the left ventricular outflow tract (LVOT).[34]

A coexisting large VSD is nearly always present. Aside from a PDA, it is the most common associated anomaly, occurring in approximately 75 percent. This anatomic anomaly (with the septum frequently being malaligned and displaced posteriorly) creates a large muscular ridge known as the muscle of Moulaert.[34,49] This structure may protrude into the subaortic region, resulting in left ventricular outflow tract obstruction (LVOTO).

An atrial septal defect can also be seen in association with IAA. It is usually of the patent foramen ovale variety but can at times be large and thus physiologically significant. Other lesions such as truncus arteriosus (common arterial trunk), transposition of the great arteries, or aortopulmonary window may coexist.

## Clinical Presentation and Diagnosis

Via ultrasound evaluation, prenatal diagnosis has become common. Infusion of $PGE_1$ is initiated immediately following birth. In infants in whom a diagnosis has not been made prenatally, clinical sequelae are often not present until ductal closure. Subsequently, generalized tissue malperfusion and profound associated acidosis is typical. End-organ issues such as liver dysfunction with elevated hepatic enzymes, kidney failure with anuria, and ischemic gut injury with necrotizing enterocolitis may occur. Myocardial and cerebral injury may also be present due to prolonged systemic acidosis. In cases where ductal closure does not occur, symptoms of congestive heart failure may result, as a consequence of increasing left-to-right shunt via the VSD as pulmonary resistance falls.[50]

Clinical examination findings include abnormal pulses, depending on the location of the interruption. Differential cyanosis between upper and lower extremities is not often present or conclusive. Cardiac murmurs and electrocardiograms are also nonspecific. Chest radiographs may reveal gross cardiomegaly as well as pulmonary congestion.

Echocardiography, the only specific diagnostic modality, is required prior to operative intervention (Fig. 79-12). Cardiac catheterization, which is challenging in neonates presenting in shock, is no longer considered a requirement for diagnosis unless unusual anatomic features require further definition. Using transthoracic echocardiography, the exact site of aortic arch interruption as well as the presence of an associated VSD can typically be determined. In addition, evaluation of the LVOT as well as any other coexisting intracardiac anomalies can be satisfactorily performed. Additional specific data such as the length of interruption, luminal diameter of the aorta, exact dimensions of the LVOT, anatomy of the aortic valve, and presence or absence of thymic tissue are helpful in designing a therapeutic strategy. Body imaging techniques, such as computed tomography and magnetic resonance imaging (Fig. 79-13), can be useful in difficult cases and to aid in surgical planning.

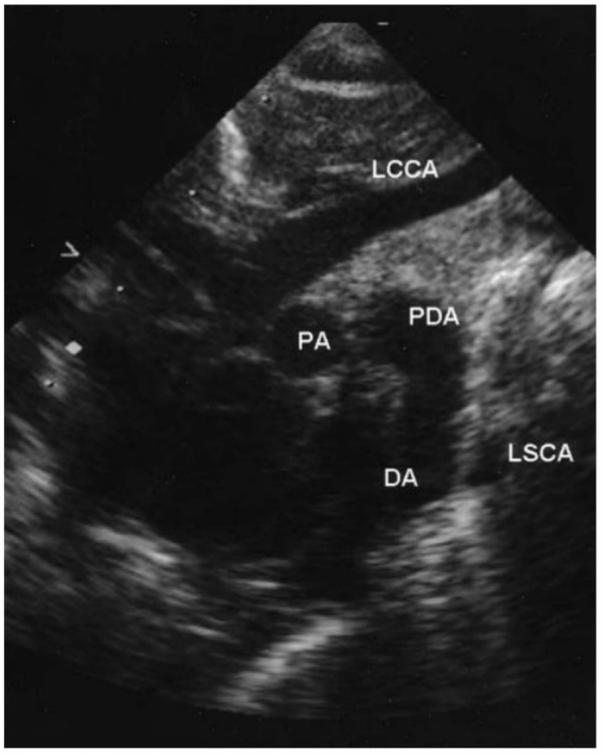

**FIGURE 79-12** Echocardiographic findings in aortic arch interruption type B. No continuity in the arch is noted echocardiographically between the takeoff of the left common carotid and subclavian arteries. AA, ascending aorta; DA, descending aorta; IA, innominate artery; LCCA, left common carotid artery; LSCA, left subclavian artery; PDA, patent ductus arteriosus. **FIGURE 79-13** Magnetic resonance imaging (MRI) in complex aortic arch interruption. Neonate with truncus arteriosus and interrupted aortic arch (type A). Truncus arteriosus (TA) giving rise to right and left (LPA) pulmonary arteries and in direct continuity with the descending aorta (DA) via a patent ductus arteriosus (PDA). The ascending aorta branched in right (RCCA), left (LCCA) common carotid and left subclavian arteries (LSCA). The right subclavian artery (not visible) originated from the proximal right pulmonary artery and was divided intraoperatively. (Courtesy of Philip J. Spevak, MD, Division of Pediatric Cardiology, the Johns Hopkins University.)

## Treatment

### MEDICAL MANAGEMENT

The introduction of $PGE_1$ in 1976 was revolutionary in the treatment of IAA. Reestablishment of ductal flow is an imperative first step in the initial management of this abnormality. Maximization of pulmonary resistance may also be beneficial in increasing systemic blood flow, improving end-organ perfusion and avoiding associated systemic acidosis. This can be achieved by minimizing administration of oxygen as well as employing a strategy of hypoventilation and permissive hypercapnea via specific ventilatory support. Metabolic acidosis should be treated. The achievement of appropriate volume status as well as the use of inotropic agents may also be critical in resuscitation. With medical management, the neonate can be stabilized and will ultimately be a more appropriate candidate for surgical intervention, markedly improving surgical outcomes.

### SURGICAL TECHNIQUES

Improvements in cardiopulmonary bypass technique as well as the use of selective antegrade or regional low-flow cerebral perfusion have changed operative strategies for the treatment of this disease entity. Single-stage repair with direct anastomosis with or without the need for circulatory arrest has become a strategy employed at most centers.[51,52] As an alternative, a staged approach with direct repair of the IAA and pulmonary artery banding for palliation of the VSD, followed by subsequent closure of the VSD, may be considered. Using this philosophy, a left thoracotomy is employed not only for cases of IAA without associated VSD but also in a staged approach for neonates with associated VSD. IAA represents a spectrum of entities; thus the surgical approach must take patient-specific factors into consideration.

In the case of type A IAA, the anatomic abnormality can be conceptually classified in the same category as coarctation. An extended end-to-end anastomosis via left thoracotomy and without the need for cardiopulmonary bypass may be the management of choice if no other intracardiac pathology is present. The choice of a single versus a staged approach for treatment of type B IAA with or without associated cardiac anomalies is more complex.

In neonates undergoing one-stage repair, it is very helpful to place an invasive arterial monitoring line in the right upper extremity. This allows perfusion pressures to be monitored and documented during periods of antegrade cerebral perfusion. Umbilical and/or femoral arterial pressure

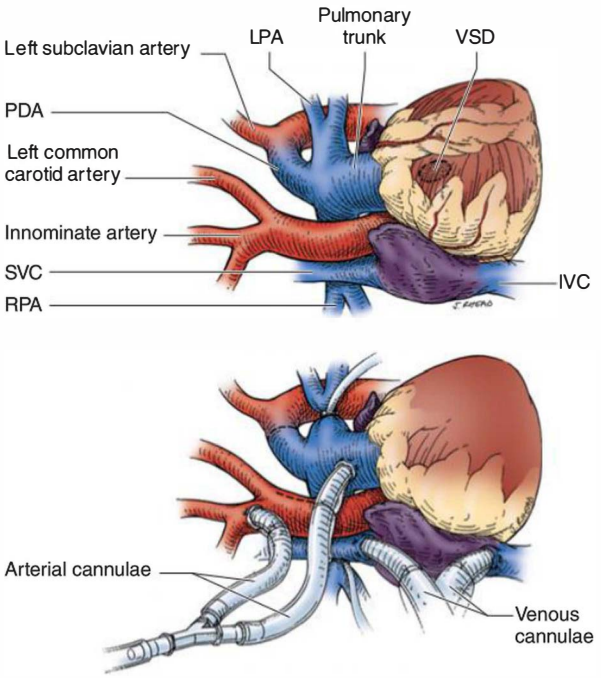

**FIGURE 79-14** Cardiopulmonary bypass (CPB) strategy for repair of type B interrupted aortic arch as schematically represented from the operating surgeon's perspective (top). The arterial return line is bifurcated and introduced into the main pulmonary artery and ascending aorta. The cannulation site for the latter is positioned opposite to the anticipated anastomosis (dotted line, bottom panel). Systemic venous drainage is provided by bicaval or single (in small neonates) venous cannulas. Pulmonary artery snares are tightened on initiation of CPB. IVC, inferior vena cava; LPA, left pulmonary artery; PDA, patent ductus arteriosus; RPA, right pulmonary artery; SVC, superior vena cava; VSD, ventricular septal defect. (From Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). Coarctation of the aorta and interrupted aortic arch. In: *Kirklin/Barratt-Boyes: Cardiac Surgery,* 3rd ed. Philadelphia: Churchill-Livingstone, 2003:1358. With permission.)

can also be monitored to document the adequacy of distal perfusion and postrepair gradients. Single or bicaval venous cannulation is employed for venous drainage. An arterial cannula circuit with a Y-connector split is used to perfuse both the aortic arch proximal to the obstruction as well as the descending aorta via cannulation of the pulmonary artery trunk and advancing it toward the patent ductus arteriosus (Fig. 79-14). Cannulation of the ascending aorta should be performed along its right lateral aspect or separately at the base of the innominate artery to keep the region of the aorta that will be incised for anastomosis to the distal aortic limb clear. Also, once cardiopulmonary bypass has been initiated, it is critical to snare tourniquets around the branch pulmonary arteries to limit pulmonary runoff and preserve distal perfusion via the ductus arteriosus into the descending aorta.

Cooling is initiated with a goal of profound hypothermia (16–18°C). During the cooling phase, the aorta and its branches are extensively mobilized to obtain a tension-free anastomosis. After achieving the desired cooling, the descending aortic perfusion cannula is removed. The distal aorta is subsequently clamped and all ductal tissue is ligated proximally and excised distally.

During arch reconstruction, cerebral and cardiac perfusion pressures should be maintained at approximately 50 mL/kg/min at 22°C if selective antegrade cerebral perfusion is utilized.[53] Flows may be further reduced if the patient is cooled more aggressively. Perfusion pressures can be monitored via a right upper extremity arterial monitoring line. A direct end-to-side aortic anastomosis is performed without tension between the distal aorta and an aortotomy in the proximal aortic limb. The incision is made along the left posterolateral aspect of the ascending aorta, and it is enlarged to approximate the lumen of the distal aortic limb. The anastomosis is initially completed, along the posterior aspect of the vertically oriented ascending aorta (Fig. 79-15). If necessary, patch augmentation of any associated regions of hypoplasia may be considered. In case of anomalous right subclavian artery takeoff, division of this structure may aid in the mobilization of the descending thoracic aorta and improve the likelihood of a tension-free anastomosis.

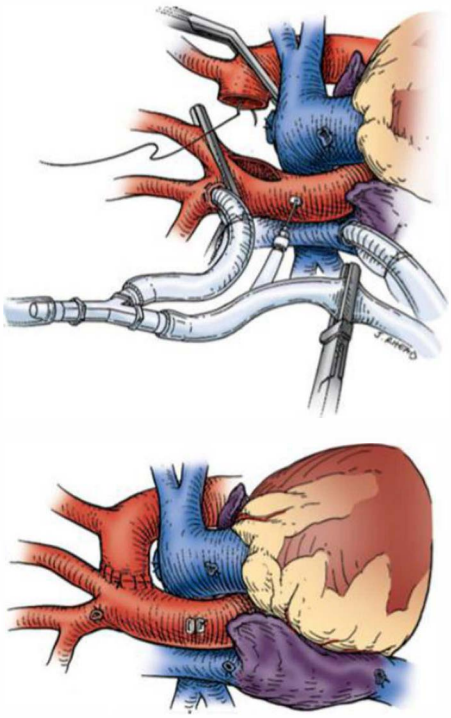

**FIGURE 79-15** End-to-side anastomosis between the ascending and descending aorta in type B aortic arch interruption. The return cannula in the pulmonary artery has been removed and selective antegrade cerebral perfusion is maintained (top). The end-to-side anastomosis is completed with a continuous polypropylene suture (bottom). (From Kouchoukos NT, Blackstone EH, Doty DB, et al. (eds). Coarctation of the aorta and interrupted aortic arch. In: *Kirklin/Barratt-Boyes: Cardiac Surgery,* 3rd ed. Philadelphia: Churchill-Livingstone, 2003:1358. With permission.)

While maintaining distal perfusion and after infusion of cold blood cardioplegia into the aortic root, the ascending aorta can be clamped and the VSD and/or other associated anomalies corrected. These can also be addressed during the initial cooling phase prior to aortic arch reconstruction. Issues related to LVOTO may be treated either via subaortic resection or, in extreme cases, by diverting left ventricular outflow through the VSD and pulmonary artery using an intracardiac baffle. The main pulmonary artery is then divided proximal to its bifurcation site and anastomosed to the side of the native aorta. Subsequently, a right ventricular outflow tract reconstruction is undertaken from the right ventricle to the confluence of the right and left pulmonary arteries.[54,55]

Alternatively, an intracardiac baffle is not performed and ventricular output is directed through both aorta and pulmonary artery [Damus–Kaye–Stansel (DKS) anastomosis] into the aortic arch. A modified Blalock–Taussig shunt is then performed to provide a source of pulmonary blood flow, deferring ventricular baffling and insertion of a right ventricle–pulmonary artery conduit to a later time.

Alternative approaches to the repair of IAA exist and should remain in consideration due to the broad disease spectrum that this entity represents. At the Indiana University School of Medicine–Riley Hospital for Children, a staged approach with the use of a left carotid artery swing-down technique has yielded excellent results. In this technique, via a left fourth interspace thoracotomy, patients underwent division of the left carotid artery with anastomosis of the divided end to the descending aorta (Fig. 79-16). Pulmonary artery banding was employed in cases with associated VSD. Although this strategy has the disadvantage of being a staged palliative approach, outcome data are quite favorable, especially with respect to early mortality. This strategy may be attractive in cases presenting other complex cardiac anomalies or other significant comorbidities such as very low birth weight.[56]

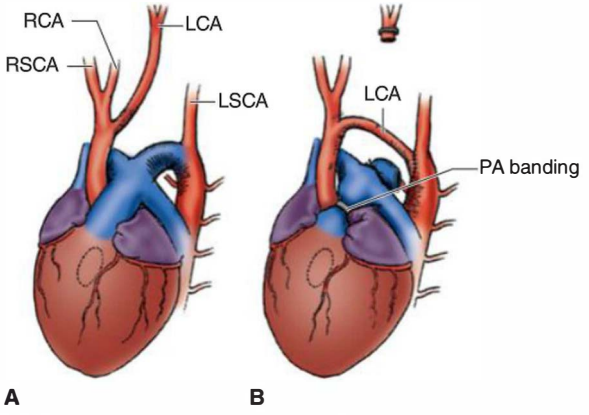

**FIGURE 79-16** Left common carotid (LCA) "turndown" repair of type B (left) aortic arch interruption. The artery is divided distally and anastomosed in an end-to-side fashion to the descending aorta (right). The ventricular septal defect (VSD) is left open and the pulmonary trunk is banded. Ao, aorta; LCA, left carotid artery; LSCA, left subclavian artery; RCA, right carotid artery; RSCA, right subclavian artery. (From Brown JW, Ruzmetov M, Okada Y, et al. Outcomes in patients with interrupted aortic arch and associated anomalies: A 20 year experience. *Eur J Cardiothorac Surg* 2006. In press. With permission.)

Postoperative care of patients with complete repair of a simple IAA should be relatively straightforward. Need for prolonged inotropic support or additional critical care monitoring should prompt a search for additional untreated hemodynamic lesions or uncorrected pathology. An undiagnosed or residual VSD may be identified by analyzing oxygen saturation data from a pulmonary artery line. Echocardiography may also be utilized. In unusual circumstances, cardiac catheterization may yield important data in regard to residual LVOTO.[48]

## Outcomes

Hospital mortality for neonatal single-stage repair of IAA in the current era is less than 10 percent.[46] This figure is unchanged by the presence of an associated VSD. Among subtypes of IAA, mortality has been described to be as low as 4 percent for type A interruption and 11 percent for type B. The highest survival is in the subgroup of patients with isolated type A IAA amenable to complete repair via left thoracotomy. Lowest survival data are published for patients with type C IAA. The presence of coexisting anomalies and the location of interruption have been shown to affect mortality risk. Other risk factors for mortality include preoperative clinical status with regard to degree and adequacy of resuscitation in addition to the presence and severity of LVOTO.[51] Following initial complete intracardiac repair, 5-year survival as high as 70 percent has been documented.[57] The most extensive reported long-term follow-up has been to 16 years and has described an overall survival of 59 percent, with a need for arch reintervention of 28 percent.[58] As additional long-term data become available, these figures will likely improve as a reflection of advances in medical and surgical therapy.

In the Indiana University School of Medicine experience using a staged approach and left carotid swing-down for arch reconstruction, operative mortality for patients with IAA and VSD, regardless of interruption subtype, was 0.3 percent (1 of 44); 27 percent of these patients had associated LVOTO. In patients with more complex associated anomalies, such as Taussig–Bing double-outlet right ventricle or truncus arteriosus, there was no mortality for staged intervention using left carotid swing-down.[56]

Morbidity issues for IAA are somewhat specific to subtype as well as anatomic variations. Left recurrent laryngeal and phrenic nerve injuries may occur owing to the extensive dissection required around the aortic arch and adjacent structures. The left mainstem bronchus passes under the arch of the aorta; as a result, anastomotic tension between the proximal and distal aortic limbs may induce a bowstring effect over the bronchus, yielding airway obstruction and associated pulmonary obstructive issues.

Late morbidity can be divided into two primary categories: persistence of a transaortic gradient or worsening

LVOTO. Pressure gradients across the anastomosis are more likely to occur in situations where synthetic patch material has been employed, owing to a lack of growth potential. The use of autologous tissue is preferable. Patients with a direct arch anastomosis have as high as a 60 percent incidence of late obstruction (gradient greater than 30 mm Hg) within 18 months of surgery.[46] Percutaneous balloon dilatation can safely relieve residual or recurrent arch obstruction in the majority of these patients. In more recent series, however, freedom from reintervention due to gradients across the reconstruction is excellent, reported at 86 percent at 3 years.[53] A more problematic long-term detrimental outcome is late subaortic obstruction or LVOTO. Freedom from reintervention for such pathology has been reported as high as 77 percent at 3 years.[57]

## Conclusions

IAA represents an extreme, life-threatening form of congenital heart disease; it is a lesion that may be treated by several approaches. In the current era, surgical repair yields excellent outcomes. The presenting clinical picture and effective medical stabilization plays a major role in overall outcome. In most centers, single-stage repair is now the preferred operative approach. However, a two-stage approach, with initial arch reconstruction using a left carotid artery swing-down and pulmonary artery banding with subsequent intracardiac repair, yields excellent results and may be considered in selected cases. Early outcomes are dependent on preoperative medical management, subtype of interruption, and extent of associated anomalies. Long-term outcomes are associated with levels of transaortic reconstruction, pressure gradients as well as issues of LVOTO.

## COARCTATION OF THE AORTA AND INTERRUPTED AORTIC ARCH BOARD REVIEW QUESTIONS (CHAPTER 79)

1. Which is not associated with CoA?
   A. VSD
   B. Bicuspid aortic valve
   C. Partial atrioventricular septal defect
   D. Taussig–Bing anomaly
   E. Shone complex

2. Which is correct regarding catheter-based interventions for coarctation?
   A. Nearly 60 percent of neonates undergoing balloon angioplasty will require subsequent surgical repair.
   B. Up to 25 percent of neonates will develop saccular aneurysms after balloon angioplasty.
   C. Less than 5 percent of neonates will develop recoarctation after surgical repair.
   D. Balloon angioplasty has about a 50 percent success rate for relieving the gradient for recurrent coarctation.
   E. There is a 5 percent incidence of restenosis after balloon angioplasty for recurrent coarctation.

3. Which is correct regarding postoperative complications after repair of coarctation?
   A. Arterial hypertension is uncommon.
   B. Postcoarctectomy syndrome occurs in 5 to 10 percent.
   C. Paraplegia occurs in 2 percent of patients.
   D. Division of arterial collaterals is not a risk factor for paraplegia.
   E. Neonatal repair has an operative mortality of 3 percent.

4. Which is not associated with IAA?
   A. Microdeletion of q11 segment of chromosome 22
   B. VSD
   C. Aberrant right subclavian artery
   D. Subpulmonary stenosis
   E. Bicuspid aortic valve

5. Which is correct regarding outcomes after repair of IAA?
   A. Hospital mortality is about 15 percent.
   B. Coexistent anomalies have little effect on risk.
   C. Five-year survival is about 70 percent.
   D. Patients with a direct arch anastomosis have a low incidence of late obstruction.
   E. Subaortic obstruction occurs in nearly 75 percent of patients at 3 years.

## ANSWERS

1. **Answer: C.** Partial AV septal defects are not typically associated with CoA. VSD, bicuspid aortic valve, Taussig–Bing anomaly, and Shone complex are all associated with coarctation.
2. **Answer: A.** Nearly 60 percent of neonates undergoing balloon angioplasty will require subsequent surgical repair. Less than 15 percent of neonates will develop saccular aneurysms after balloon angioplasty. Nearly 20 percent of neonates will develop recurrent coarctation after surgical repair. There is a 90 percent success rate for balloon angioplasty in these patients in relieving the gradient, and about 15 percent will require reintervention.

3. **Answer: B.** Postcoarctectomy syndrome (abdominal discomfort) occurs in 5 to 10 percent of patients for a few days after surgery. Arterial hypertension is common despite adequate repair. Paraplegia occurs in less than 1 percent of patients and has been associated with division of arterial collaterals. Neonatal repair has an operative mortality of less than 2 percent.
4. **Answer: D.** Subaortic, not subpulmonary, stenosis is associated with IAA. As with CoA, VSD and bicuspid aortic valve are common associations. Anomalies of the great vessels are relatively common. Type B interrupted arch is associated with DiGeorge syndrome and 22q11 microdeletions.
5. **Answer: C.** Five-year survival is about 70 percent. Hospital mortality is less than 10 percent in most series. Coexistent anomalies have a significant impact on operative risk. Patients with a direct arch anastomosis have an incidence of late obstruction approaching 60 percent. Subaortic obstruction is less common and occurs in about 25 percent of patients at 3 years.

# 80 Cor Triatriatum

*Giancarlo Crupi*

**KEY CONCEPTS**

- Epidemiology
  - Cor triatriatum is an uncommon congenital cardiac anomaly in which either the left (cor triatriatum sinister) or right (cor triatriatum dexter) atrium is divided into two chambers by a membrane. Subdivided left atrium represents the most frequent anatomic variant of this lesion, and accounts from 0.1 to 0.4 percent of all congenital heart defects.
- Morphology
  - The pulmonary veins enter a proximal chamber (common pulmonary venous chamber) separated by a fibromuscular membrane from a distal chamber where the left atrial appendage and the mitral valve are found. The proximal and distal chambers may communicate through one or more openings within the dividing membrane, and an atrial septal defect (ASD) is usually present.
- Pathophysiology
  - In the absence of associated cardiac lesions, the pathophysiology of subdivided left atrium depends on the resulting obstruction to pulmonary blood flow. Pulmonary overcirculation is present when left-to-right shunting occurs through an ASD between common pulmonary venous chamber and right atrium.
- Clinical features
  - The clinical presentation in infancy is similar to that of total anomalous pulmonary venous connection, with low cardiac output, pallor, tachypnea, poor peripheral pulses, and failure to thrive. Death may occur within the first year of life in 75 percent of untreated patients with significant obstruction. Children and young adults present with signs of pulmonary venous hypertension of various importance.
- Diagnosis
  - Diagnosis is usually established by transthoracic and transesophageal echocardiography, although magnetic resonance imaging (MRI) can be used in selected cases. Cardiac catheterization may be indicated in the presence of associated cardiac lesions.
- Treatment
  - Resection of the membrane through a right atrial approach is recommended in infants, whereas a left atrial approach through the common pulmonary venous chamber may be used in older children and adults and in the presence of associated anomalies. Percutaneous catheter disruption of the membrane may represent an alternative to surgery in selected cases of subdivided right atrium. Outcomes are dependent on the preoperative clinical condition.

## DEFINITION

The classic definition of cor triatriatum is based on the recognition that either the left atrium (cor triatriatum sinister) or the right atrium (cor triatriatum dexter) is divided into two chambers by an abnormal fibromuscular membrane. The terms *subdivided left* or *right atrium*[1-4] will be used throughout this chapter, highlighting in a more comprehensible fashion the basic anomaly of this uncommon cardiac malformation.

In the commonest left-sided variant of this lesion, the pulmonary veins enter a proximal common pulmonary venous chamber, which is separated by a fibromuscular membrane from a distal chamber containing the mitral valve and left atrial appendage.

Subdivided right atrium is a much rarer anomaly in which a membrane, originating from the crista terminalis, divides the trabecular portion of the right atrium from the venae cavae. This entity should be distinguished[5] from the more common occurrence of prominent eustachian or thebesian valves.

## HISTORICAL BACKGROUND

The typical findings of subdivided left atrium were first described in 1868 by Church,[6] although the term *cor triatriatum* was initially applied to this anomaly by Borst in 1905.[7]

Subdivided left atrium was first diagnosed with angiography by Miller in 1964[8] and with echocardiography by Ostman-Smith in 1984.[9] Surgical repair was first accomplished in 1956.[10,11] Cor triatriatum dexter was described by Rokitanski in 1875,[12] yet noninvasive diagnosis by means of echocardiography has been increasingly reported only since 1987.[13] Successful surgical repair of subdivided right atrium was first reported in 1972.[14,15]

## BASIC EMBRYOLOGY

The morphogenesis of subdivided left atrium remains unclear, and the various hypotheses reported thus far[5] fail to explain all the anatomic variants of this anomaly. The entrapment theory proposed by Van Praagh and Corsini[16] is consistent with the findings observed in most cases of subdivided left atrium as well as with the hourglass and the tubular types described by Marin-Garcia and colleagues,[17] where no membrane is seen to divide the common pulmonary venous chamber from the mitral valve and the left atrial appendage. The entrapment theory postulates that subdivided left atrium results from the entrapment of the left atrial ostium of the common pulmonary vein by tissue of the right horn of the sinus venosus, leading to failure in the incorporation of the common pulmonary veins into the left atrium during the fifth week of embryonic development. Consequently, these authors use the term *common pulmonary vein chamber* to describe the proximal chamber, which receives the pulmonary veins. The entrapment theory fails, however, to explain the coexistence of subdivided left atrium with either total or partial anomalous pulmonary venous drainage.[4]

The morphogenesis of subdivided right atrium is less controversial.[3–5] During early cardiac development, the opening of the sinus venosus in the right portion of the common atrium is delineated by two valves, which join superiorly to form the septum spurium. The left valve becomes incorporated in the septum secundum, whereas the superior portion of right valve (which regresses at around 12 weeks of gestation) forms the crista terminalis; the remnants of the inferior portion form the eustachian and thebesian valves. According to Gharagozloo,[5] the obstructing membrane in subdivided right atrium originates from the crista terminalis and should be distinguished from the more commonly observed prominent eustachian or thebesian valves. In essence, subdivided right atrium is caused by the persistence of an unusually prominent right valve of the sinus venosus.

## MORPHOLOGY

The most comprehensive classification of the anatomic variants of subdivided left atrium was reported by Krabill and Lucas.[18] In its classic form (Fig. 80-1), the right and left pulmonary veins enter a common pulmonary venous chamber (proximal chamber), which is, in most instances,

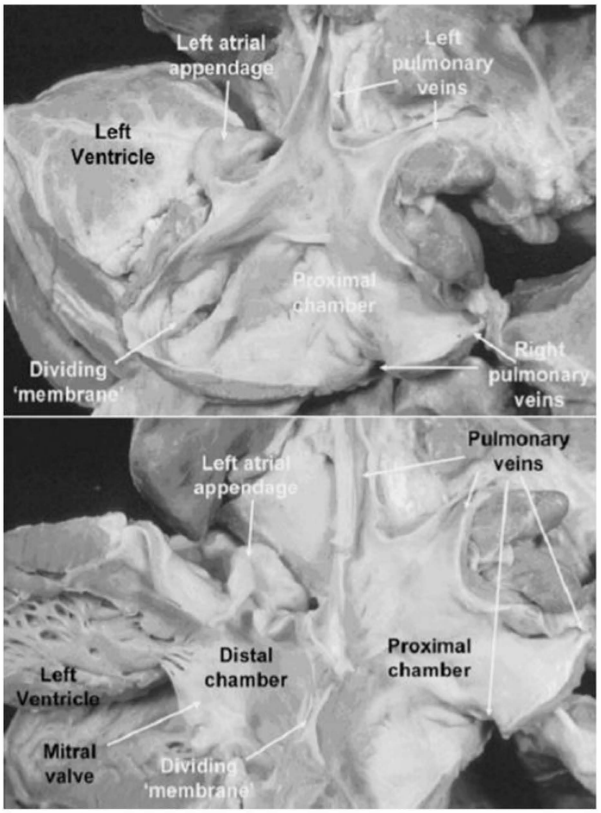

**FIGURE 80-1** Autopsy specimen of subdivided left atrium. Top: The common pulmonary venous chamber (proximal chamber) is opened to show the drainage of the left and right pulmonary veins and the dividing membrane with a fenestration in its center. Bottom: The distal chamber and the left ventricle are opened to show the membrane separating the proximal from the distal chamber, where the mitral valve and the left atrial appendage are seen. (Courtesy of Professor RH Anderson, Institute of Genetic Medicine, Newcastle University.)

separated by a fibromuscular diaphragm from a distal chamber where the mitral valve and the left atrial appendage are found. The dividing membrane may show a single orifice ranging in diameter between less than 3 mm to about 1 cm; occasionally, several small defects might be seen. In two unusual variants of subdivided left atrium (the so-called hourglass and tubular types), no membrane is found to divide the left atrium (Fig. 80-2).[16] In these variants, the thicker-walled common pulmonary vein chamber is usually posterior and somewhat superomedial to the thin-walled proximal chamber. Associated anomalies may be present in more than 50 percent of patients with this lesion. In addition to the more frequent finding of partial and total anomalous pulmonary venous connection, associated anomalies include ventricular septal defect (VSD), atrioventricular septal defect (AVSD or AV canal), tetralogy of Fallot, and coarctation of the aorta. A left superior vena cava[19] is found more frequently than in other types of congenital heart defects and may be associated with a partially or totally unroofed coronary sinus.[20]

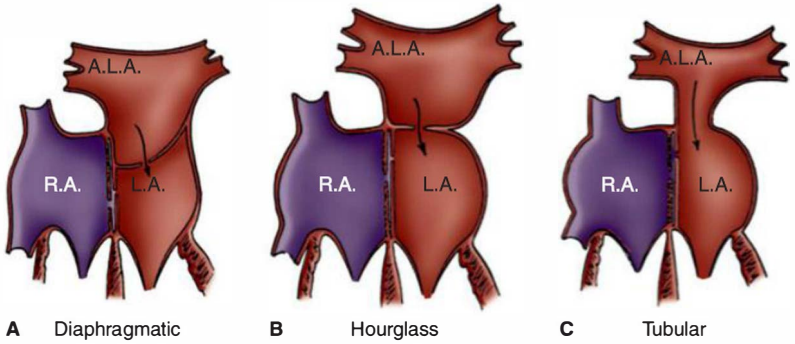

**FIGURE 80-2** Anatomic types of cor triatriatum (subdivided left atrium). **Type A** is the commonest anatomic variant: a fibromuscular membrane divides the accessory left atrial chamber (ALA, representing the common pulmonary venous chamber) from the true left atrium (LA, or distal chamber) where the mitral valve and the left atrial appendage are found. In **type B**, described as the *hourglass type*, a constriction is seen externally at the junction between the common pulmonary venous and distal chambers, where no membrane is found. No dividing membrane can also be found in **type C** (*tubular type*), where a tubular channel receives all the pulmonary veins (common pulmonary venous chamber) and joins the distal chamber. RA, right atrium. (From Marin-Garcia J, Tandon R, Lucas RV Jr, et al. Cor triatriatum: Study of 20 cases. *Am J Cardiol* 1975;35:59. With permission.)

The typical finding of subdivided right atrium is the presence of a membrane separating the right atrial appendage and the tricuspid orifice from the venae cavae and the coronary sinus. The term *subdivided right atrium* should be reserved for those hearts where the dividing membrane originates from the crista terminalis (Fig. 80-3) and, as mentioned above, this entity should be distinguished from those cases of unusual prominence of either the eustachian or thebesian valves, which do not originate from the crista terminalis.[3,5] Yet the former lesion has often been described at necropsy, whereas the latter anatomic variant has been increasingly diagnosed clinically by echocardiography. The most commonly observed cardiac malformations associated with subdivided right atrium include pulmonary valve stenosis or atresia, hypoplastic right ventricle, and tricuspid valve stenosis or atresia.[21,22]

## PATHOPHYSIOLOGY

Obstruction of pulmonary venous return to the left atrium is the key hemodynamic feature of subdivided left atrium. The severity of obstruction is multifactorial and depends not only on the size of the fenestration in the dividing membrane but also on both the presence and size of an ASD between the chamber of the common pulmonary veins and the right atrium, as well as on associated cardiac lesions. Severe pulmonary venous hypertension, indistinguishable from that observed in obstructed total anomalous pulmonary venous connection, is present when the size of the fenestration is severely restrictive (3 mm or less) and the atrial septum is intact. Conversely, when a large ASD is present between the common pulmonary venous chamber and the right atrium or in presence of either a partial or a total unobstructed pulmonary venous return, left-to-right shunting will be present and pulmonary venous obstruction may not be obvious.

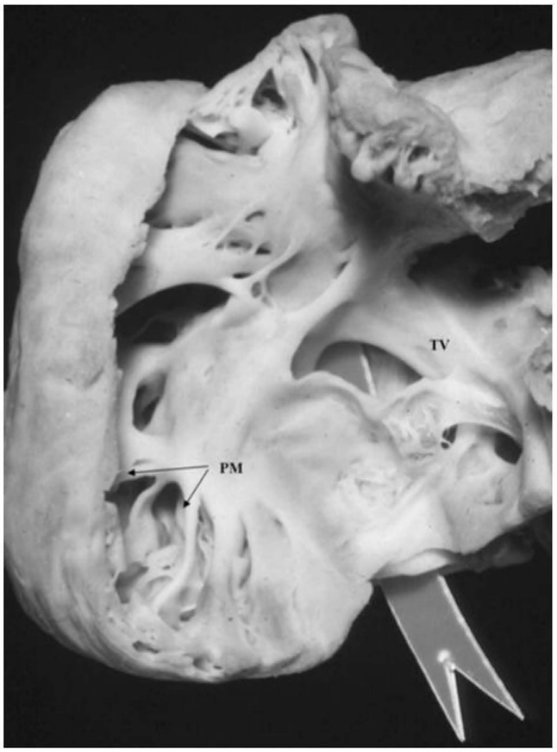

**FIGURE 80-3** Autopsy specimen of subdivided right atrium due to persistence of the right venous valve. The right atrium and the right ventricle are opened to show a large fibrous membrane originating from the crista terminalis and dividing the right atrial appendage and the tricuspid valve from the venae cavae. The membrane deflects blood from the inferior vena cava (through which an arrow is placed) into the left atrium via the fossa ovalis. The opening of the superior vena cava is also behind the venous valve and is not visible. The vestibule of the tricuspid valve is seen to the right lower corner of the figure. PM, pectinates muscles; TV, tricuspid valve. (Courtesy of Professor RH Anderson, Institute of Genetic Medicine, Newcastle University.)

The hemodynamic features of subdivided right atrium are equally based on the severity of obstruction to systemic venous return and on the presence of an ASD. Cyanosis may in fact be frequent due to shunting of inferior caval blood into the left atrium through an ASD. Right-sided congestive heart failure with elevated central venous pressure may be present in cases with intact atrial septum and right ventricular inflow or outflow obstruction.

## CLINICAL FEATURES

The clinical presentation of patients with subdivided left atrium but without major associated lesions will depend on the degree of obstruction to pulmonary blood flow through the dividing membrane. If the communication between the common pulmonary venous chamber and the mitral valve is small (3 mm or less), the patient may become symptomatic in the first few months of life as a consequence of ongoing low cardiac output with pallor, poor peripheral pulses, tachypnea, and growth failure. In the presence of associated anomalous pulmonary venous return or when an ASD is present between the common pulmonary venous chamber and the right atrium, symptoms due to increased pulmonary blood flow (such as recurrent respiratory infections, congestive heart failure, and failure to thrive) may coexist.[23]

The severity and quality of symptoms in patients with subdivided right atrium also seem to depend largely on two variables: the degree of obstruction produced by the membrane and the state of the interatrial septum. With only a minor degree of obstruction, this lesion is often asymptomatic and may be detected only incidentally at surgery for correction of other cardiac anomalies or during echocardiography. Cyanosis due to shunting of the inferior caval blood in the left atrium through an ASD is the dominant clinical feature when the membrane is severely obstructive. This situation is often well tolerated into adult life, and rarely results in severe hypoxemia in infancy. Right-sided heart failure with elevated central venous pressure due to obstruction of the tricuspid valve or the right ventricular outflow tract may occur when the atrial septum is intact.[24]

## DIAGNOSTIC MODALITIES

Echocardiography is the method of choice for identification of both subdivided left and right atrium.[25,26] Two-dimensional transthoracic echocardiography (Fig. 80-4) may be supplemented by transesophageal imaging (Fig. 80-5) for further evaluation.[27] The use of magnetic resonance imaging (MRI) has been increasingly reported in recent literature for diagnosis and preoperative planning. MRI is thought to have a higher sensitivity than echocardiography and angiography.[28] In general, MRI provides better spatial resolution and superior tissue contrast when compared with

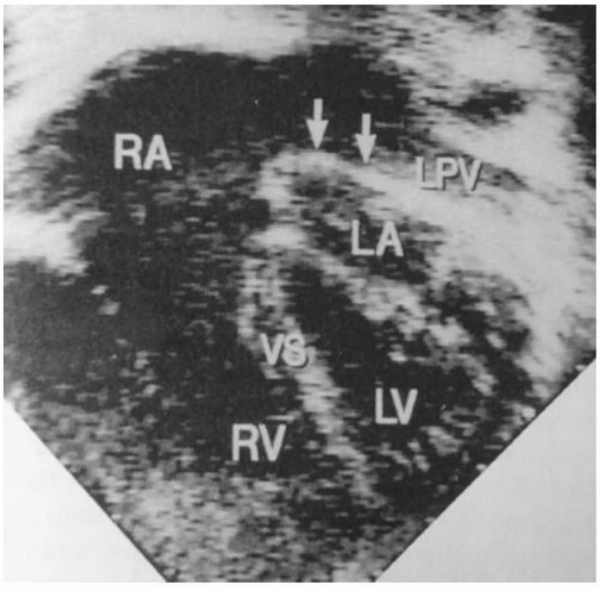

**FIGURE 80-4** Transthoracic echocardiographic imaging (apical four-chamber view) of subdivided left atrium. The common pulmonary venous chamber communicates via a large atrial septal defect with the right atrium and is separated by a membrane (arrow) from the left atrium (distal chamber). LA, left atrium; LV, left ventricle; RA, right atrium; RN, right ventricle; VS, ventricular septum. (From Van Son JA, Autschback R, Mohr FW. Repair of cor triatriatum with partially unroofed coronary sinus. *Ann Thorac Surg* 1999;68:1414. With permission.)

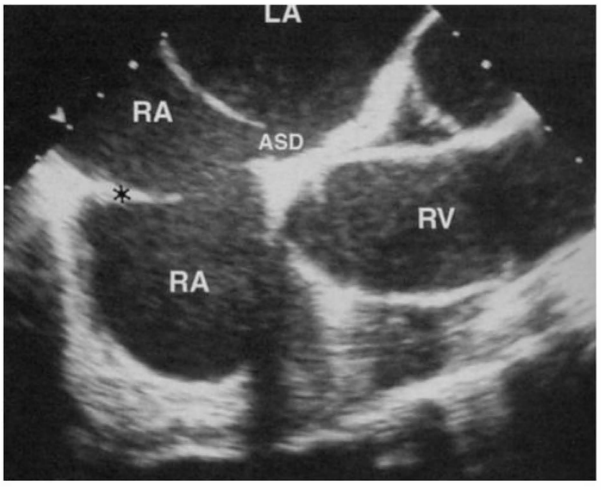

**FIGURE 80-5** Transesophageal echocardiographic imaging of subdivided right atrium. Long-axis view demonstrates the dividing membrane (*) in the right atrium. ASD, atrial septal defect; LA, left atrium; RA, right atrium; RV, right ventricle. (From Joe BN, Poustchi-Amin M, Wooddard PK. Cor triatriatum dexter. *Radiology* 2003;226:702. With permission.)

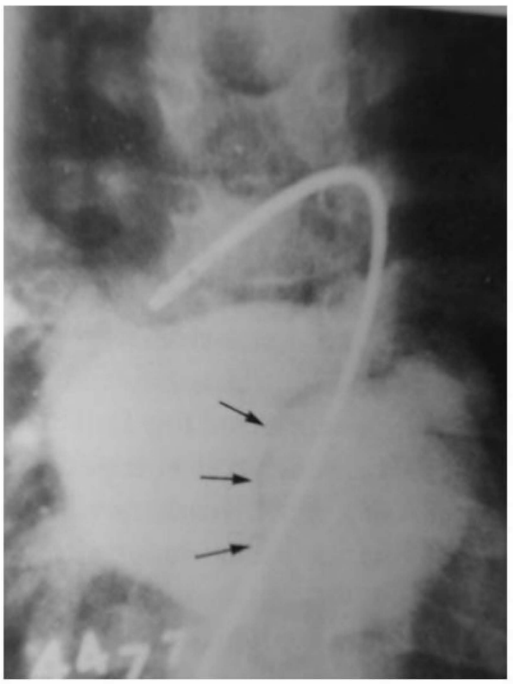

**FIGURE 80-6** Angiographic imaging of subdivided left atrium. Pulmonary artery injection of contrast medium delineates the dividing membrane (arrowed) between the common pulmonary venous chamber and the distal chamber, where the left atrial appendage is seen. The atrial septum was intact. (From Arciniegas E, Farooki ZQ, Hakimi M, et al. Surgical treatment of cor triatriatum. *Ann Thorac Surg* 1981;32:571. With permission.)

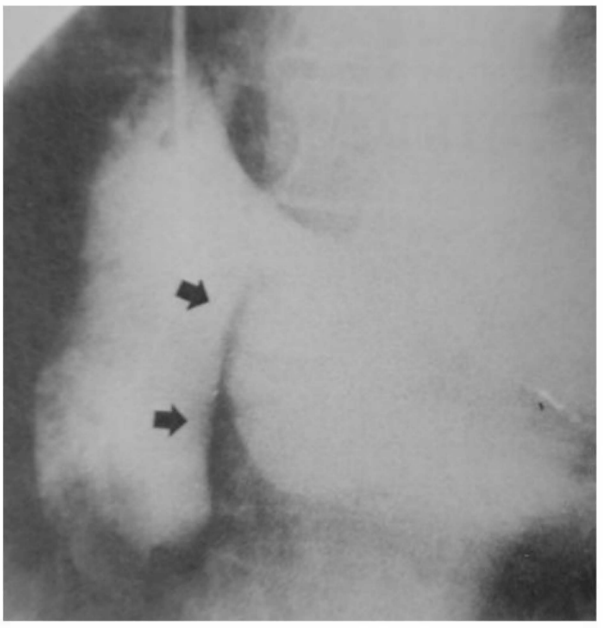

**FIGURE 80-7** Angiographic imaging of subdivided right atrium. Superior vena cava injection of contrast medium demonstrates the division of the right atrium by an abnormal remnant (arrowed) of the right valve of the sinus venosus. (From Ott DA, Cooley DA, Angelini P, et al. Successful surgical correction of symptomatic cor triatriatum dexter. *J Thorac Cardiovasc Surg* 1979;78:573. With permission.)

echocardiography. Cardiac catheterization and angiography (Figs. 80-6 and 80-7) are no longer indicated for the diagnosis of subdivided atrium unless major associated cardiac lesions are suspected.

## SURGICAL MANAGEMENT

Surgery is the only mode of treatment for symptomatic patients with subdivided left atrium. Timing of operation is based primarily on the clinical status, and prompt surgery is indicated for those infants who present with symptoms of severely obstructed pulmonary blood flow. Without surgical treatment, 75 percent of patients born with a significant degree of obstruction die in infancy.[29] Urgent repair is also indicated in older patients presenting with chronic symptoms. Planning of the operation is based on the coexistence and the complexity of associated lesions. Before operation, the drainage of all pulmonary and systemic veins should be ascertained. In the presence of a left superior vena cava (frequently associated with subdivided left atrium), the possibility that the coronary sinus may be partially or totally unroofed should be ruled out.

Moderately hypothermic or normothermic cardiopulmonary bypass with bicaval cannulation and antegrade cold blood cardioplegia may be routinely used in straightforward cases. The strategy of normothermic versus hypothermic cardiopulmonary bypass remains controversial[30–32]; hypothermic circulatory arrest should be used only in the presence of complex associated lesions.[33]

A right atrial approach (Fig. 80-8) is recommended for infants and small children, especially in the presence of an enlarged common pulmonary venous chamber. After aortic cross-clamping, the right atrium is opened through a longitudinal incision parallel to the atrioventricular groove. A longitudinal septal incision is carried out through the fossa ovalis, obtaining optimal exposure of the fibromuscular membrane and of the mitral valve below it. The membrane can be excised completely while preserving the integrity of the mitral valve. The atrial septum is reconstructed with a pericardial patch.

A longitudinal incision in the common pulmonary vein chamber just posterior to the interatrial groove (Fig. 80-9) can be satisfactorily used in older children and adults. Anterior retraction of the atrial septum allows adequate exposure of the membrane for subsequent resection. A potential pitfall of this approach is the initial difficulty of assessing the relationship between the membrane and the mitral valve below it. Closure of the fossa ovalis or patch reconstruction of the atrial septum may be more technically demanding with this approach. Modified ultrafiltration and the use of nitric oxide in infants with severe

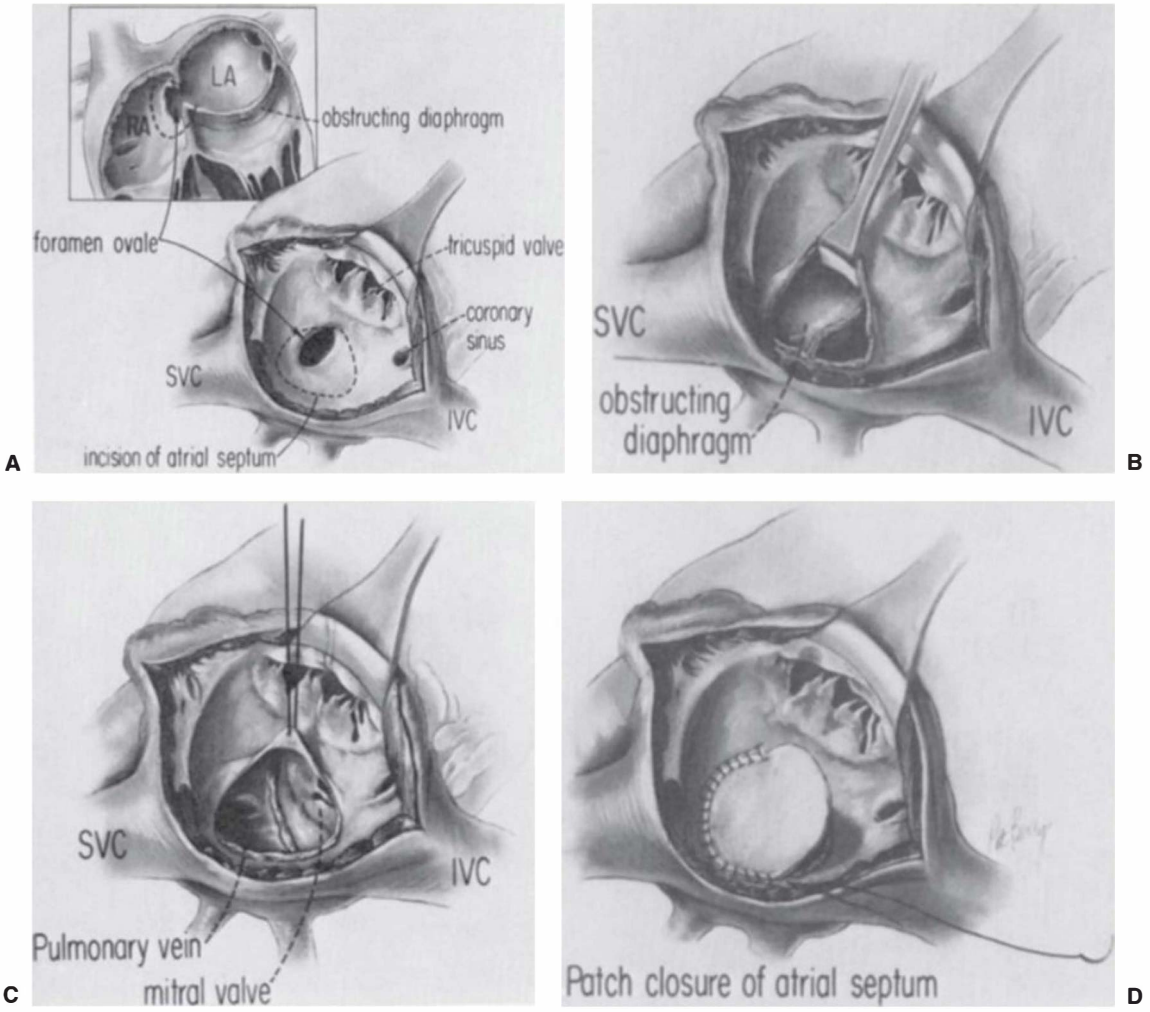

**FIGURE 80-8** Right atrial approach for repair of subdivided left atrium. **A.** Right atrial incision through the superior and inferior margins of the foramen ovale. **B.** These incisions are carried to the right atrial wall, providing simultaneous exposure of both the common pulmonary venous chamber and the distal chamber. This allows careful evaluation of the relationship between the dividing membrane and the mitral valve. **C.** Complete excision of the membrane brings the pulmonary veins and the mitral valve in continuity. **D.** Reconstruction of the septal incision with a pericardial patch. IVC, inferior vena cava; SVC, superior vena cava. (From Richardson JV, Doty DB, Siewers RD, et al. Cor triatriatum (subdivided left atrium). *J Thorac Cardiovasc Surg* 1981;81:232. With permission.)

pulmonary hypertension can be a very useful therapeutic adjunct in the early postoperative phase.

Resection of the obstructing membrane is the treatment of choice in patients with subdivided right atrium, although percutaneous catheter disruption of the membrane[34] may represent an alternative to surgery in selected cases without associated lesions. Transesophageal echocardiography may be useful for a better definition of the relationship of the membrane with the surroundings structures. Normothermic cardiopulmonary bypass on a beating heart with bicaval cannulation may be used in simple cases of subdivided right atrium without septal defects. The surgical approach in the presence of associated anomalies should be tailored to the individual case.

## OUTCOMES

Aside from the description of occasional individual cases,[20,35] there are only a few reports in the literature of relatively large cohorts of patients with cor triatriatum.[23,36] Most of the literature regarding this topic was published in earlier decades,[2,19,37,38] making any comparison with modern practice in the surgical management of infants and small children not entirely meaningful. Regardless of the time of publication, it is not surprising that most reported deaths occurred within the first year of life in infants who were severely symptomatic, or in the presence of complex associated lesions. In high-risk cases, hospital mortality has been reported between 33 and 60 percent.[23,37] These results underscore the importance of an

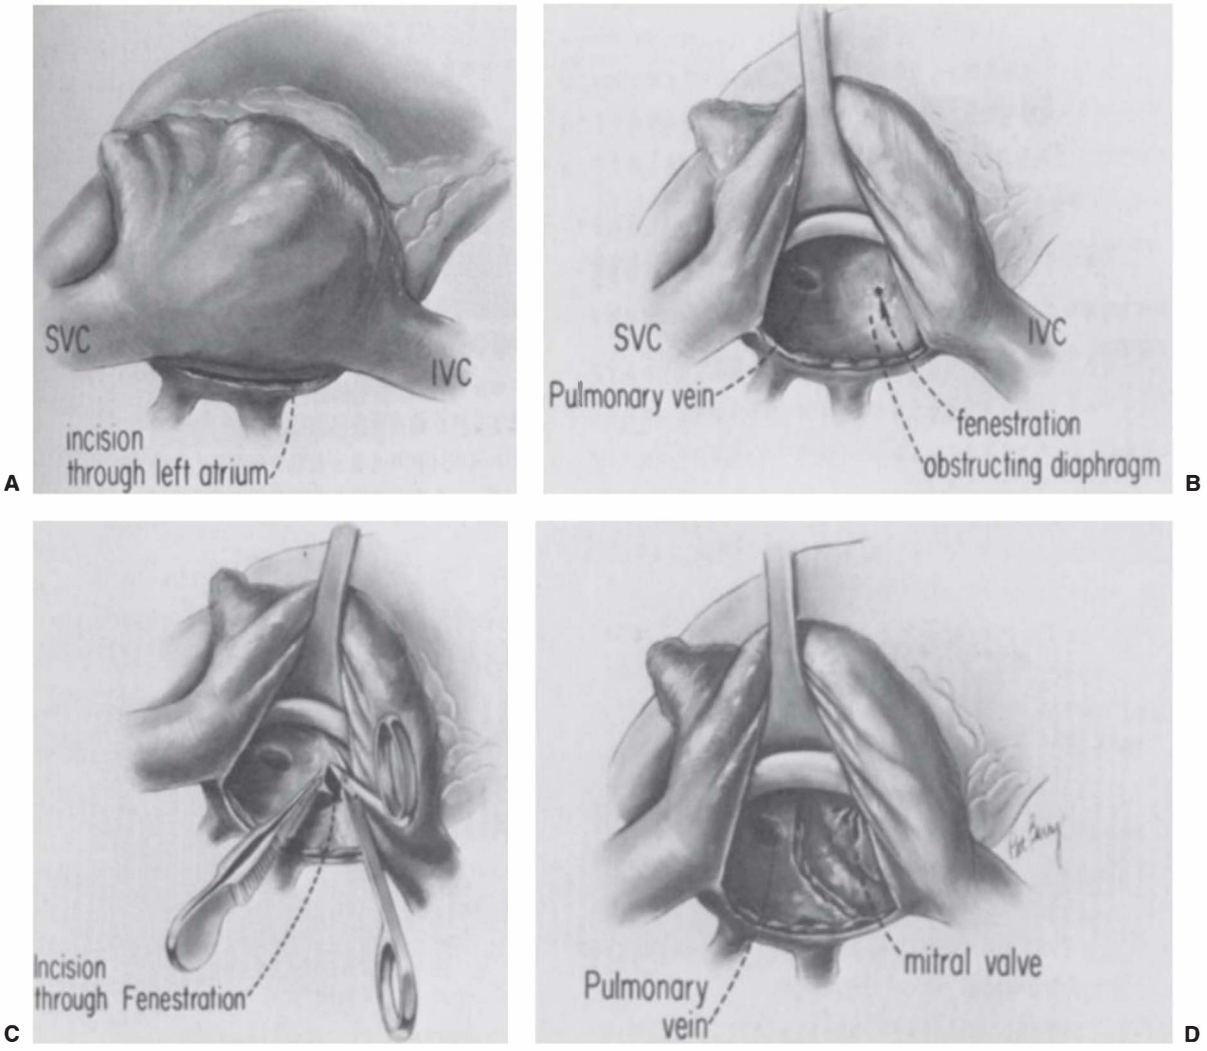

**FIGURE 80-9** Left atrial approach for repair of subdivided left atrium. **A.** A longitudinal incision is made in the left atrium (common pulmonary venous chamber) posterior to the interatrial groove. **B.** The atrial septum is retracted superiorly, exposing the dividing membrane with central fenestration. **C.** Excision of the dividing membrane is commenced by opening the fenestration and continued leftward after visualization of the left inferior pulmonary vein and of the mitral valve. **D.** The pulmonary veins are seen in continuity with the mitral valve. LA, left atrium (common pulmonary venous chamber); RA, right atrium; SVC, superior vena cava; IVC, inferior vena cava. (From Richardson JV, Doty DB, Siewers RD, et al. Cor triatriatum (subdivided left atrium). *J Thorac Cardiovasc Surg* 1981;81:232. With permission.)

early and detailed preoperative diagnosis, particularly when complex lesions are associated. In contrast, hospital mortality is uncommon after repair of this lesion in older patients.

Unfavorable late events leading to restenosis—such as pulmonary vein stenosis[2] and incomplete resection of the dividing membrane between the common pulmonary venous and the distal chamber—are exceedingly rare.[39]

The life expectancy of patients with subdivided left atrium without major associated cardiac lesions approaches that of the general population, particularly if repair is performed in infancy.

With the exception of the reports by Hansing and coworkers[14] and Trento and associates,[3] most descriptions of the surgical management of patients with subdivided right atrium have been single case reports.[15,40] This may represent the primary lesion, and successful surgical treatment has been reported even in the first few months of life.[3,15] On the other hand, an obstructing membrane within the right atrium may be found at operation associated with other lesions causing obstruction to pulmonary blood flow, and treatment and prognosis depends on that of the dominant lesion.

## COR TRIATRIATUM BOARD REVIEW QUESTIONS (CHAPTER 80)

1. Which is not associated with subdivided left atrium?

   A. VSD
   B. Partial atrioventricular septal defect
   C. Tetralogy of Fallot
   D. Left superior vena cava
   E. Pulmonary stenosis

2. Which is true regarding surgical management of subdivided atrium?

   A. Fifty percent of patients born with subdivided left atrium die in infancy without treatment.
   B. Urgent repair is indicated in older patients with chronic symptoms.
   C. Hypothermic circulatory arrest is used in all patients with subdivided left atrium.
   D. A left atrial approach is recommended for repair of subdivided left atrium in infants.
   E. Percutaneous disruption of the obstructive membrane is the preferred approach in patients with subdivided right atrium.

3. Which is correct regarding pathophysiology of subdivided atrium?

   A. Severe pulmonary hypertension occurs when the fenestration is small and the atrial septum is open.
   B. A large ASD increases pulmonary hypertension due to left-to-right shunting.

C. Cyanosis is frequent due to preferential shunting from the IVC through an ASD.
D. Elevated central venous pressures can occur with a large ASD and RVOT obstruction.
E. Obstruction of pulmonary arterial outflow is the key hemodynamic feature.

## ANSWERS

1. **Answer: E.** Pulmonary stenosis is not associated with subdivided left atrium. VSD, AV canal defects, tetralogy of Fallot, coarctation of the aorta, and left superior vena cava are all associated with this defect.
2. **Answer: B.** Urgent repair is indicated in an older patient with subdivided left atrium that presents with chronic symptoms. Up to 75 percent of patients with severe obstruction will die without treatment during infancy. Hypothermic circulatory arrest is typically only used when there are associated complex anomalies. A right atrial approach is recommended for repair of subdivided left atrium in infants. Surgical repair remains the preferred approach for patients with subdivided right atrium.
3. **Answer: C.** Cyanosis is frequent due to preferential shunting from the IVC through an ASD. Severe pulmonary hypertension occurs when the fenestration is small and the atrial septum is intact. A large ASD relieves pulmonary hypertension due to left-to-right shunting. Elevated central venous pressures can occur with an intact atrial septum and RVOT obstruction. Obstruction of pulmonary venous return is the key hemodynamic feature.

## MITRAL VALVE DISEASE IN CHILDREN

### Anatomy and Embryology

#### ANATOMY

Precise knowledge of the normal anatomy of the mitral valve and the interpretation of echocardiographic studies is essential to understanding the mechanism of mitral valve regurgitation or stenosis (functional classification), elucidate the location of leaflet dysfunction (segmental valve analysis), and plan and achieve successful surgical repair. The anatomy of the normal mitral valve in the child does not differ from that in the adult.[1]

#### EMBRYOLOGY

The embryology of the mitral valve is complex. Our understanding of the formation of the leaflets and suspension apparatus has evolved, so that the current approach is mainly based on immunohistochemistry, in vivo labeling of cushion tissue, and scanning electron micrography of human and avian embryos.[2,3] In humans, the mitral valve develops between the 5th and 15th weeks of embryonic life. During the fifth week, the atrioventricular canal is defined and lined with two cushions mostly toward the left side of the canal. The anterior leaflet of the mitral valve derives from the junction of the superior and inferior cushions, whereas the posterior leaflet derives from an infolding of the atrioventricular–muscular wall and the development of a lateral cushion. The wedging of the aortic root into the superior bridging leaflet (mostly originating from the superior cushion) will separate the developing mitral valve from its septal attachments and create the aortomitral continuity.[4] The process required for the transformation of the endocardial cushion into valvar tissue is poorly understood. The presence of calcineurin and periostin is required. As the cushion tissue elongates and grows toward the ventricular cavity, it is gradually delaminated from the underlying myocardium and the leaflet becomes progressively shaped as a funnel-like structure totally attached to the myocardium. Perforations then appear into the valve leaflet and grow to form the chordae tendineae. The atrial aspect of the cushion will generate the spongy atrial layer and the ventricular layer will generate the fibrous part of the mitral valve and chordal apparatus. The separation between atrial and ventricular myocardium is dependent on the sulcus tissue located on the epicardial side of the junction. The development of the papillary muscles takes place simultaneously, originating from the myocardium. A horseshoe-shaped ridge lies within the left ventricle. The anterior and posterior parts of this ridge lose contact with the ventricular wall, forming the papillary muscles and increasing in size, while maintaining structural continuity with the cushion tissue at the tip of the papillary muscle. The midportion of the muscular ridge will be incorporated into the apical trabeculations of the left ventricle.[5]

### PATHOLOGY

#### CONGENITAL ANOMALIES OF THE MITRAL VALVE

Congenital stenosis and insufficiency of the mitral valve are presented together, as their pathology and associated lesions are similar. Moreover, they frequently coexist in the same patient.

***Supravalvar Mitral Ring.*** A common cause of congenital mitral valve stenosis, the supravalvar mitral ring is an acquired fibrous structure attached to the posterior annulus of the mitral valve, running from both commissures to the mid-height of the anterior leaflet. The lesion is stenotic and often more significant than the extent of the ring would suggest. This is mostly due to the consequent limitation in the opening mechanism of the anterior leaflet rather than to the actual diaphragm-like effect of the ring. Strictly attached to the mitral valve annulus, it is to be differentiated from cor triatriatum (Chapter 80). The supravalvar mitral ring is thought to develop as a consequence of turbulent flow through the mitral orifice. The primary lesion of the mitral

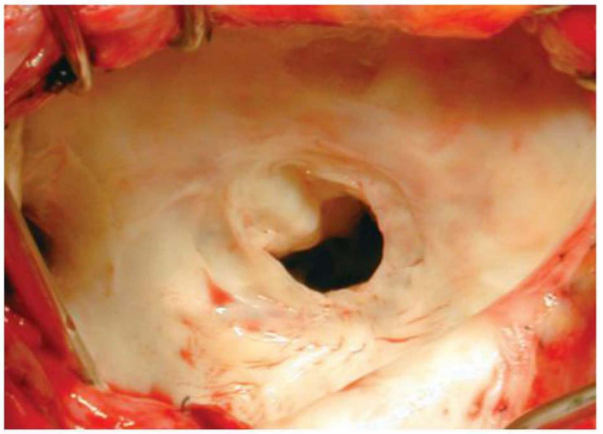

FIGURE 81-1 Supravalvar ring. Intraoperative photograph. Note the implantation of the supravalvar ring high, close to the annulus on the posterior leaflet side (inferior side of the picture) and at the midlevel of the anterior leaflet (left side of the picture).

valve responsible for this turbulent flow can be stenotic or regurgitant or can be very discrete and difficult to identify (Fig. 81-1). It can be related to a prominent coronary sinus, as found in hearts with persistence of the left superior vena cava.[6] The stenosis may be initially functional and created by a very large left-to-right shunt. For these reasons, the supravalvar mitral ring is probably prone to recur after surgical resection unless (or even when) the underlying anatomic anomaly has been identified and corrected. The supravalvar ring can be encountered very early in life, in the neonate or young infant. It should be suspected when a transvalvar gradient appears to increase at follow-up or when the Doppler gradient is greater than what the anatomy depicted with echocardiography would suggest; sometimes, it is only found at operation.

***Cleft Mitral Valve.*** Very often isolated, a cleft mitral valve can be easily differentiated from a left atrioventricular valve in a partial atrioventricular septal defect.[7,8] It is an actual cleft with no suspension apparatus on the edges of the defect. The cleft is centered on the aortic commissure between the noncoronary and left coronary cusps. Each half of the anterior leaflet at midportion bears the attachment of the strut chordae. Both papillary muscles are normal. Rarely, a cleft mitral valve is associated with a leaflet tissue shortening and thickening of the cleft edges. These are acquired lesions secondary to chronic regurgitation through the cleft. The defect is never stenotic and may generate only little regurgitation for a long time.

***Accessory Valve Tissue and Valvular Tags.*** In this specific anomaly, the interchordal spaces are filled with a dense network of immature valve tissue. When there is continuity between the anterior and posterior leaflets, the accessory valvar tissue may be generating a gradient inversely correlated with the size of the perforations in the accessory tissue

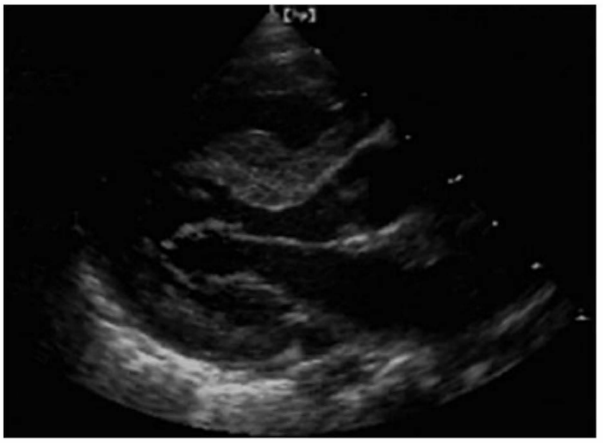

FIGURE 81-2 Accessory mitral valve tissue in diastole.

(Fig. 81-2). When the accessory valve tissue is entrapped in the left ventricular outflow tract, the mitral valve may become regurgitant due to the traction exerted by the accessory valvar tissue on the anterior leaflet, making the valve incompetent in midsystole.[9] Left ventricular outflow tract obstruction is nevertheless the predominant hemodynamic lesion observed with this pathology.[10] Very often, patients are asymptomatic and show no hemodynamic disturbances on echocardiographic studies.

***Lesions Associated with Lack of Valvar Tissue.*** Three major anatomic types of lesions are associated with lack of valvar tissue. The functional endpoint of the lesion can be either normal, predominantly regurgitant or stenotic, or both.

**Parachute Mitral Valve.** A parachute mitral valve (PMV) can be found in isolation and is also observed in association with Shone complex.[11,12] The most common finding is that of a predominant single papillary muscle with the orifice of the mitral valve overriding its tip. With this particular pathology, there is a spectrum of abnormality of the suspension apparatus, ranging from complete fusion of the tip of the papillary muscle to the free edge of the valve to relatively normal-looking chordae with good mobility of the leaflet. Accessory papillary muscles are usually very small and connected to only a short segment of the free edge or even to the undersurface of the leaflet tissue (as would be the case in a larger-than-normal secondary chorda). The functional anatomy of the PMV depends on the interaction between the amount of tissue and the mobility of the leaflet, the presence and size of the fenestrations, and the presence, length, and quality of the chordae.[11] The PMV almost always has a stenotic component. Double-orifice mitral valve is an exceedingly rare variant of PMV, with the lesser papillary muscle supporting a complete orifice. This lesion should be differentiated from the left atrioventricular valve, in which an accessory orifice is often found in the case of diminutive or absent left lateral leaflet (mural leaflet). The second orifice is almost always competent and should not be closed at the time of the repair.

FIGURE 81-3 Papillary muscle to commissure fusion. Postmortem photograph.

**Papillary Muscle-Commissure Fusion.**[11] This anomaly, which can be limited to only one papillary muscle, ranges from cases with short chordae to those in which the tip of the papillary muscle is actually directly attached or fused to the commissural area of the free edge. The valve is generally more regurgitant than restrictive; this is due to the lack of valvar tissue and the consequent restriction of leaflet motion (Fig. 81-3). When the papillary muscles are hypertrophied, the bulk of their mass is generally responsible for a predominantly restrictive physiology. Some Anglo-Saxon authors refer to this anatomy as arcade mitral valve.[4]

**Hammock Valve (Arcade Mitral Valve).**[11] Here the suspension apparatus may have lost all resemblance to the normal anatomy. No papillary muscle may be identifiable or there may be multiple very small ones behind the posterior leaflet. The leaflets are suspended by a network of chordae directly attached to the posterior wall of the ventricle. This attachment is generally displaced toward the base of the heart, with an excess of tension on the anterior leaflet and extreme limitation in the motion of the posterior leaflet. The valve is most often predominantly regurgitant.

***Regurgitant Mitral Valves with Normal Anatomy Associated with Congenital Cardiac Lesions.*** It is difficult to ascertain the congenital origin of these lesions, since the anatomy of the mitral valve is otherwise normal. Although most publications on congenital anomalies of the mitral valve include them,[12] there is no evidence of their congenital origin. Unlike the previously mentioned anomalies, they are in fact not found at birth. They are usually associated with conditions characterized by significant volume loading of the left ventricle [i.e., large ventricular septal defect (VSD) or large patent ductus arteriosus]. The pathophysiology is that of initial dilation of the posterior annulus due to the effect of the increase in volume overload. Secondarily, the marginal chordae elongate and create prolapse of the free edge of the anterior leaflet. These lesions are not rare, as they account for 15 to 40 percent of the patients reported in the literature with congenital mitral valve regurgitation. Functional mitral regurgitation secondary to cardiomyopathy is not included in this chapter.

**Anomalous Left Coronary Artery from the Left Pulmonary Artery.** Mitral valve regurgitation found in an anomalous left coronary artery from the left pulmonary artery (ALCAPA) is of ischemic origin and is described in detail in Chapter 83. In this particular anomaly, mitral regurgitation is a constant finding and is quantitatively almost always greater than moderate. The typical patient is between 2 and 4 months of age at diagnosis. Correction of the ALCAPA reduces the grade of regurgitation but rarely suppresses it entirely. Structural modification of the suspension apparatus with infarction of the anterolateral papillary muscle and elongation of the chordae originating from the latter usually prevent complete regression of the regurgitation without concomitant mitral valve repair at some point.[13]

***Mitral Valve Disease with Excess Leaflet Tissue: Mitral Valve Prolapse and Connective Tissue Disorder.*** Whether to include the mitral valve prolapse syndrome (limited in its more common form to the middle scallop of the posterior leaflet) in the congenital group is debatable. The histologic anomalies are limited in adults to the middle scallop of the posterior leaflet, with predominant alteration of the elastic fibers and proliferation of myxomatous tissue; these anomalies, in all likelihood, have a genetic etiology.[14,15] In the more extensive form of mitral valve prolapse (Barlow's disease, with excess of tissue distributed to both the anterior and posterior leaflets), histology demonstrates extensive infiltration of the spongiosa with myxomatous tissue. This more extensive form can also be seen in neonates and infants. It is encountered in sporadic cases or in familial forms and has been associated with at least one locus mutation on chromosome 16. The histologic anomalies are identical to those found in Marfan,[16] Loeys–Dietz, and Elher–Danlos syndromes. Similar valvar alterations are found in Hurler syndrome (mucopolysaccharidosis type I).

## ACQUIRED MITRAL VALVE DISEASE

***Rheumatic Heart Disease.*** Acute rheumatic fever (ARF) is an autoimmune disorder in which the immune response to group A streptococcal (GAS) M protein generates T cells and antibodies that cross-react with cardiac antigens.[17,18] ARF does not generate long-term sequelae to brain, joints, or skin. Only the heart (specifically the mitral and/or aortic valves) may be permanently affected. The acute damage to the valves may cause chronic and evolving lesions secondary to the scarring process and/or to modifications in hemodynamics. This chronic picture is known as rheumatic heart disease

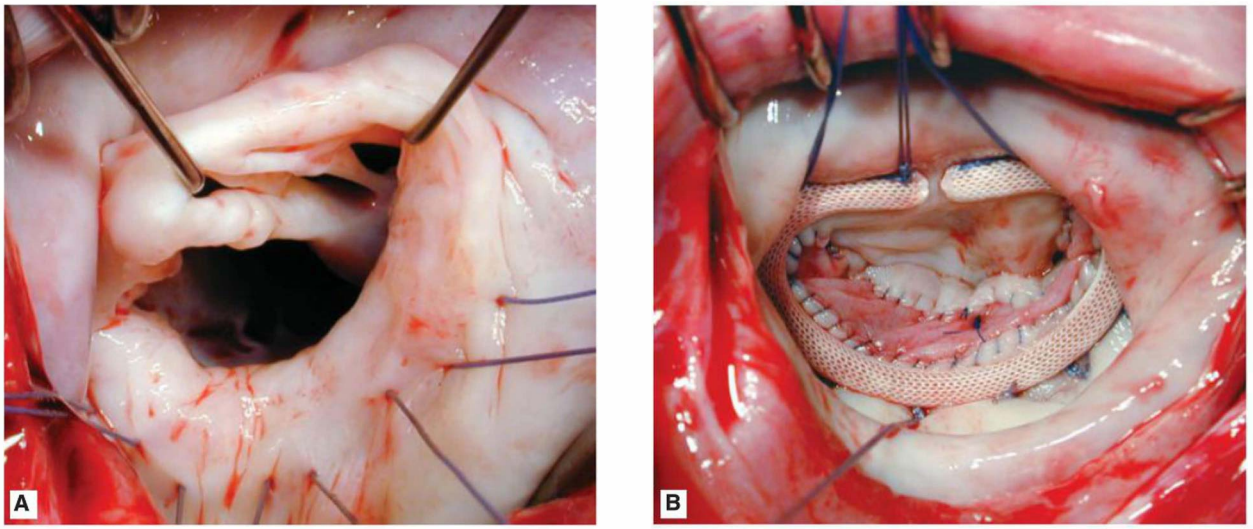

**FIGURE 81-4** **A.** Chronic evolved rheumatic mitral insufficiency. The anterior and posterior leaflets are severely retracted. There is limitation of the posterior leaflet motion, prolapse of the anterior leaflet, commissural fusion, and paucity of chordae, which are thickened and fused. **B.** Repair with posterior leaflet extension, correction of anterior type II and remodeling annuloplasty.

(RHD), which is the most common pediatric heart disease in developing countries. Not all individuals are equally susceptible to ARF. Only 3 to 5 percent have an inherited susceptibility, although the basis of this is unknown. Also, only a limited number of GAS strains can initiate ARF in the susceptible host.

**Acute Lesions.** Acute lesions are exclusively regurgitant. On inspection, the valvar tissue and chordae are swollen but supple. Prolapse of either leaflet can be seen, but the anterior leaflet is predominantly affected.[19] This prolapse is usually related to elongation of limited groups of chordae, while chordal rupture is rare. Multiple small nodules (2–3 mm in diameter) can be seen on the free edge of either of the mitral leaflets. Mitral regurgitation is a combination of annular dilation (secondary to rheumatic pancarditis) and various degrees of prolapse.

**Chronic Lesions.** The scarring process generates retraction of the valvar tissue and, to a lesser degree, the chordae. This process is sometimes sufficient to correct the prolapse of the acute phase. The healing of the spongiosa induces fusion of chordae, as demonstrated by the dramatic reduction in the number of chordae together with the large increase in their size. The physiology of the regurgitation is a combination of prolapse of the anterior leaflet, retraction of the posterior leaflet, and annular dilation (Fig. 81-4). In the pediatric age group, the mitral valve is exclusively or predominantly regurgitant, while stenosis typically appears later in the chronic phase of the disease with continuation of the retraction process. The degree of stenosis and the age at which stenoses can be found varies from population to population. The younger the age during the primary attack of rheumatic fever, the younger the patient when stenosis appears. Other factors may play a role. Calcifications are rare in the pediatric population with RHD.

***Infective Endocarditis.*** Bacterial endocarditis (BE) of the mitral valve is rare and, excluding patients with RHD, represents less than 2 percent of all BE in children. At the Royal Children's Hospital (RCH), Melbourne, a history of mitral valve anomaly before the diagnosis of BE was uncommon. The resulting physiology is always that of a regurgitant lesion. Intraoperatively, a vegetation is the most common finding and typically grows on the atrial side of the mitral valve; however, vegetations are not always present at the time of surgery. Rarely the vegetation will have embolized and, more commonly, it will either regress with medical therapy or have never been there. Other findings are perforation of the leaflet (Fig. 81-5), abscess formation within the mitral annulus, or extension toward the aortic valve. Histologic examination of vegetations discloses microorganism-infiltrated fibrin thrombi. Findings in the affected valvar tissue at the vegetation implantation site suggest a strong inflammatory reaction with neovascularization and infiltration of lymphocytes, giant cells, and fibroblasts. At the time of surgical repair, it is very important to differentiate intact valvar tissue (supple, thin, and resistant) from infected tissue (thickened, edematous, and friable).

## CLINICAL FEATURES AND PRESENTATION

### NEONATES AND YOUNG INFANTS

For both stenosis and regurgitation, the clinical presentation in this age group includes cardiac failure, with dyspnea on exertion (feeding) and tachypnea at rest. Severe failure to thrive

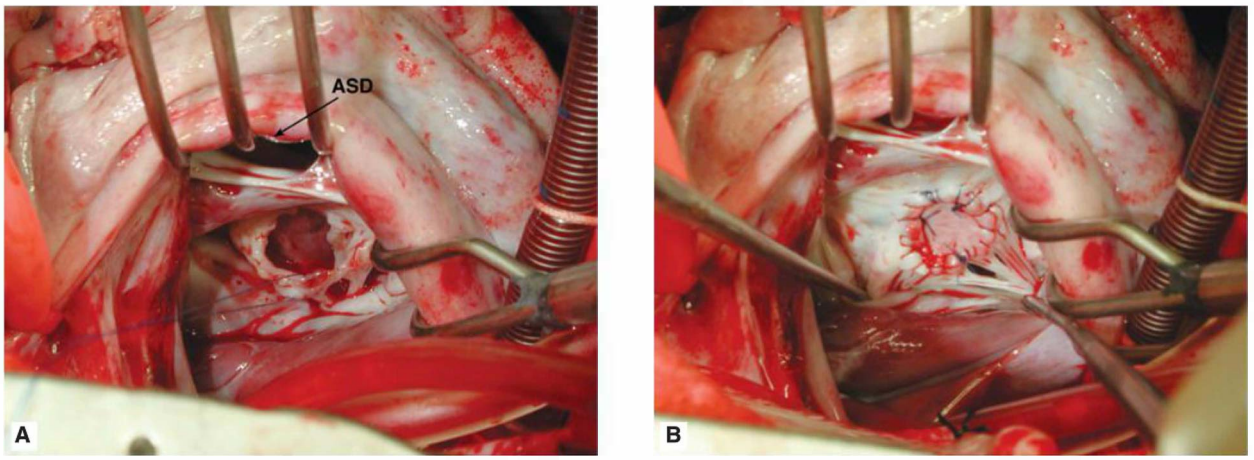

**FIGURE 81-5** Acute endocarditis of the mitral valve. Perforation of the anterior leaflet (**A**). Result following the repair with autologous pericardium treated with glutaraldehyde (**B**). ASD, atrial septal defect. (Image courtesy of Luca Vricella, Division of Cardiac Surgery, The Johns Hopkins University.)

is usually present. Clinical examination shows hepatomegaly and cool extremities. Cyanosis may be present. Auscultation is often unyelding, but a strong apical systolic murmur should indicate significant mitral regurgitation, whereas a diastolic murmur in the case of mitral stenosis can be difficult to auscultate or may even be absent in the context of low cardiac output or associated atrial-level left-to-right shunting.

### OLDER INFANTS AND TODDLERS

Beyond the neonatal period, failure to thrive, dyspnea on exertion, and a history of repeated chest infections are predominant in mitral stenosis. Pallor and cold extremities, tachycardia, and dyspnea suggest low cardiac output. Signs of pulmonary hypertension, with an exacerbated second heart sound, prominent right ventricular impulse, and hepatomegaly are frequent. A diminished first sound with a low-intensity mid-diastolic murmur suggests thickened leaflets with limited excursion and can be absent in a low-output state. Older infants and toddlers with mitral regurgitation present with various degrees of failure to thrive and dyspnea with feeds or on exertion. An enlarged left ventricular impulse (with a high-frequency, high-intensity holosystolic murmur heard at the apex and extending into the axillae) is easily auscultated, with signs of right heart failure rarely being seen.

## Diagnostic Modalities in Mitral Valve Disease

### ELECTROCARDIOGRAPHY

There is left atrial enlargement in both mitral stenosis and regurgitation and left ventricular enlargement in mitral regurgitation; right atrial and right ventricular enlargement is seen when pulmonary hypertension is present. In the pediatric population, the rhythm is almost always sinus.

### CHEST X-RAY

Chest x-ray will typically demonstrate the "double density" seen in left atrial enlargement; this is more often the case in regurgitation than in stenosis; other findings are those of variable pulmonary plethora and enlarged contour of the main pulmonary artery. In the presence of mitral valve regurgitation, left ventricular enlargement is responsible for most of the prominence of the cardiac silhouette.

### ECHOCARDIOGRAPHY

Echocardiographic assessment is obligatory and essential. Systematically conducted, it provides all the information necessary to diagnose the mitral anomaly, determine its severity,[20,29] and assist the surgeon with the repair.[21,30]

The transthoracic four-chamber view is best for obtaining an accurate transvalvar gradient and, together with the parasternal long axis view, defining the precise amplitude of any prolapse or restriction; in general, it is much more accurate than other views in grading the degree of regurgitation. The short-axis view of the mitral valve and the left ventricle provides direct imaging of the area of the mitral orifice as well as the location of origin of the regurgitation jet (in the *en face* view). It allows a precise analysis of the papillary muscles (presence, size, location, and symmetry) and of anterior leaflet integrity. Transesophageal echocardiography (TEE) is superior in defining the anatomic details of the suspension apparatus and evaluating the functional classification. By moving the probe within the esophagus, the operator can obtain precise localization of the area of prolapse along the free edge of the anterior leaflet, using the anterior commissure (probe up) and the posterior commissure (probe down) as anatomic landmarks.

For mitral stenosis, the peak instantaneous and mean gradients across the valve must be interpreted according to the quality of diastolic function and of associated lesions. The overall impact of the gradient on the surgical indication

must be weighed against pulmonary artery pressure and clinical context.

***Functional Classification.*** Transthoracic echocardiography (TTE) and TEE make it possible to classify mitral valve pathology, according to the motion of the leaflets, into one of the three following types (Carpentier's functional classification). This classification is irrespective of anatomy and etiology but is essential for carrying out accurately the repair.[22,31]

**Type I: Normal Leaflet Motion.** Mitral regurgitation results from a lack of coaptation between the leaflets.

**Type II: Leaflet Prolapse.** The free edge of one or both leaflets overrides the plane of the orifice during systole.

**Type III: Restricted Leaflet Motion.** The motion of one or both leaflets is limited. This can be secondary to short or stiff leaflet tissue or suspension apparatus (type IIIa or diastolic) or because the leaflet is pulled away from the coaptation area by a paradoxical motion of the ventricular wall (type IIIb or systolic).

### THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Currently, the major benefit of three-dimensional (3-D) echocardiography is to provide a surgical view of the mitral valve to the surgeon (from the atrium, with the anterior commissure to the left and the posterior commissure to the right) and to precisely localize on this view the prolapse and restriction of the leaflets. 3-D echocardiography has made very important progress in the past few years. Pediatric probes are now available and can be inserted in patients smaller than 5 kg. Even if spatial definition, speed of acquisition and slice thickness have improved, thin and fast-moving structures like leaflet tissue and chordae are less well seen in infants and young children than in adults. In larger patients (weighing more than 12 kg), information on the origin of the regurgitant jet, the volume of the jet, and ventricular ejection volume can be obtained as in adults.[23]

### MAGNETIC RESONANCE IMAGING AND ELECTRON-BEAM COMPUTED TOMOGRAPHY

Computed tomography (CT) allows precise calculation of the mitral valve regurgitant fraction with flow measurement, so does magnetic resonance imaging (MRI) when correction for the modification of the plane of the valve with three-directional velocity-encoded MRI is used. The mitral valve area is calculated with MRI, and correlations with echocardiographic findings are very strong.[24] Whatever the imaging technique employed, there are limitations in small patients, in whom resolution is critical. Neither MRI nor CT has enough spatial resolution to visualize valvar tissue or suspension apparatus in small children.

### DIAGNOSTIC CARDIAC CATHETERIZATION

In the current era, there is very limited indication for an invasive diagnostic and hemodynamic study in the assessment of mitral valve disease. Associated lesion or consideration for balloon valvuloplasty may warrant cardiac catheterization.

### LABORATORY DIAGNOSTIC MODALITIES IN RHEUMATIC FEVER

There is no laboratory test for the diagnosis of ARF, hence the diagnosis remains clinical. The diagnosis requires the evidence of a preceding GAS infection (elevated or rising antistreptolysin O titers, a positive throat culture, or positive rapid antigen test for group A streptococci); although this is necessary, it is not sufficient. The probability of a diagnosis of ARF varies according to geographic location (according to ARF incidence) and ethnicity. For diagnostic purposes, clinicians follow Jones's criteria, updated in 1992.[25]

## Treatment

### MEDICAL THERAPY

Medical treatment must be vigorous when the annulus is too small to allow implantation of a mechanical prosthesis in the anatomic position. In the setting of predominant mitral regurgitation, the treatment should include diuretics, and, if necessary, blood transfusion[26] and positive pressure ventilatory support. In patients who do not yet require surgery, the benefit of angiotensin-converting enzyme (ACE) inhibitors is not clear.[27] In mitral stenosis, any vasodilator or afterload-reducing agent is obviously contraindicated.

### SURGICAL TREATMENT

***Indications.*** Indications for surgical intervention in chidren are different than in adults. Within the pediatric age group, the cut-off point is more related to the size of the mitral valve annulus than to the age of the patient. The rationale for this is in the risk involved with valve replacement in nonanatomical position or with oversized prosthesis.

**Large Mitral Valve Annulus.** "Large" implies an annulus greater than 30 mm in female patients and greater than 32 mm in males. Using a wide range of mitral valve repair techniques, the probability of a successful repair of the valve with a large annulus is very high. A mitral annuloplasty or even a remodeling annuloplasty will not be outgrown and will not generate stenosis with the growth of the patient. The repair of virtually all valves is, when a sizeable annulus is present, an accessible goal.

**Small Mitral Valve Annulus.** In neonates (<28 days), infants (>28 days and <1 year), and generally in every pediatric patient with a mitral valve annulus less than 19-20 mm in size, repair is technically very challenging, while replacement is possible only with the use of surgical artifacts

associated with significantly increased mortality.[28] In these patients, surgical intervention should be deferred as long as the patient can be managed with intense medical therapy, including transfusion and continuous positive airway pressure (CPAP). Aggressive medical therapy allows, in some cases, postponement of surgical intervention for several months, often generating significantly more favorable operating conditions.

**Intermediate Mitral Valve Annulus.** In these patients, with a mitral valve annulus greater than 20 mm but smaller than adult size, mitral valve replacement (MVR) can be safely performed in the anatomic position.[29] Therefore, the timing of the mitral valve repair does not have to be delayed for fear of replacement in an unfavorable position. In this age group, this anatomic situation is found in patients between the ages of 1 to 12 years; it is generally safe to wait for quite a long time (up to several years) in cases of severe regurgitation provided that adequate monitoring of pulmonary artery pressure and ventricular function is achieved.[30,31]

***Mitral Valve Repair.*** At our institution, cardiopulmonary bypass is conducted with moderate hypothermia (32°C), hemoglobin of 10 to 12 g/dL, pump flow of 150 to 200 mL/min/kg, or 2.4 L/min/$m^2$. Myocardial protection is achieved with warm blood cardioplegia administered every 20 min. The time for preparation for bypass is used for mandatory intraoperative TEE. Venous cannulation should allow as much access as possible to the atrioventricular groove. Direct cannulation of the superior vena cava at a distance from the cavoatrial junction and of the inferior vena cava immediately at its origin allows for precise application of the retractor blades. Limited dissection of the groove is performed and, after cross-clamping, the left atrium is entered in the interatrial groove. Exposure is enhanced with mattress sutures inserted into the posterior annulus, pulling the valve upward and to the right, toward the operator. The tourniquet on the inferior vena cava is pulled upward and to the left. A self-retaining retractor for mitral surgery adapted to the size of the patient is used in our practice. Approach through the interatrial septum provides a lesser edge for anchoring of the retractor blades and exposes the conduction tissue to more pressure. Approach through the roof of the left atrium does not expose the posterior commissure and the posterior papillary muscle well. We also believe that the ranseptal approach provides lesser exposure.

Once satisfactory exposure of the mitral valve is achieved, the valve is systematically analyzed and findings are compared with the echocardiographic information. The functional classification is confirmed as well as its location (A1, A2 or A3, P1, P2 or P3), but the extent of the mitral valve prolapse or restriction is based on echocardiographic studies of the beating heart. Then analysis of the anatomy follows: a supravalvar ring is confirmed or eliminated; the diameter of the annulus is carefully assessed; texture, aspect, and size of the mitral valve leaflets are noted; the presence and location of any jet lesion is determined as well as the number, aspect, and distribution of the chordae; finally, the presence of commissural tissue and dedicated suspension apparatus as well as the size, location, and morphology of the papillary muscles are assessed. The examination ends with a careful check for accessory mitral valve tissue in the interchordal spaces. The diameter of the annulus and of the opening of the mitral valve is compared to the normal values reported for the patient's body surface area. We use a modification of the sizes provided by Kirklin.[32] The treatment is adapted to the predominant functional class.

**Correction of Type I Functional Abnormalities.** With the exception of some isolated type I abnormalities without annular dilation (mostly the cleft mitral valve), an annuloplasty is mandatory in all cases of mitral valve insufficiency. In most other cases, attempts to perform mitral valve repair without annuloplasty have resulted in recurrence.[12] In order to accommodate an adult-size device or a larger-size annulus than what would be indicated from the area of the anterior leaflet, leaflet enlargement with glutaraldehyde-treated autologous pericardium of the posterior leaflet (Fig. 81-6), the anterior leaflet (Fig. 81-7), or both are used.[12,33] When no remodeling annuloplasty is available for the size of the patient or the device is thought to be too small, an annuloplasty limited to the posterior annulus is indicated. The annuloplasty must incorporate both fibrous trigones and can be interrupted to allow for further growth. In our hands, the best method for posterior annuloplasty, allowing for growth without compromising the inflow, is a row of interrupted

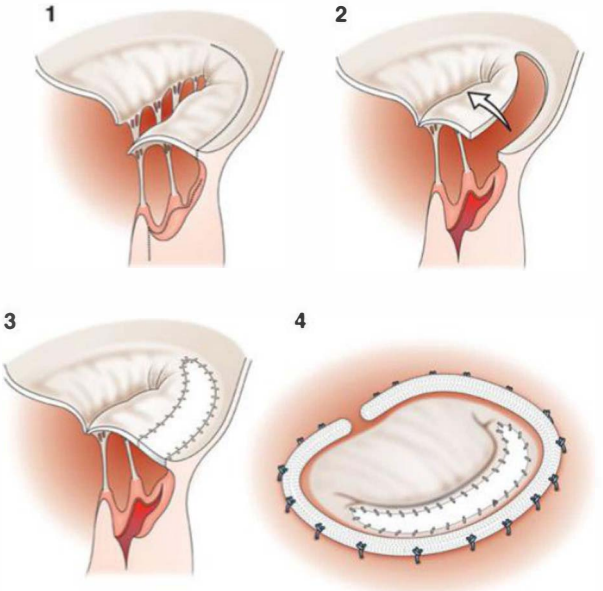

**FIGURE 81-6** Detachment of the posterior leaflet allows access to the suspension apparatus for mobilization (here in a hammock valve). The patch enlargement of the posterior leaflet treats the type III and allows for a larger annuloplasty.

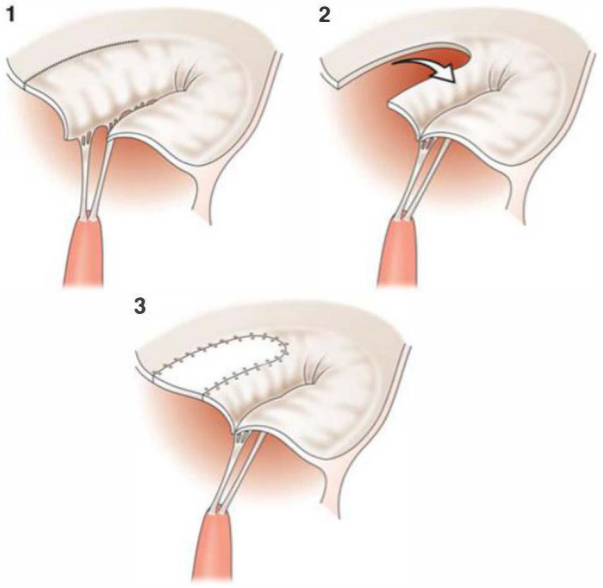

FIGURE 81-7 Patch enlargement of the anterior leaflet to treat the lack of tissue in congenital valve or the retraction of the rheumatic leaflet.

compression U stitches tied individually (Fig. 81-8).[21] Also, for bigger patients, a single layer of ePTFE (expanded polytetrafluoroethylene/Goretex) band can be used. We try to avoid bulky material in small annuli; this can be later responsible for fibrosis of the posterior leaflet.[34]

**Correction of Type II Functional Abnormalities.** Multiple techniques are available to correct the enhanced leaflet motion seen in this functional class. Whether these techniques are to be used in isolation or in combination depends on the extension in width of the prolapse (localized or extended to the whole width of the free edge). It is the height of the prolapse (based on the findings of TEE) and the quality of the chordae that will dictate the choice of technique.

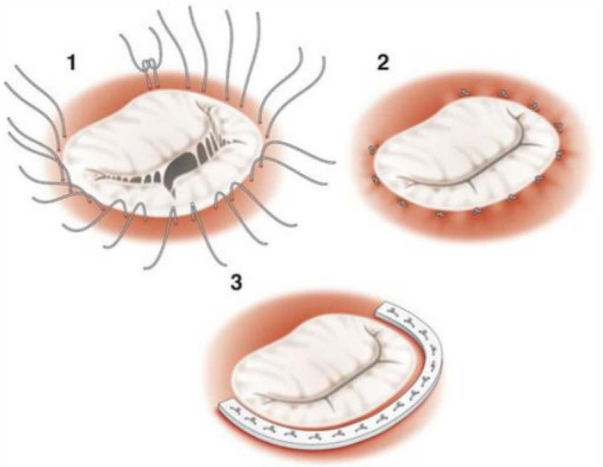

FIGURE 81-8 Annuloplasty limited to the posterior annulus in patients with less than adult size annulus. Two techniques are represented and used at the Royal Children's Hospital, Melbourne. Mattress sutures are implanted along the posterior annulus from one commissure to the other. (1) The mattress sutures are tied over themselves and compress the annulus. (2) A band of PTFE is used to calibrate the shortening. Care is taken not to overtighten the knots.

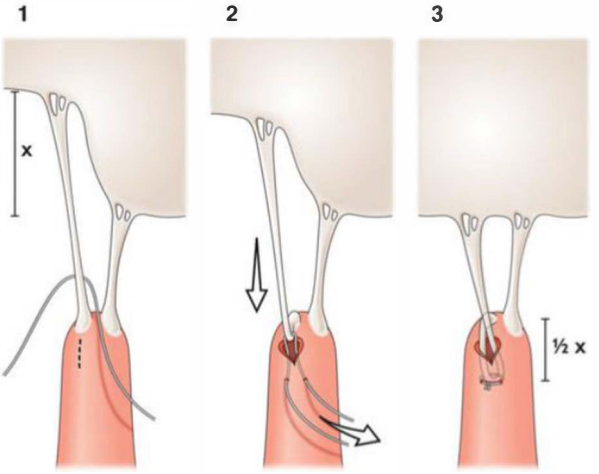

FIGURE 81-9 Chordal shortening: Note the extent of the shortening achieved.

As long as the anatomic correction is adequate (restoring a large surface of apposition between the anterior and posterior leaflets), all techniques are effective and reliable. Overcorrection will generate stress directly on the repaired area and deprive the valve of the relief of stress provided by the surface of apposition. All overcorrections eventually fail, most often in the first few days postoperatively.

*Chordal shortening.* This technique requires thin and flexible chordae.[22] This form of correction generates important shortening of the chordae and is only adopted when the prolapse is wide (Fig. 81-9). It is a time-consuming procedure and is to be considered if multiple chordae are to be shortened, requiring also access to the mid-height level of the papillary muscles.

*Chordal transfer.* Chordal transfer between secondary chordae and the free edge (more than chordal transfer from the posterior leaflet to the anterior leaflet) allows for correction of localized prolapse. The chorda should be detached from the body of the anterior leaflet with a minimal amount of valvar tissue. It is then attached to the free edge directly at the required length with a small running suture (Fig. 81-10).

*Wedge resection of the papillary muscle.* Wedge resection of the papillary muscle (Fig. 81-11) and sliding plasty (Fig. 81-12) generate different degrees of correction of prolapse of multiple chordae. These techniques are very well adapted to prolapse involving a large segment of the anterior leaflet.

*Papillary muscle shortening.* This technique can be used in combined anterior and posterior type II deformity. It is useful

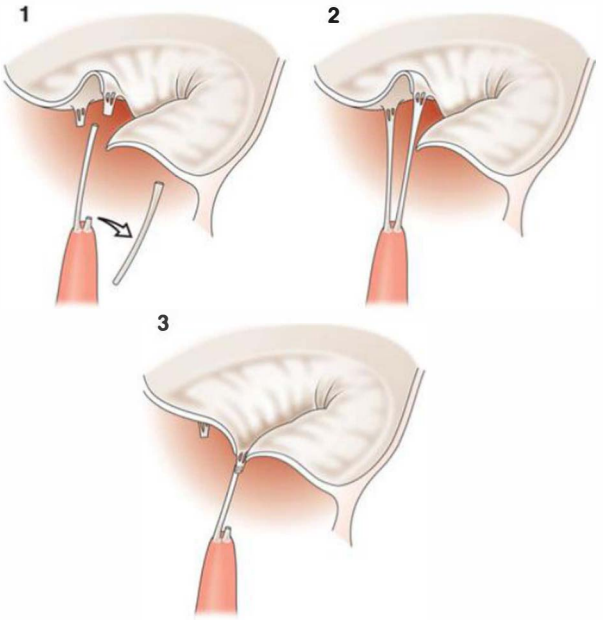

FIGURE 81-10 Chordal transfer: Only secondary chordae should be used and *not* the basal chordae.

when the papillary muscle as a whole has to be shortened, as is usually the case in chronic ischemic papillary muscle or in Barlow's disease (Fig. 81-13).

*Artificial chordae.* Artificial chordae should be used only in the absence of available chordae of appropriate strength and quality in the area of prolapse. The insertion requires rigorous technique to avoid overcorrection and large knots at the free edge (Fig. 81-14).

**Correction of Type III Functional Abnormalities.** Successful correction of restricted leaflet motion and insufficient

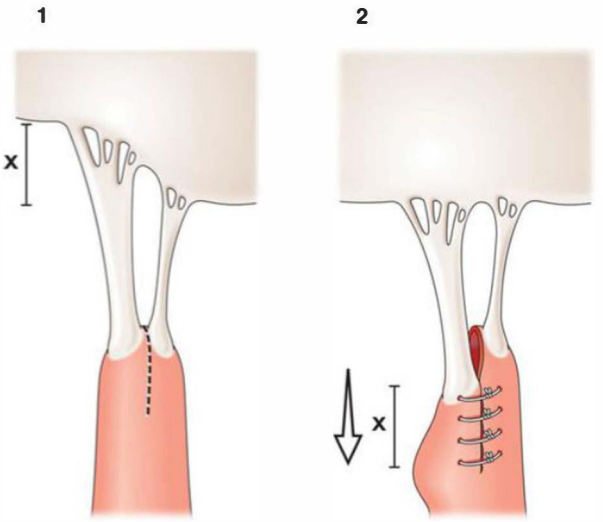

FIGURE 81-12 Sliding plasty: achieves controlled shortening for thickened chordae.

leaflet tissue is the essence of working with congenital mitral anomalies, especially in the first year of life. It falls into three general categories:

1. *Posterior leaflet mobilization and enlargement associated with mobilization of the papillary muscles.* Access to the suspension apparatus is the key to adequate mobilization of the latter. It can be done through the mitral valve orifice when it is sufficiently large. Most often, it is very small and does not allow for good access to the suspension apparatus. In these situations, detachment of the posterior leaflet generates a good view of the papillary muscles. Adequate thinning, mobilization from the posterior wall, and splitting and fenestration of the papillary muscles can then be performed safely with good exposure. After full mobilization, the posterior leaflet is reconstructed with enlargement of the valvar tissue (see Fig. 81-6).[12,21]
2. *Enlargement of valvar tissue using autologous pericardium treated with glutaraldehyde.* Augmentation of the valvar

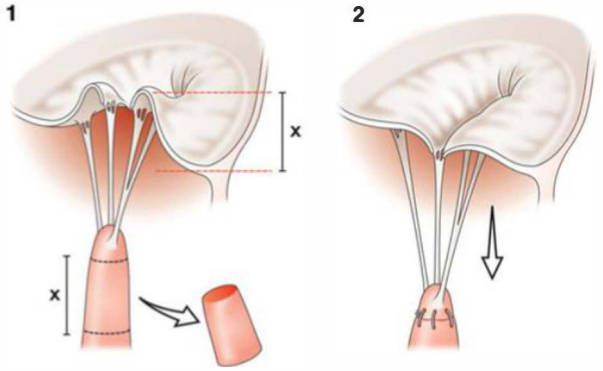

FIGURE 81-13 Papillary muscle shortening by resection and reconstruction.

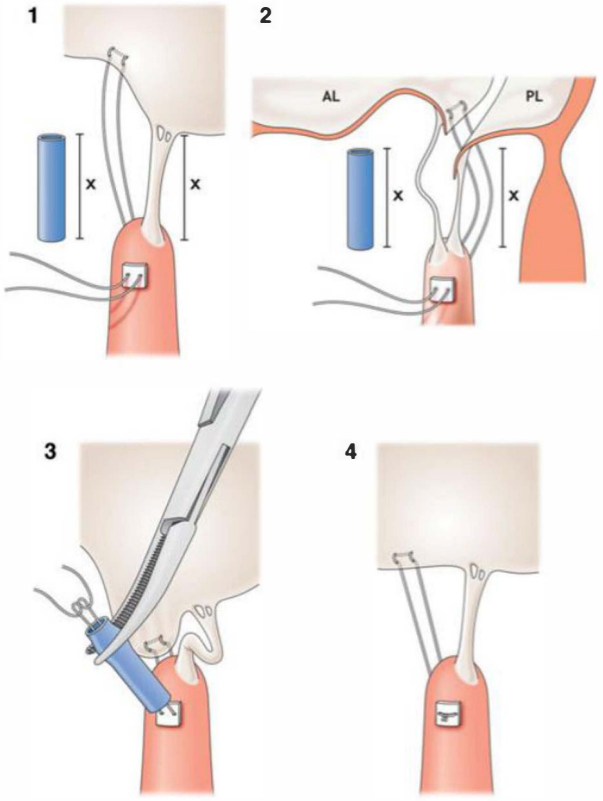

**FIGURE 81-14** Technique for insertion of ePTFE chordae: (1) A template is made from a short plastic tube cut at the required length and slid over the distal part of the stitch. (2) This template can be taken from the facing posterior leaflet edge. (3) The free edge of the leaflet is lowered to the contact of the papillary muscle. The artificial chordae is tied while the template is clamped. (4) The template is removed and the mattress suture is pulled to bring the knot in contact of the papillary muscle.

leaflet tissue is the only way to treat a lack of valvar tissue. It can be limited to the anterior leaflet (see Figs. 81-6 and 81-7) or the posterior leaflet or be used for both. Extension of the posterior leaflet should be limited to less than half of the height of the leaflet. It can be limited to the area of the middle scallop; alternatively, when the detachment extends from one commissure to another, the extension should reproduce a shape with three scallops and two subcommissures to allow for a large opening in diastole. Extension of the anterior leaflet should be done in the body of the leaflet (leaving a strip of valvar tissue close to the hinge point) in order to avoid mechanical stress at this level. The height of the extension should not be greater than two-fifths of the height of the anterior leaflet, leaving the area close to the free edge intact to allow for a supple and efficient surface of coaptation. Unless required by a specific anatomy, the enlargement should be symmetrical from trigone to trigone.

3. *Resection of supravalvar rings and accessory mitral valve tissue.* Resection of supravalvar tissue requires excellent exposure of the leaflets. The supravalvar tissue can sometimes be peeled off the valvar tissue. More often, there will be the need for a careful cleavage plane with blunt dissection. Perforation of the anterior leaflet may occur; this should be closed with a figure-of-eight suture (Fig. 81-15). The resection of accessory mitral valve tissue requires a similarly rigorous surgical technique, and very good exposure of the subvalvar apparatus is needed to perfectly differentiate the mitral valve chordae from what can be resected without compromising the integrity of the suspension apparatus. Various approaches to the suspension apparatus may have to be combined: through the mitral valve orifice and the aortic valve or by detachment of the posterior leaflet (Fig. 81-16).

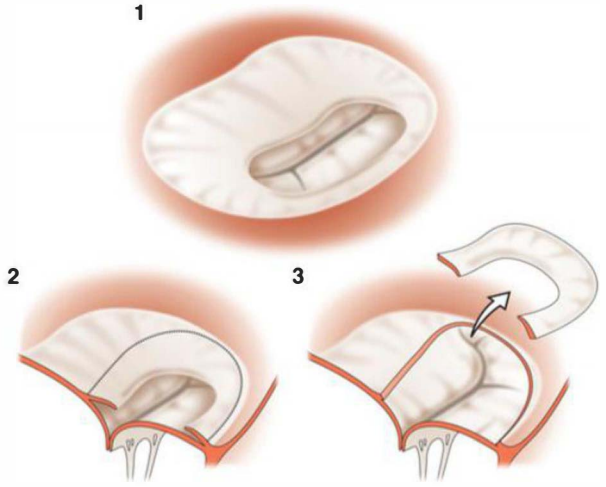

**FIGURE 81-15** Excision of supravalvar mitral ring.

***Valve Replacement.*** MVR should be avoided at all costs in pediatric patients; however, it may be the only option when the valve cannot be repaired. The risk of death in pediatric MVR with a mechanical prosthesis increases with the

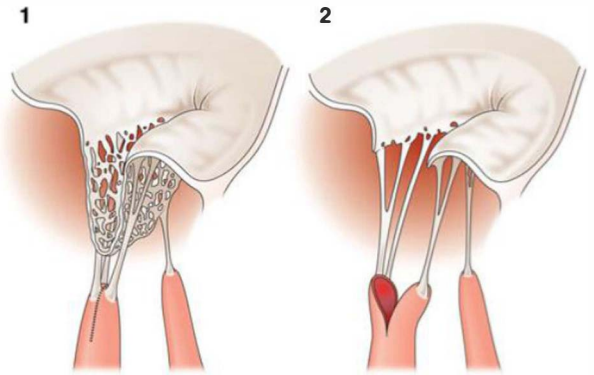

**FIGURE 81-16** Excision of extra valvular tissue, here within a parachute mitral valve. Great care must be taken to preserve the suspension apparatus.

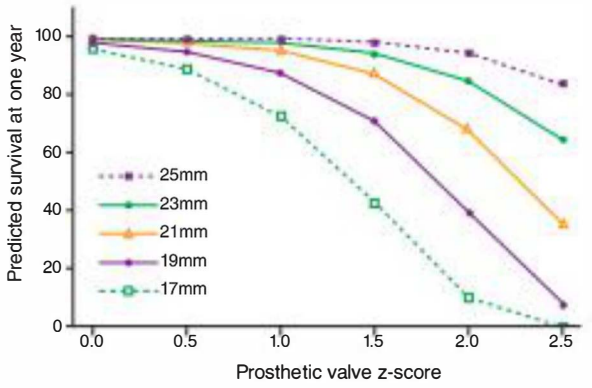

**FIGURE 81-17** Predicted survival at 1 year is plotted against prosthetic valve *z*-score. Note that as disparity between prosthetic valve size and normal mitral annulus size increases (increasing *z*-score), 1-year survival falls precipitously. This effect is greatest at smaller valve sizes. (Reproduced with permission from Caldarone CA, Raghuveer G, Hills CB, et al. Long-term survival after mitral valve replacement in children aged <5 years: A multi-institutional study. *Circulation* 2001;104 (12 Suppl 1):I143–I147.)

prosthetic size/body-weight ratio, with highest mortality in patients with smaller annular diameters (Fig. 81-17).[35]

**Mitral Valve Replacement in the Supra-annular Position in Infants.** This procedure should be avoided as much as possible because it is responsible for the majority (or totality) of perioperative and late deaths in units with experience with MVR in children.[28] Mitral valve repair is often a palliation or a short-term palliation, but allows for annular growth and eventually replacement with a larger prosthesis.

**Mitral Valve Replacement with a Larger Annulus.** This is now possible with excellent long-term results, and only mechanical valves should be implanted in pediatric patients. The introduction of low-profile aortic valves has proven to be very useful in the management of pediatric MVR, since in patients with smaller annular diameters (=20 mm), an aortic prosthesis can be implanted in an "upside-down" position. Bioprostheses have been associated with early degeneration and the need for reoperation in younger patients,[36] and mitral valve homografts have not produced satisfactory results in children.[37]

***Replacement of Mechanical Prostheses.*** This procedure has become not uncommon in most pediatric units. The need for prosthesis replacement is dictated by the size of the first prosthesis implanted and the age at first implantation.[38] The indication is usually the development of a transmitral gradient with pulmonary hypertension, at rest or during exertion. A larger size prosthesis can usually be implanted, but it is in rare instances more than two sizes larger than the one previously implanted. For a 17-mm mechanical prosthesis implanted in infancy, two further valve replacements will typically be required until a 25-mm mechanical valve can be implanted. On the other hand, a palliative repair should allow for a larger prosthesis to be implanted at the time of the first MVR. Technically, the replacement of a pediatric mechanical prosthesis differs significantly from the same procedure in the adult. Great care must be taken to remove all cuff tissue and pledgets; everting mattress sutures (especially with pledgets) should be avoided, as they may reduce the size of the annulus. Preference is given in our practice to simple interrupted sutures.

### *Special Considerations*

**Rheumatic Heart Disease in Children.** Appropriate timing for mitral valve repair in children with RHD is essential but unfortunately rarely achieved. Surgery should be delayed from the acute rheumatic episode to allow for spontaneous regression of regurgitation with attenuation of the carditis under appropriate treatment. Early surgery is more difficult, as tissues are swollen and fragile. Mitral valve repair during the acute phase of RHD carries high recurrence rates.

At the RCH, Melbourne, we favor a short period of follow-up (6-12 months) when severe mitral regurgitation has become chronic. At that time, morphologic conditions are usually better than those encountered earlier than 12 months after the acute phase. The leaflets should still be thin and pliable, and the suspension apparatus moderately elongated but not thickened. Under such operating conditions, excellent results can be achieved with a low residual inflow gradient.

Operation on long-standing chronic mitral valve regurgitation will, on the contrary, generate difficult operating conditions: severe retraction of both leaflets, intense thickening of the suspension apparatus, and commissural fusion with fibrosis and sometimes calcification even in pediatric age group.

**Bacterial Endocarditis.** We advocate very aggressive and early intervention for infective BE in children. When mitral regurgitation is greater than moderate, and as soon as the antibiotic therapy is initiated, we believe that surgery is indicated to prevent further damage of the valve or extension of the endocarditic process to the aortic valve.

## Outcomes

### MITRAL VALVE REPAIR

***Neonates and Infants.*** Between 1996 and 2006 at the RCH in Melbourne, 22 patients less than 1 year of age underwent mitral valve repair. Thirteen with predominant mitral valve regurgitation and nine with predominant mitral valve stenosis. All infants underwent initial valve repair, with three reinterventions in the regurgitation group. There was one early death in a neonate with severe Marfan syndrome, which was unrelated to an otherwise successful mitral valve repair, and one late death.

During the same time interval, nine patients with a median age of 5 months (range 1 week to 10 months) were operated for congenital mitral stenosis. All had severe failure to thrive and severe pulmonary hypertension. The mean

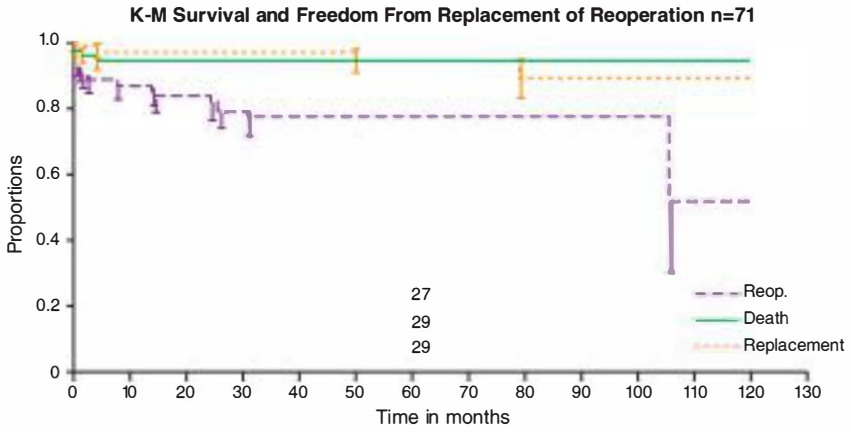

**FIGURE 81-18** Actuarial freedom from reoperation and death or reoperation for repair of congenital mitral valve regurgitation at the Royal Children's Hospital, Melbourne, between 1996 and 2006. (From Oppido G, Davies B, McMullan DM, et al. Surgical treatment of congenital mitral valve disease: Midterm results of a repair-oriented policy. *J Thorac Cardiovasc Surg* 2008;135(6):1313–1320.)

preoperative gradient was 13 ± 2.3 mm Hg. The underlying malformations included papillary muscle-commissure fusion ($n = 6$), PMV ($n = 2$) and supravalvar ring ($n = 1$). Three patients had reoperations. The first patient had three reoperations, leading ultimately to MVR with a mechanical valve. The second patient (neonatal Shone's complex and interrupted aortic arch) underwent reoperation (resection of supravalvar membrane) 2 years following initial intervention. Other teams have similar results in this age group, justifying early operation in severely symptomatic patients.[39]

***Outcomes Beyond Infancy.*** From the most recent available literature,[12,21,40,41] repair should be suitable for more than 90 percent of patients in this age group with mitral regurgitation, with operative mortality below 10 percent and expected reoperation rates lower than 15 percent at 15 years (Fig. 81-18). Hospital mortality should be low when mitral stenosis is isolated. Mitral stenosis with associated cardiac lesions generates higher mortality and reoperation rates, but such associations are rare beyond infancy. After mitral valve repair for mitral stenosis, residual gradients are frequent but are often well tolerated, with the need for reintervention indicated by the level of pulmonary hypertension.

***Rheumatic Mitral Valves.*** In centers with large surgical volumes, successful mitral valve repair can be accomplished in greater than 90 percent of pediatric patients with RHD,[42] with operative mortality often below 2 percent. Large variations in reoperation rates are reported (from <10 to 45 percent at 5 years).[43] This variability could be attributed to the quality of the follow-up, but, most importantly, to compliance with secondary antibiotic prophylaxis and also access to reoperation. In analyzing the success of surgical mitral valve repair, the age of the patient at the time of the first rheumatic episode and the interval to surgical intervention is also to be considered as a potential factor. At our institution, 88 patients (6–24 years of age) have undergone surgery for rheumatic mitral valve insufficiency between 1996 and 2005. All patients underwent initial mitral valve repair. Freedom from reoperation at 70 months (32 patients at risk) was 78 percent. There were 15 reoperations in 13 patients, of which 7 were replacements and 8 were further repairs. There was one early and one late death.

***Mitral Valve Replacement.*** Current warfarin therapy in children is safe, with recent advances in INR monitoring that more often allow for a stable value in the range of 3 to 3.5.[44]

Recent series of mechanical MVR in the pediatric age group (including small patients)[29,45] suggest that MVR is performed with low operative mortality provided that the native annulus is large enough to accommodate the prosthesis in the anatomic position. Series of supra-annular implantations report elevated early and late mortality.[28,35] Freedom from second valve replacement is directly related to the age at initial MVR and to the size of the prosthesis implanted.[38]

## AORTIC VALVE DISEASE IN CHILDREN

### Definition

The study of aortic valve disease in children has usually been limited to those children born with an aortic valve abnormality. But in the present era, an increasing number of children are reaching adulthood with anomalies of the aortic root related to a birth defect or subsequent to a surgical procedure, and we decided to focus on this new developing field. Subaortic membrane stenosis, supravalvular aortic stenosis, Shone anomaly, infective endocarditis, and rheumatic valve disease, which are treated separately in other chapters, will only be briefly mentioned.

## History

Aortic valvotomy under direct vision was among the first congenital cardiac procedure to be reported as early as 1956.[46] Cabrol and Senning later paved the way to modern era aortic valve repair.[47,48] The introduction of the pulmonary autograft aortic valve replacement by Ross in 1967 has opened a new era of alternative replacement for those small children with no access to prosthetic valves.[49]

## Embryology

The mechanisms leading to the formation of the semilunar leaflets are not yet fully elucidated. It is believed that the aortic valve arise from three endocardial cushions appearing on the inner surface of the septated distal primitive outflow tract and that most of the malformations observed result from variable degree of fusion of the zone of apposition of these primitive leaflets. The fact that most valves (even unicuspid ones) present three interleaflet triangles seems to substantiate this theory. The few exceptions are represented by the cases of bicuspid and quadricuspid valves.[50,51] Intrauterine flow restriction through the aortic valve will accordingly model the size of the left ventricle. This seems to be a late phenomenon, because similar second trimester aortic lesions can result in either a normal-sized or a hypoplastic left ventricle.[52] The modeling of left ventricular size by flow through the aortic valve opens the potential for fetal aortic valve balloon dilatation to prevent the occurrence of hypoplasia of the left ventricle.[53]

## Pathophysiology

### CONGENITAL AORTIC VALVE DISEASE

Stenosis is the predominant feature of symptomatic congenital aortic valve disease in neonates and infants. With the fusion of the zone apposition between leaflets, the commissural area supporting the leaflets disappears, leading to a dome-like appearance of the valve. According to the number of zone of apposition between leaflets remaining open, the valve can be tricuspid, bicuspid, or unicuspid.[54] These valves often present considerable degree of fibrous dysplasia and nodular thickening. Due to the modeling of the heart components by flow during the fetal life, the more severe the obstruction, the smaller the ascending aorta.[55]

Bicuspid aortic valve is the most common morphological abnormality in patients who present as teenagers. The prevalence of aortic regurgitation (7 percent) or stenosis (3 percent) is low in these patients.[56]

### ACQUIRED LESIONS

A variety of congenital cardiac lesions are responsible for a deformity of one or more components of the aortic root.

***Tetralogy of Fallot and Pulmonary Atresia.*** Patients with right-to-left shunts and large collateral circulation as in pulmonary atresia have dilated aortic roots because their aorta has been subjected to high blood flow before definitive repair. Aortic root dilatation may cause central regurgitation by lack of coaptation of the leaflets related to dilatation of the sinotubular junction. This dilatation can progress even after surgical repair. Noninflammatory loss of smooth muscle cells with mucoid degeneration and fragmentation of the elastic fibers of the media has also been observed in the aortic wall of these patients.[57] It is yet unclear whether these abnormalities of the media are genetically inherited and related to their disorder or are induced by high flow in the aorta and/or cyanosis.[58]

***Ventricular Septal Defect–Related Regurgitation.*** This particular form of aortic valve regurgitation is seen in two particular forms of VSD: A perimembranous defect lies immediately underneath the interleaflet triangle between non- and right coronary cusps, whereas the doubly committed or infundibular defect corresponds to a lack of fusion underneath the right sinus of Valsalva and the crest of the septum; the defect is in this case strictly limited to the right cusp. Classically, the Venturi effect associated to the high velocity jet of restrictive VSD is responsible for the attraction of aortic leaflets into the VSD orifice.[59] Over time, the leaflet elongates and prolapses. At a later stage, the sinus dilates. Finally, the prolapsed leaflet may occlude the opening of the VSD. We believe that the lack of support to the right coronary cusp in doubly committed VSD is at least as important as the Venturi effect.[60] This would explain why the regurgitation is much less frequent in perimembranous VSDs.

***Iatrogenic Lesions: The Arterial Switch.*** All procedures involving the aortic root are prone to alter its geometry. In the arterial switch operation, the insertion of the coronary buttons in the neoaortic root at the level of the sinotubular junction may be responsible for regurgitation, as it may alter the ratio between sinotubular junction and the length of the cusp's free edge. It is disputed whether punch techniques, or any technique that inserts the buttons low into the sinuses, cause less distortion of the aortic root. There is a significant body of evidence suggesting that the neoaortic valve is structurally a pulmonary valve, therefore prone to dilation when exposed to systemic pressure. The physiopathology of the regurgitation is therefore not solely mechanical and related to the disruption of the sinotubular junction.[61]

***Subaortic Membrane.*** Valvular lesions observed in association with subaortic membrane are thought to be due to the systolic jet and vary from minimal damage to extensive fibrous proliferation extending to the ventricular surfaces of the leaflets, sometimes completely obstructing the interleaflet triangles.[62] Half of these patients present with some aortic regurgitation, even when the stenosis is responsible for mild gradients. The progressive incorporation of the valve in the fibrous proliferation of the membrane may ultimately lead

to severe valvar stenosis. In infants and children, valvular lesions are progressive, and surgery is recommended as soon as traces of regurgitation appear. This evolution might be slower during adulthood.[63]

***Supravalvar Aortic Stenosis.*** William's syndrome is found in half of the patients presenting with supravalvar aortic stenosis. The most frequently observed lesions are peripheral and supravalvar stenosis. In most instances, supravalvar narrowing is accompanied by considerable abnormalities of the aortic root.[64] The valve is bicuspid or stenotic in up to half the patients. Thickening and retraction of the sinuses, along with the fusion of the commissures to the sinotubular ridge is frequently responsible for various degree of coronary ostial stenosis. Left ventricular outflow tract obstruction is identified in as many as one fourth of the patients.[65] After operation, regurgitation due to distortion of the aortic root is not uncommon and we therefore favor the three-patch technique to repair these lesions, taking care to enlarge the sinotubular junction no more than the length of the free edge of the cusp.[66,67]

## Clinical Features

### EPIDEMIOLOGY

***Congenital Aortic Valve Disease.*** The exact incidence of aortic valve disease in children is difficult to evaluate, because most of the minor deformities of the valve will not become symptomatic for several decades. There seems to be male predominance in the disease.[68] A bicuspid aortic valve is observed in up to 2 percent of the general population, with males being affected four times more commonly than females.[56]

#### *Acquired Lesions*

**Pulmonary Atresia and Tetralogy of Fallot.** Almost 75 percent of repaired tetralogy patients present aortic root dilatation when they reach adulthood, accompanied by some degree of regurgitation; nevertheless, relatively few become symptomatic, and aortic catastrophe (rupture or dissection) is exceedingly rare.[69] Only 1 percent of the patients need surgery in the 20 years following their initial repair.[70,71] The progression of dilatation of the aortic root seems faster in patients becoming symptomatic than in those remaining asymptomatic.[72]

**Ventricular Septal Defect–Related Aortic Regurgitation.** Aortic valve prolapse is far more frequently encountered in doubly committed than in perimembranous VSDs. Eleven percent of the patients with perimembranous VSDs will have some aortic valve prolapse and a third of the prolapsing valves will cause more than trivial regurgitation. Up to two thirds of the patients with doubly committed VSD will show some degree of valve prolapse, with 40 percent of those having significant regurgitation. This incidence is even higher in men.[73,74] The severity of regurgitation invariably increases with time. Aortic regurgitation may appear after VSD closure even if the valve was not prolapsing before surgery. When present at the time of surgery, its progression seem to be halted by the closure of the VSD.[75,76]

#### *Iatrogenic Lesions*

**The Arterial Switch.** After an arterial switch operation, neoaortic regurgitation is very frequent but rarely significant. In 35 percent of the neonates regurgitation will appear, but only 2 percent of the total will need a reoperation for aortic insufficiency in the 10 years following the procedure.[77,78] Nonetheless, careful examination has revealed that as many as 25 percent of those having aortic regurgitation might have slow progression of their regurgitation over time.[79]

**Marfan Syndrome.** In early infancy, mitral pathology is responsible for most of the mortality of patients affected by Marfan syndrome. In childhood and adolescence, mitral valve prolapse and aortic dilatation have similar cumulative incidence. Four out of five Marfan patients reaching adulthood present aortic root dilatation, one in five with aortic regurgitation necessitating surgery.[16] Aortic dissection has only been exceptionally reported in patients with Marfan syndrome in the pediatric age group.[80] Aortic root involvement in the Marfan syndrome is discussed in detail in Chapter 82.

**Rheumatic Valve Disease.** In children and adolescents, the aortic valve and the mitral valve are, respectively, involved in 54 and 85 percent of the cases.[81]

**Infective Endocarditis.** The incidence of active infective endocarditis has increased in children in the last decade, mainly because of the improved survival of the patients at risk, such as hospitalized neonates and infants with indwelling catheters. Before 1970, the most important factor predisposing to endocarditis was rheumatic valve disease. Nowadays, the predominant predisposing factor has become the presence of congenital heart disease. The incidence is highest among patients with cyanotic heart disease, especially in patients who had operations for restricted pulmonary blood flow and those who had aortic valve replacement.[82]

## Clinical Features

Neonates and infants aged less than 3 months with aortic stenosis and reduced left ventricular function or duct-dependant systemic circulation are described to have critical neonatal aortic stenosis. At the time of ductal closure, if the aortic obstruction is severe, the neonate may be found in cardiovascular collapse. Later in the first year of life, the first symptoms may be tachypnea, poor feeding, and failure to thrive.

Most of the patients presenting after the age of 1 year with aortic stenosis or regurgitation will be asymptomatic.

Poor growth, angina, and syncope are found in less than 10 percent of the patients with aortic stenosis. In older patients, the most frequently encountered symptom is easy fatigability. Awareness of increased neck pulsation comes only in an advanced stage of aortic valve regurgitation.[83]

## Diagnostic Modalities

### EXAMINATION

In neonates presenting with critical aortic stenosis, poor pulses, hyperactive precordium, peripheral edema, and hepatomegaly may be noted. Although a murmur can be usually auscultated, the typical left sternal edge murmur radiating to the neck is present in only 20 percent of the patients.[84] In older children with aortic stenosis, the heave of the apical impulse can be detected on inspection and palpation. Visible bounding arterial pulses accompanying aortic valve regurgitation are more obvious with increasing severity of the disease.[85]

### ELECTROCARDIOGRAM

The electrocardiogram (ECG) is usually noncontributory to the diagnosis of neonatal aortic stenosis and can display signs of left or right ventricular hypertrophy. Under the age of 1 month, the predominant pattern is that of right ventricular hypertrophy. Older patients with severe aortic stenosis or regurgitation will show signs of left ventricular hypertrophy.[83,85]

### CHEST X-RAY

The chest X-ray of symptomatic neonates will invariably display cardiomegaly and, in 50 percent of patients, signs of pulmonary congestion. Older patients have a normal-size cardiac silhouette.[83,85] The presence of cardiomegaly with aortic stenosis is associated with a poor prognosis.[86]

### ECHOCARDIOGRAM

2-D echocardiography gives invaluable information about the morphology of the valve and the severity of the disease. Echocardiography should determine the morphology of the valve leaflets, their number, their quality, their mobility, and the presence of calcifications, fibrous nodules, or raphe. The commissures and hinge points have to be particularly scrutinized. The aortic root dimensions need to be measured at the level of the hinge points of the leaflets, of the sinuses and at the sinotubular junction and the ascending aorta. The evaluation of aortic regurgitation relies on the source of the jet, its orientation, and, if possible, the mechanism of the regurgitation. Dilatation of the aortic root, leaflet prolapse, and restrictive motion of the leaflets can all be responsible for aortic regurgitation. The short-axis view will better determine the opening of the valve and the source of the regurgitation, while the long-axis view will give details on the direction of the regurgitant jet, the coaptation area, and the eventual prolapse. In this latter view, the leaflet morphology should be carefully examined. Billowing of the body of the leaflet should be distinguished from true prolapse, in which the free edge falls below the level of the free edge of the facing leaflets. The coaptation area between the leaflets should be carefully assessed, as well as whether coaptation occurs adequately above the hinge points of the valve.

Pulse Doppler echocardiography allows the detection of even mild degrees of obstruction. Continuous-wave Doppler echocardiography provides a way to estimate the instantaneous pressure gradient through the valve by the simplified Bernoulli equation [pressure gradient = $4 \times$ (peak velocity)$^2$]. This calculated gradient slightly overestimates the peak-to-peak gradient measured invasively.[87] The evaluation of the transaortic flow is essential but has to be subjective. In this context, left ventricular function, especially shortening fraction and size of the left-to-right shunt at the interatrial or interventricular levels are key indicators. The presence of an open duct and the direction of the shunt at that level may give indication on the aortic pressure and may help with interpretation of the pressure gradient. Eventually, the severity of the obstruction is based on clinical judgment. The severity of aortic regurgitation is best assessed with pulsed Doppler echocardiography. The cross-sectional area of the regurgitant jet in the left ventricular outflow tract, and the holodiastolic abdominal aortic flow reversal seem to be better predictors of the degree of regurgitation than the length of the jet or the slope of the aortic regurgitation.[88,89] In the neonate, the dimensions of the left-sided chambers are evaluated, indexed for body surface area, and a $z$-score is determined. These measurements will help to determine the likelihood that the left heart will sustain the systemic circulation and, consequently, the patient's suitability for a biventricular repair. In particular, length of left ventricular cavity, mitral valve area, and presence of endocardial fibroelastosis should be recorded.[90–92]

Echocardiography is sufficient to elaborate the diagnosis of aortic valve disease in children. A thorough screening of associated anomalies is nonetheless mandatory.

### DIAGNOSTIC CARDIAC CATHETERIZATION

In the neonate, cardiac catheterization should be reserved for the evaluation of associated lesions. Beyond that age, catheterization will exceptionally help in the decision-making process in cases with borderline indications for surgery or valvuloplasty, or when there is a discrepancy between symptoms and echocardiographic findings.

### EXERCISE TESTING

Exercise testing is sometimes performed to assess patients with peak gradients inferior to 60 mm Hg in order to demonstrate ST changes, arrhythmias, or obtain precise evaluation

of the exercise capacity of adolescents with vague complaints of fatigability. Its usefulness in determining the indication for an invasive procedure remains to be established.

### MAGNETIC RESONANCE IMAGING

MRI is sometimes necessary and has been advocated for the evaluation of borderline left ventricle (LV) in critical aortic stenosis.[93,94] MRI allows calculation of LV volume and size irrespectively of the septal shift and interaction with the right ventricle. On the other hand, MRI is of limited help in delineating the anatomy of the valve.

## Medical Therapy

### CRITICAL NEONATAL AORTIC STENOSIS

The life-saving resuscitative measure in a neonate arriving in cardiovascular collapse is the administration of Prostaglandin $E_1$. Inotropic support and mechanical ventilation are required to treat heart failure. Thereafter, the evaluation of the child should enable the clinician to make the decision between a biventricular repair and a Norwood procedure. The largest study to date examining outcomes for critical aortic stenosis has identified the following parameters allowing prediction of survival with either of the two options: age, *z*-score of the aortic valve at the sinuses, grade of endocardial fibroelastosis, ascending aortic diameter, presence of moderate or severe tricuspid regurgitation, and *z*-score of the ventricular length.[90]

### INDICATION FOR SURGERY OR BALLOON VALVULOPASTY

Urgent intervention after adequate resuscitation is indicated for the infant presenting in shock or showing clinical or echocardiographic evidence of poor left-ventricular function. Patients presenting with high-peak gradients should be offered an early procedure, but there is increasing evidence that in asymptomatic patients, intervention can be delayed if they are submitted to a close follow-up.[95,96] The cut-off mean gradient for intervention has been usually set at 50 mm Hg, but this level has been decided arbitrarily. In children and adolescents, surgery or interventional catheterization will be recommended for symptomatic disease, repolarization or ischemic changes seon on ECG at rest or on exercise, and when the peak instantaneous transvalvular gradient is greater than 75 mm Hg. In aortic regurgitation, the presence of symptoms, left ventricular dysfunction (ejection fraction <50 percent) or an increase in left end-systolic diameters are indications for surgery.[97] In rheumatic valve disease, an operation is often required for the mitral component of the disease, while there is concomitant moderate aortic regurgitation. Valve repair in these circumstances seems rewarding with freedom from aortic valve dysfunction of 68 percent at 8 years.

### MEDICAL MANAGEMENT OF THE PATIENT WITH AORTIC VALVE LESION

There has been recent evidence that ACE inhibitor treatment in growing children with aortic regurgitation limits excessive increases in left ventricular mass and volumes.[98]

## Surgical Therapy

### APPROACH TO THE AORTIC VALVE

Many have advocated that a transverse aortotomy should be the preferred approach for aortic valve repair. In the pediatric population, this statement may not be necessarily true, because the main feature of aortic valve disease in the young age is valvar stenosis with its corollary, a small-sized ascending aorta. Therefore, the surgeon should not hesitate to perform an oblique aortotomy, extending the incision into the noncoronary sinus almost down to the level of the annulus in order to gain optimal exposure of the aortic valve and have, subsequently, the opportunity to enlarge the diminutive root and ascending aorta.

### AORTIC VALVE REPAIR

Once stay sutures are placed on the commissures or at 120 degrees from each other (where commissures should normally be positioned), one can appreciate the valve and the the eventual mechanism of regurgitation. In our experience, only the lack of mobility of the leaflets at their hinge points will preclude repair. Thereafter, the fused commissures are opened up to the aortic wall. The calcifications and fibrous nodes are resected. Local thickenings are shaved with caution. It has been our policy to remove thickening when it impairs the mobility of the leaflet or when it is obstructive per se, but to avoid "cosmetic" shaving of the cusps as we believe that it may promote further fibrosis and retraction. Tears from previous balloon dilatation are then closed directly or, if the regurgitation at this level caused a retraction of the cusp, by the adjunction of a glutaraldehyde-preserved autologous pericardial patch.

***Congenital Aortic Stenosis: Creation of Neocommissures.*** Congenital aortic stenosis often results from the partial or complete fusion of the zone of apposition of adjoining leaflets, followed by the involution of the apposed area. Therefore, the valve takes the appearance of a dome. Classical commissurotomy consisted of opening the roof of this dome-like structure, leaving the severed elements unsupported and thereby causing regurgitation. A typical bicuspid valve would be opened largely between its two main components, leaving the area of the raphe untouched. It has now been shown that tricuspid valve repair of congenital lesions give the best chances for long-term success.[99] Because the aorta is naturally small in these patients, it has been our policy to transform unicuspid valves into bicuspid valves and bicuspid valves into tricuspid ones by creating new commissures.[100]

The surgical instrumentation to achieve good valvotomy and commissuroplasty is very important. We use ophthalmic micro blades and specially modified ophthalmic tooth forceps (0.2-mm teeth).

The area of the potential commissure is identified and leaflets are opened in their direction, up to the aortic root wall. Calcifications and fibrous thickenings present in the raphe are resected. Stay sutures are placed at the highest point of the planned neocommissures, at the level of the planned sinotubular junction. Two separate patches of glutaraldehyde–preserved autologous pericardium are cut in a triangular shape. Each patch is then sutured with a continuous suture to the severed leaflet whether it corresponds to an opened doming valve or a previous raphe. The two patches are then secured together at the level where they join on the aortic wall. Both patches are trimmed if necessary in order to achieve the appropriate height and to leave the adequate tension on the free edge of the new leaflets. A continuous suture secures both patches to the aortic wall up to the previously positioned stay suture, marking the superior aspect of the neocommissure (Figs. 81-19 and 81-20).

***Cusp Extension.*** We leave the native tissue in place as long as mobility along the hinge points is preserved. As patch material, we favor autologous pericardium treated for 4 to 8 min in 0.625 percent glutaraldehyde and rinsed thoroughly. Three rectangular strips of pericardium patches are tailored as follows. The length of each patch is cut slightly longer than the free edge of the leaflet. The height of the patch should be calculated so that even with unequal leaflets, the newly recreated free edges are all at the same level. The patch extensions should not be redundant to avoid prolapsing, but should be high enough to achieve 4 to 5 mm of apposition in order to reduce the stress on the valve. The strips of pericardium are then sutured with a continuous suture to their respective leaflets, with the mesothelial face on the ventricular side and taking great care to avoid any gathering unless there is significant elongation of the free edge (as compared to the adjacent one). Stay sutures are positioned a few millimeters above the apices of commissures. It is at this stage that the length of the newly created free edge is set by cutting the redundant extremities of each patch. Theoretically, all three patches should have the same length, equal to the diameter of the sinotubular junction. In practice, this is done by bringing the three patches into a closed position with a temporary stitch at the center of the valve as would be done with a "Frater" apposition stitch. Then each adjacent half-free edge are apposed to give them the appropriate length and minimal tension, while maintaining the new commissures in their expected natural position, and the extremities of the strips of pericardium are cut. Each commissure is then recreated by suturing the two adjacent strips of pericardium to the aortic wall, progressing cephalad from the natural commissure. Great care should be taken to be perfectly aligned with the axis of the natural commissure. The suture is then passed outside of the aorta (Figs. 81-21 and 81-22A and B).

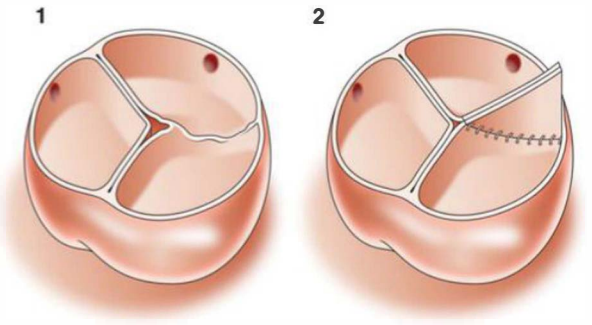

**FIGURE 81-20** Commissurotomy of a bicuspid valve and creation of a neocommissure leading to a tricuspid valve.

## SPECIFIC CONSIDERATIONS

***Bicuspid Valve.*** Beyond infancy, the dominant feature of bicuspid aortic valve will guide the surgical strategy. In pediatric patients, the bicuspid valve will almost always have

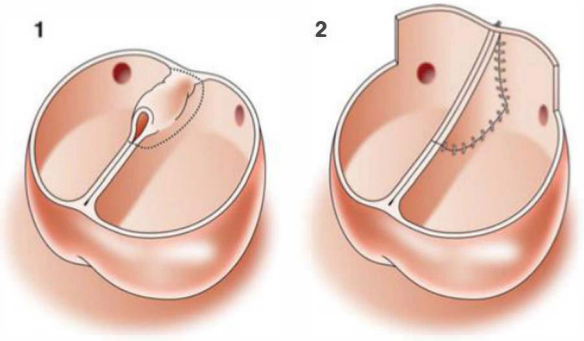

**FIGURE 81-19** Critical aortic stenosis: Commissurotomy of a unicuspid valve and construction of a neocommissure, with creation of a bicuspid valve.

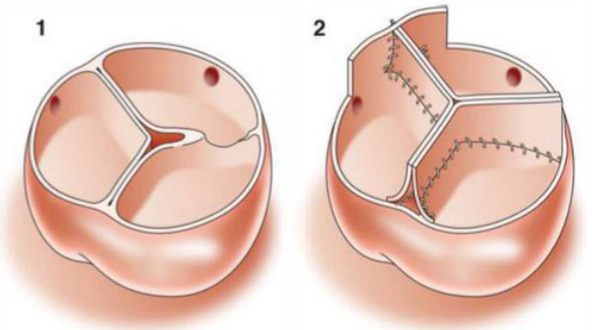

**FIGURE 81-21** Creation of a tricuspid valve by cusp extension with glutaraldehyde-treated autologous pericardium.

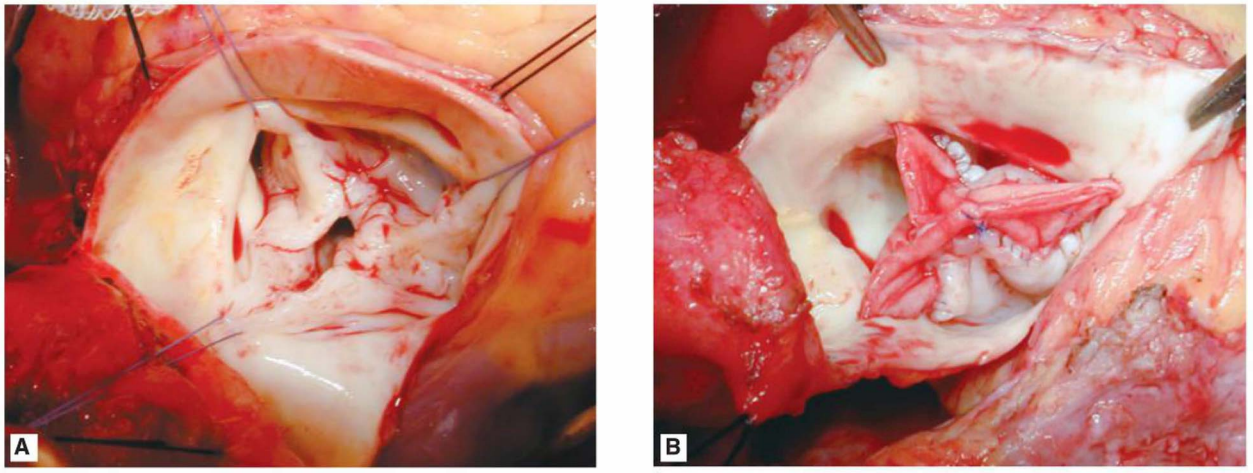

**FIGURE 81-22** Stenotic and regurgitant bicuspid valve. After tricuspidization and cusp extension.

some degree of stenosis; however, when the valve is predominantly regurgitant, the valve is most likely amenable to repair. The type of repair is guided by the size of the aortic root and the quality of the leaflet. If the root is of normal size and the leaflet thickened we would perform a tricuspidization of the valve by opening the raphe and performing a cusp extension. Exceptionally, in pediatric patients, we would find a very large aortic root with thin leaflets. The repair would be similar to the one performed in adults (second–fourth decade) with purely regurgitant bicuspid valve (Fig. 81-23). According to the anatomical finding, triangular resection of the raphe, free edge reinforcement with a PTFE suture, and subcommissural annuloplasty can be performed.[22,101]

***Ventricular Septal Defect and Aortic Regurgitation.*** A large number of techniques have been reported for this condition, but their application depends on the severity of the disease and the extent of prolapse. The primary lesion involves the displacement of the hinge point of the prolapsing leaflet through the VSD orifice, thereby limiting the effective height of right coronary cusp, with consequent reduction of the coaptation area and increasing the stress on its free edge. The free edge then elongates, the regurgitation increases, and secondary lesion appears on the adjacent cusps. We favor a technique with no patch, where the emphasis is on the repositioning of the hinge point toward the aortic lumen and the restoration of the normal height of the right coronary cusp together with triangular resection at the free edge whenever indicated.[60] In that case, to preserve the growth potential together with the fine mechanical properties and stress-relief ability of the commissure, a triangular resection is done at the midportion of the free edge (Fig. 81-24), or where it is most thickened (particularly if this allows maintaining the relationship with the other nodduli of Arantius). Through the aortotomy, pledgetted sutures are secured on the right ventricular edge of the VSD, passed through the mobilized leaflet hinge point (Fig. 81-25). Others have described a two-patch technique, using one patch for the VSD, and another for the dilated sinus.[102]

***Subaortic Membrane.*** Extensive resection of all extensions of the membrane is necessary. In the most severe cases, this necessitates peeling the surface of the interleaflet triangle and detaching finely the fibrous formation from the ventricular

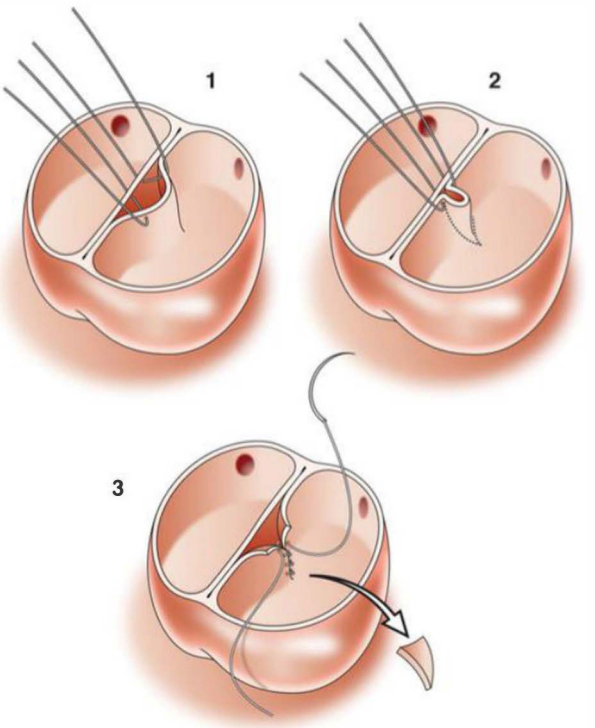

**FIGURE 81-23** Triangular resection at the free edge of a purely regurgitant bicuspid valve.

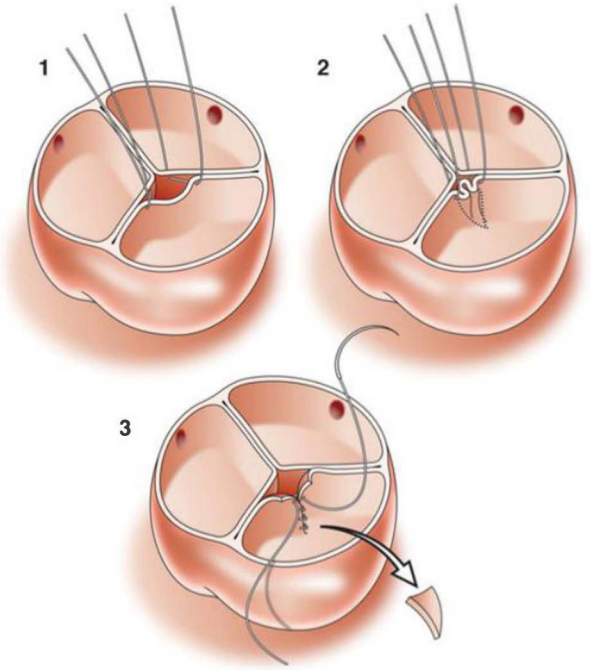

FIGURE 81-24 Method to calculate the width of the triangular resection at the free edge in a tricuspid valve.

aspect of the aortic leaflets. A systematic and aggressive myectomy of the interventricular septum away from the conduction has been shown to reduce the risk of recurrence.[62]

***Marfan Syndrome.*** Either mild or more severe, the aortic regurgitation in the Marfan syndrome in pediatric patients very rarely justifies surgical intervention in isolation. The treatment of the aneurysm of the sinuses and dilation of the sinotubular junction with or without aortic regurgitation is best dealt with by utilizing a valve-sparing procedure (see Chapter 82). The reimplantation technique should be favored over the remodeling technique.[103,104]

## AORTIC VALVE REPLACEMENT

The techniques of prosthetic valve replacement, Bentall procedure, and Ross procedure are essentially performed in infants and children as they are in adult patients. The main constraint is the limited size of the aortic root. For that reason, we avoid use of pledgetted or everting sutures to secure the valve in children, as these reduce significantly the effective annular diameter. Although the smallest mechanical valve available is a 17-mm prosthesis, we strive to insert at least one with a 19-mm diameter in order to reduce the need for reoperation. Techniques of annular enlargement are often necessary, either by incision of the commissure between left and noncoronary cusps and patching of the annulus onto the anterior mitral valve leaflet as described by Manouguian,[105,106] with a Konno procedure[107] or both.

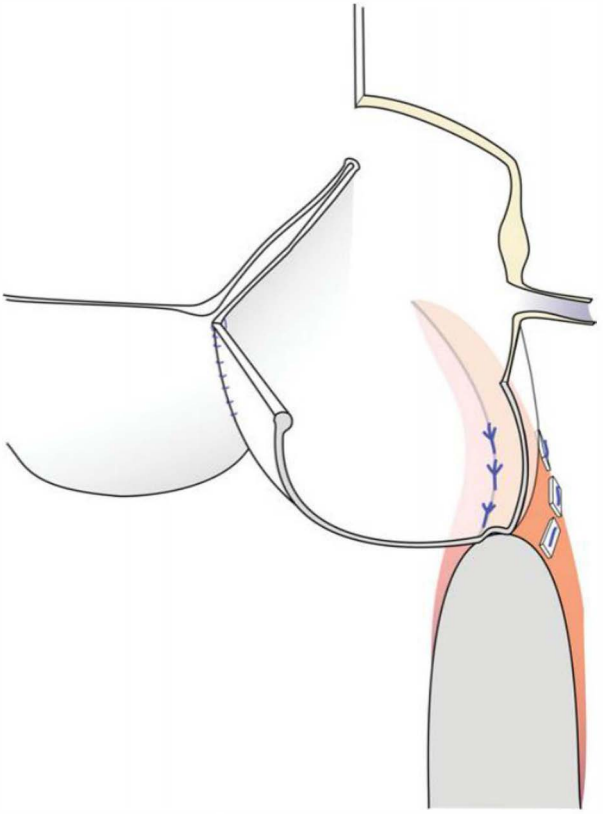

FIGURE 81-25 Repair of Infundibular VSD with aortic regurgitation: mobilization of the right coronary cusp. Fixation of the right coronary cusp to the crest of the defect at the point chosen to restore the height of the cusp. Triangular resection at the free edge.

The size constraint has in effect made the Ross procedure almost the only aortic valve replacement used in infants and small children. When performing a Ross procedure, it is essential to match the diameter of the aortic orifice with the one of the pulmonary autograft. In the presence of a small aortic orifice or a subaortic tunnel an aortoventriculoplasty as described by Konno (see Chapter 78) has to be performed. The latter actually is facilitated by excision of the autograft. When the pulmonary autograft is smaller than the aortic annulus, this has to be corrected by a subcommissural annuloplasty or even by a small triangular resection (reverse Konno or Manouguian) as well as an implantation very low into the left ventricle outflow tract. The correction of the mismatch with a large autograft cuff should be avoided at all cost[108] and, generally, the height of pulmonary autograft tissue (subpulmonary infundibulum) below the hinge point of the pulmonary cusps has to be kept to the strict minimum. An inclusion technique has been recommended as the procedure of choice when performing a Ross in the adults, but it is only exceptionally feasible in children because of the diminutive size of the aortic root.

## Outcomes

### BALLOON DILATATION VERSUS SURGERY

The outcomes of neonates with critical aortic stenosis is significantly worse, and the issue of congenital aortic stenosis in the neonatal period should therefore be addressed separately.[109] In this age group, the mortality seems independent of the type of procedure used, and ranges between 0 and 20 percent. The cause of death in this group is mostly related to the inadequacy of the left heart structures to fully sustain the systemic circulation.

Percutaneous procedures and surgical interventions relieve stenosis with fundamentally different modes of action, and this is reflected by the differences in the clinical consequences of both procedures. The inflation of a balloon angioplasty catheter will tear the valve in the plane of least resistance (mostly in the supple and mobile component of the valve), while classical surgical commissurotomy will open the fibrotic fused zones of apposition, leaving thickened leaflets with reduced mobility. Therefore, classically, balloon valvuloplasty will decrease the transvalvular gradient by 40 percent, while the surgical procedure will decrease it by 20 percent, but it will also be responsible for more aortic regurgitation. Avulsion of the valve with severe aortic regurgitation occurs after 5 percent of balloon dilatations.[110] Despite these differences, an extensive comparative clinical study performed in neonates failed to demonstrate significant difference between these procedures in their respective early mortality or long-term rate of reoperation. Thirty percent of the patients need a reoperation after 6 months and 50 percent after 5 years (Fig. 81-26). Preprocedural need for inotropic support, lower weight at valvotomy, and moderate-to-severe aortic valve regurgitation immediately after valvotomy were predictive factors for reoperation.[109]

In the older age group, the mortality is extremely low and, again, the results are remarkably comparable. The decrease in peak-to-peak gradient is around 50 percent after both types of procedures, and the transvalvular gradient and the severity of aortic regurgitation will gradually increase over time. The actuarial freedom from any reintervention is 80 percent at 7 years for surgical aortic valvotomy and repair,[111] while it is 54 percent at 10 years for the balloon valvuloplasty.[112]

Because of the similarity in results offered by interventional catheterization and surgery, the choice between the two procedures should depend on individual center preference and their relative expertise in both fields. However, all comparative studies to date have compared balloon valvuloplasty with classical techniques of surgical commissurotomy; we believe that with the more recently developed techniques of repair and new material becoming available, improved results with surgery will soon be evident.[100] It has been clearly demonstrated that the best results after balloon dilatation are achieved in patients with structurally tricuspid valves with fusion at the commissural level.[113] On the other hand, patients with truly bicuspid valves will not have a relief of their stenosis if the raphe is kept intact, and in this setting it is reasonable to think that surgery will achieve superior and more durable results. Therefore, irrespective of the age of the patients, we limit in our practice the indication for balloon dilatation to tricuspid valves with commissural fusion and annular *z*-value 0 or greater than 0, and prefer surgical correction for all remaining patients.

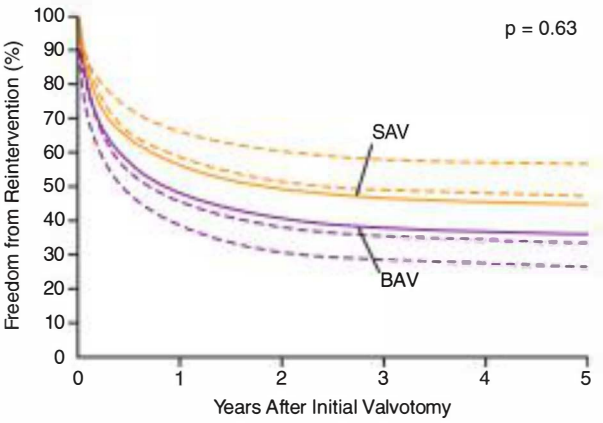

**FIGURE 81-26** Freedom from aortic valve-related reintervention stratified by type of initial aortic valvotomy (SAV, surgical valvotomy; BAV, balloon valvotomy), adjusted for differences in group characteristics. Solid lines represent parametric determination of continuous point estimates and dashed lines enclose 70 percent confidence interval (CI). Are outcomes of surgical versus transcatheter balloon valvotomy equivalent in neonatal critical aortic stenosis? *Circulation* 2001 Sep 18;104(12 Suppl 1):I152–I158.)

### AORTIC VALVE REPAIR

Modern techniques of valve repair such as neocommissure reconstruction have only been introduced recently in the pediatric population, and the long-term results of valve repair in children can only be extrapolated from the adult experience and from the cusp extension techniques applied in rheumatic valves. Some authors have quoted a freedom from structural valve deterioration for cusp extension or cusp replacement with autologous pericardium of greater than 90 percent at 9 years after repair, without any need for anticoagulation.[114,115] Adults with biscuspid valve repair *without* cusp extension have a 7-year freedom from reoperation of 84 percent.[101]

Valve-sparing procedures can successfully be performed in children with good midterm outcome.[103] At the RCH, Melbourne, we have introduced the tricuspidization of bicuspid aortic valve with cusp extension in 1999 and 2005[116] to reduce the residual gradient after repair. The freedom from reintervention is 66 percent at 7 years in this series.[111] Two deaths occurred in this series and may have been linked to coronary obstruction. This has led us to limit the usage of this technique to aortic roots with symmetrical sinuses and well-positioned coronary ostia.

Recurrence of regurgitation is rare after valve repair for VSD-related aortic regurgitation, and 15-year freedom from reoperation as high as 81 percent has been reported.[117] Long-term valve function depends greatly on the regurgitation grade at the time of the repair. All authors insist on early intervention as soon as traces of aortic regurgitation become evident during follow-up.

The aortic regurgitation associated with subaortic membranes regresses in the majority of operated cases, especially when aggressive resection of all the proliferative tissue is undertaken.[62]

## AORTIC VALVE REPLACEMENT

***Bioprosthesis.*** The use of bioprostheses has been abandoned in children due to their unacceptable rate of calcification and degeneration leading to reoperation in 75 percent of the patients within 5 years.[118] They should only be considered as a last resort in patients in whom anticoagulation is strictly contraindicated, and for those patients who are not candidates for a Ross procedure, such as female patients of childbearing age.

***Mechanical Valves.*** The operative mortality of children undergoing a mechanical valve replacement is higher than for adult patients (between 2 and 13 percent), mainly as a result of concomitant risk factors such as previous surgery, associated conditions necessitating repair, and poor ventricular function.[105,119] In this age group, major bleeding and thromboembolic events are remarkably rare, with an estimated linearized rate of 0.3 percent per patient year for each of these complications. The events are usually due to lack of compliance with anticoagulation treatment in the adolescent age group.[120,121] Ten-year freedom from reoperation is approximately 92 percent in this age group. The 10-year survival rate is around 75 percent.[119,122] Some authors have pointed out that congenital patients may be prone to late pannus formation in the subvalvar area and that they might be more susceptible to late valve failure than their adult counterpart.[123]

***Homografts.*** The 10-year freedom from tissue failure for aortic valve replacement with homografts is 62 ± 3 percent in large series of adult patients. The incidence of valve deterioration is higher in the adolescent and in the young adult, and is highest in infants; these data preclude liberal use of homografts in this age group.[124] The risk of requiring reoperation after allograft aortic valve replacement is greater than 50 percent in the 3 years following implantation when performed in children aged less than 3 years.[125]

***Ross Procedure.*** Reported mortality for Ross procedure in children usually varies between 0 and 6 percent.[126,127] The advantages of the Ross procedure are obvious in children. The procedure allows the best anatomical restoration of the left ventricular outflow tract, with no residual gradient, no need for anticoagulation, and can be performed in all age groups. It has also been demonstrated that the growth of the autograft parallels somatic growth.[128]

Comparative retrospective studies seem to underline the superiority of the pulmonary autograft when considering both survival and valve-related complications.[123,129] The actuarial risk of autograft failure in pediatric patients is around 12 percent at 2 years; 40 percent of patients will have equal or greater than moderate regurgitation at 6 years and almost all patients will eventually demonstrate a neoaortic root $z$-score greater than 4.[130]

The Ross procedure can also be performed for aortic rheumatic valve disease, but long-term results are very disappointing and its use should be avoided in this particular subgroup of patients.[131]

The Ross procedure may be the only valve replacement procedure in pediatric patients, especially neonates and infants, but it is not the only surgical alternative.

Despite its apparent ideal characteristics, the Ross procedure may not be the panacea to offer to all children. Geometric mismatch between the aortic and the pulmonary root seem to be responsible for a high rate of autograft failure, especially when the procedure is performed for aortic valve regurgitation.[108] There is an increasing concern that all autografts implanted as a root are subjected to progressive dilatation, and it is not yet known how many will need a reoperation for neoaortic regurgitation in the future.[132] Studies have reported that, at 5 years, 25 percent of autografts will present with more than mild regurgitation.[127]

We therefore believe that aortic valve repair should be attempted in all circumstances where feasible, especially in infants and children. It is likely that a number of these repairs will fail with time, especially those involving extensive reconstruction with pericardium. In addition, because geometric mismatch between the pulmonary and the aortic root predisposes to the autograft failure after a Ross procedure, we offer primary valve repair for all infants, in the hope that it might allow for near-normal growth of the aortic root; the Ross procedure can then be performed at a later age, when inclusion or other means of reinforcement of the autograft can be used with more favorable long-term results. When the primary concern is aortic regurgitation, the rate of autograft failure is substantial. These lesions seem the best suited for repair, and we strongly recommend repair in these situations. When the lesion is predominantly stenotic and the annulus is small, a Ross procedure is indicated.

# Cardiac Surgical Intervention in Pediatric Patients with Connective Tissue Disorders

*Giorgio Zanotti*
*Duke E. Cameron*
*Luca A. Vricella*

**KEY CONCEPTS**

- Thoracic aortic aneurysm syndromes are due to genetic disorders inherited as autosomal dominant traits with reduced penetrance and incomplete expression. Hence, clinical phenotype is complex and highly variable with often no genotype-phenotype correlation.
- Altered TGF-β signaling and proteolytic metabolism involving the entire aortic wall are now challenging old pathophysiologic models by which aortic aneurysms were solely caused by extracellular matrix structural protein deficiency in the media.
- Indications for surgery are still mainly based on aortic diameter as well as aortic growth rate and family history of early rupture/dissection. However, efforts are made to identify circulating markers associated with early complications to guide risk stratification.
- Surgery is the only treatment that can modify the natural history of pediatric patients with thoracic aortic aneurysm syndromes. Although promising, medical treatment has not yet been validated.
- Aortic valve-sparing root replacement (AVSRR) is currently the favored surgical approach, whereas the Bentall operation should be reserved for patients with acute aortic dissection, unrepairable leaflet damage, or failed AVSRR. Early and midterm results of AVSRR in pediatric patients are excellent and comparable to those obtained with composite valve graft root replacement. Long-term event-free survival in this particular group of patients has yet to be assessed.

## INTRODUCTION

Arterial aneurysms in children are typically due to a genetic abnormality and represent the most lethal clinical feature observed in the setting of connective tissue disorders. The most prevalent sites of vascular catastrophe in these young patients are the aortic root and the ascending aorta.

Pediatric aortic surgery for patients affected by connective tissue disorders is a rapidly evolving field. As a better understanding of the underlying aortic wall pathology is achieved, diagnosis is improved and treatment objectives, surgical indications, operative strategies, and expected outcomes change.

Although over the past 20 years treatment goals have shifted from life-saving measures to preemptive surgery in the hopes of achieving long-term event-free survival, risk stratification and surgical decision-making are still imperfect. Surgical indications are mostly based on clinical diagnosis, aneurysm size, and family history. The absence of biomarkers predictive of malignant clinical course, along with the lack of a large body of data on natural history and true long-term treatment outcomes impact our ability to predict the aortic size at which vascular complications may occur in each patient. Aortic root pathology and aneurysms are described in detail in Chapter 39. We will hereby expand on the topic by focusing on patients in the pediatric age group.

## PATHOPHYSIOLOGY

Thoracic aortic aneurysm in the setting of connective tissue disorder is a syndromic disease with multiple, complex phenotypes. Within each disease, clinical heterogeneity due to mosaicism, incomplete penetrance, and age-dependence of the phenotype is common. These features account for the lack of a complete understanding of the pathophysiology underlying thoracic aneurysm syndromes.

Historically, pathogenetic models of ascending aortic aneurysm were centered on abnormalities of structural protein of the extracellular matrix as a cause of connective tissue weakness leading to aneurysm formation. The near-uniform finding of elastolysis in the media ultimately leading to cystic medial necrosis was the anatomic hallmark. Along these lines of reasoning, Marfan syndrome was thought to be exclusively caused by deficiency of the microfibrillar protein fibrillin-1, Elhers–Danlos vascular type caused by qualitative and/or quantitative alteration of collagen type III, and bicuspid aortic valve with aneurysm caused by altered vascular collagen production.

Recent insights gained while studying Marfan syndrome highlighted the importance of cytokine dysregulation and, in particular, the potential role of TGF-β in the pathogenesis of aortic aneurysms. Deficiency of fibrillin-1 would lead to failed sequestration of TGF-β in the matrix and hence deregulated activation of and signaling by TGF-β in arterial wall tissues. TGF-β signaling, in turn, would result in the activation of proteolytic enzymes such as thrombospondin-1 and matrix metalloproteinases, causing extracellular matrix degeneration and loss of elastic properties ultimately leading to aneurysm formation.

Even though the etiology of most aortic aneurysm syndromes is still largely unknown, convincing evidence of amplified TGF-β signaling in the aortic wall has also been observed in patients with bicuspid aortic valve and aneurysm and Loeys-Dietz syndrome.[1,2] In patients with Loeys-Dietz syndrome, mutations in the genes for either TGF-β receptor 1 or 2 are associated with increased downstream TGF-β signaling within the arterial media; this in turn leads to increased collagen synthesis, loss of elastin content, and elastic fiber disarray. The ultrastructural end-result is an extremely thin aortic wall that has decreased elastic properties and is prone to dilatation and dissection.

Recent studies on aneurysm progression strongly emphasize molecular events taking place in the adventitia during aneurysm formation, challenging the long-held assumption that aneurysms originate from a disease processes harbored in the media.[3] This new concept by which the adventitia assumes an active role in aneurysm formation is supported by the old observation of maintenance of wall integrity following endarterectomy and the fact that patients with failed elastogenensis and generalized medial disorganization will typically not manifest aneurysm formation.[4]

Currently, the pathogenesis of ascending aortic aneurysm in pediatric patients is conceived as the final result of a complex and yet incompletely understood interplay between signaling pathways, most likely orchestrated by altered TGF-β signaling throughout the entire aortic wall. Alteration of specific matrix proteins in the arterial wall may be the initiating event as well the end-result of this process.

## CLINICAL FEATURES

### Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder with complete penetrance but variable expression that affects 2 to 3 in 10,000 individuals.[5] In approximately 25 percent of patients, the disease is due to a de novo mutation.[6] Cardinal clinical findings include annuloaortic ectasia, dislocation of the ocular lens, and long bone overgrowth (Table 82-1).

Clinical course is heavily dependent on age of presentation. The infantile form of Marfan syndrome has an early onset of aneurysm formation and is distinguished by an aggressive clinical course.[6–9] Yet the aggressiveness of the clinical course is usually dominated by mitral valve disease, which stands as the leading cause of morbidity and mortality in this particular age group.[10] In fact, aortic catastrophes are exceptionally rare in Marfan patients younger than 12 years of age, almost irrespective of the degree of aortic dilatation; in this age group, aortic rupture/dissection occurs mainly in the case of giant aneurysms, often following progressive aortic insufficiency.[6,7,9,11,12] Rupture of an enlarged aortic root is instead the leading cause of death in adolescents.[5,13,14] In these patients, aortic regurgitation rarely begins at an aortic diameter <6 cm, but many experience dissection at significantly smaller root diameters.[15]

In children, determinants of aortic complications are aneurysm absolute size and growth rate, and family history of premature dissection.[5] In young patients, the average size of the aortic root at the time of dissection is 5.1 cm and when aortic diameter exceeds 6 cm, there is a 4 to 8-fold increase in the cumulative risk of rupture.[16–18] Also, if the aortic root expands at a rate greater than 15 mm/year, aortic dissection is more common.[14] Finally, family history of aortic complications at relatively small diameters suggests the presence of a particularly frail aortic wall and a greater propensity for premature aneurysm rupture.

### Loeys–Dietz Syndromes

Loeys–Dietz syndrome is an autosomal dominant connective tissue disorder caused by mutations in the genes encoding for transforming growth factor β receptors 1 and 2 (*TGF-β*). It is characterized by premature ascending aortic aneurysm and dissection at small aortic diameters and at younger age compared with any other connective tissue disorder (Table 82-1 and Fig. 82-1).[19]

Clinical expression is variable with features that, on the mild end of the spectrum, are similar to those of Marfan syndrome.[20,21] On the opposite end of the clinical spectrum, is a complex phenotype in which aortic dissection or rupture

**TABLE 82-1: Characteristic Features of Aortic Aneurysm Syndromes in Children**

| | Aortic Involvement[a] | Earliest Presentation[b] | Dissection in Childhood/ Adolescence | Dissection at Small Diameter | Life Expectancy[c] following Repair (Years) | Systemic Features |
|---|---|---|---|---|---|---|
| Marfan syndrome | Root | Infancy | Possible | Possible | 70 | Ectopia lens<br>Skeletal deformities |
| Loeys–Dietz syndrome | Root | In utero | Likely | Likely | 37 | Hypertelorism<br>Bifid uvula<br>Arterial tortuosity |
| Ehler–Danlos syndrome | Ascending aorta | Adolescence | Probable | Likely | 48 | Facial appearance<br>Translucent skin<br>Visceral rupture |
| Bicuspid aortic valve | Ascending aorta | Childhood | Unlikely | Possible | Undefined, most likely similar to the general population | None |

[a]Most prevalent site of aneurysm occurrence.
[b]Earliest presentation of aortic aneurysm/dissection/rupture.
[c]Life expectancy in treated patients.

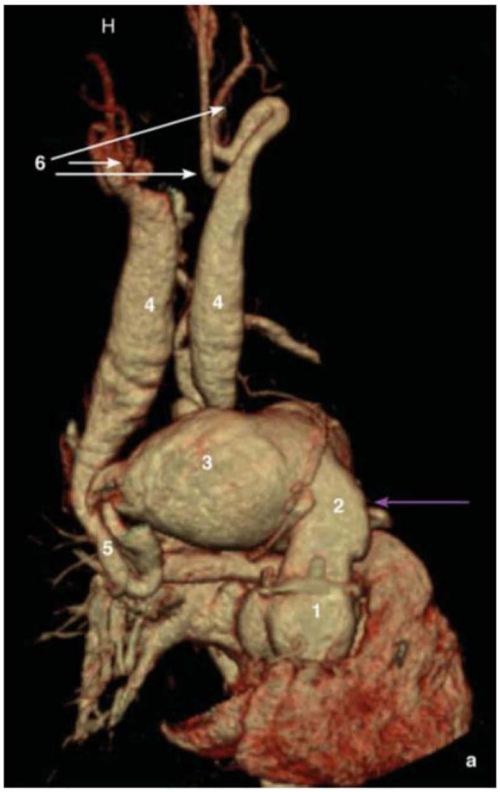

**FIGURE 82-1** Severe aortic pathological findings in a 2-year-old child with Loeys–Dietz syndrome. Three-dimensional computerized tomographic reconstruction, posterior view. This child experienced an acute type A aortic dissection requiring replacement of a portion of the ascending aorta with an interposition graft (2). Of note is the very prominent vascular tortuosity (5) and the diameter of the epiaortic vessels (4). The patient required total arch replacement and valve-sparing root replacement at 5 years of age. commonly becomes apparent in early childhood.[19] Two main syndromic pictures have been described. Patients with Loeys–Dietz syndrome type I are characterized by the clinical triad of hypertelorism (90 percent), bifid uvula and/or cleft palate (90 percent) (Fig. 82-2) and generalized arterial tortuosity with aneurysm formation (84 percent). None of these clinical features are present in patients with Marfan syndrome and are key for clinical diagnosis. Ninety-eight percent of these patients develop aortic root aneurysm early in life.[2] Patients with Loeys–Dietz syndrome type II lack these craniofacial features (though bifid uvula may be present) and

**FIGURE 82-2** Typical craniofacial features of child with Lowys–Dietz syndrome type 1. (Reproduced with permission from Williams JA, Loeys BL, Nwakanma LU, et al. Early surgical experience with Loeys-Dietz: a new syndrome of aggressive thoracic aortic aneurysm disease. *Ann Thorac Surg* 2007;83(2):S757–S763.)

have at least two manifestations of the Ehlers–Danlos syndrome (easy bruising, characteristic facial appearance, wide and atrophic scars, joint laxity, translucent/velvety skin, visceral rupture) with no type III collagen biosynthesis deficit. Patients with Loeys–Dietz syndrome type I endure a more severe cardiovascular course than those with Loeys–Dietz type II. Importantly, more severe craniofacial abnormalities are related to worse cardiovascular outcomes among type I patients.[2]

The most important feature of Loeys–Dietz syndrome is that aneurysms commonly dissect at sizes smaller than those seen in patients with Marfan syndrome. In children with Loeys–Dietz syndrome, aortic dissection often occurs at diameters well under 5.0 cm.[2,22] It is imperative therefore to normalize aneurysm size to age and body size ($z$-score) to guide risk stratification for aortic complications and appropriately plan for surgery.

## Vascular Ehlers–Danlos Syndrome

Vascular Ehlers–Danlos syndrome is a rare autosomal dominant disorder, characterized by extreme fragility of the connective tissue leading to arterial and hollow organ rupture as well as anastomotic complications following surgical intervention (Table 82-1). Dissection and rupture of large arteries are the hallmark of this disease. The estimated prevalence of all Ehlers–Danlos syndromes (six subtypes) ranges between 1:10,000 and 1:25,000, and the vascular type represents about 5 to 10 percent of all cases.[23] Mutations in the COL3A1 gene coding for type III procollagen (mainly located in skin, vessel walls, and hollow organs) cause the phenotype, with no genotype–phenotype correlation.

Cardinal clinical findings are: facial appearance (emaciated face with prominent zygomata and sunken cheeks, thin nose and undefined lip edges), thin skin with visible veins and easy bruising, rupture of arteries, gravid uterus or intestine.[23,24] Diagnosis is often missed, with approximately 75 percent of patients presenting in adulthood with major vascular complications.[25] Median survival is 48 years and the primary cause of death is arterial dissection or rupture (80 percent), often involving the thoracic aorta.[24,25] Although vascular complications are rare in early childhood, patients with vascular Ehlers–Danlos syndrome have a 25 percent risk of experiencing a major vascular complication by the age of 20 years.[23–25] As for virtually all the orphan diseases, diagnosis is often missed until severe complications occur.

## Congenitally Bicuspid Aortic Valve

Congenitally bicuspid aortic valve is a common cardiac anomaly that clusters in families and has a prevalence of 0.5 to 2 in 100 individuals among the general population.[26–28]

There are three major types of aortic aneurysms associated with a congenitally bicuspid aortic valve. The most common is the fusiform aneurysm of the ascending aorta (Table 82-1), which begins above the sinotubular junction and terminates proximal to the innominate artery. The most rare type involves the aortic root and extends below the sinotubular junction, resembling aneurysms found in patients with Marfan syndrome. An intermediate type may also be observed.

In patients with a congenitally bicuspid aortic valve, aortic dilatation is a well-known phenomenon and its evolution has been recently characterized since the early phase. In these patients, aortic dilatation begins by 1 year of age and steadily progresses throughout childhood. About one-third of the patients with an initially normal aortic size develop an ascending aortic aneurysm by adulthood. Predictors of larger ascending aortic aneurysm and aortic root diameter are age and smaller body surface area, whereas valve gradient and right–left valve fusion have been found to be predictors of more rapid aneurysmal growth in the ascending aorta.[29] Although aortic dissection is more likely in patients with a dilated aorta, in some families dissection has been described at diameters under 5.0 cm similarly to other thoracic aortic syndromes.[11,30] Again, risk factors for malignant course are mostly unknown.

# MEDICAL (NONSURGICAL) THERAPY

Current nonsurgical management of thoracic aortic syndromes includes serial aortic imaging along with echocardiographic studies and use of oral medications aimed at reducing mechanical stress on the aortic wall.

Imaging of the entire aorta and large vessels is performed at diagnosis and yearly thereafter unless the clinical course of the disease warrants a more frequent reassessment computed tomography (CT or MR angiography). Similarly, echocardiograms are obtained at diagnosis and subsequently every 6 months unless otherwise indicated by severity and progression of aortic valve insufficiency. Following surgery, ventricular and aortic valve function are assessed to establish a baseline for subsequent evaluations performed at 1-month follow-up and yearly thereafter.

β-adrenergic blockers (e.g., atenolol) have been a pharmacological cornerstone in the treatment of Marfan syndrome for years, only substituted by calcium channel blockers or angiotensin receptor blockers (ARBs) when β-blocker intolerance occurs (mostly due to asthma, depression, fatigue). β-blocker agents may stabilize aortic root growth, although this has not been a consistent finding.[31] As murine models of Marfan syndrome showed the key role of TGF-β overexpression in aortic root enlargement, ACE-inhibitors (e.g., perindopril) and ARBs (e.g., losartan), known to have intrinsic anti-TGF-β activity, were tested in small cohorts of Marfan patients.[32] Although observed reduction in aortic root enlargement raised hope for medical treatment for this syndrome, the small sample of the patient population investigated and the relatively short study time posed some legitimate concerns on the beneficial effect of anti-Angiotensin II medications, especially when the underlying genetic variability is taken

into account. Mechanisms of action, relative potency, and duration of protection with each class of medication remain to be elucidated. The lack of circulating markers to assess short-term efficacy also affects the ability to individualize treatment. While awaiting final results of randomized clinical trials comparing Losartan with β-blockers in children and young adults with Marfan syndrome, β-adrenergic blockade remains as first line of treatment in patients with ascending aortic aneurysms.

It cannot be overemphasized that, when size criteria are met, surgical intervention is warranted. Despite the fact that medical therapy is promising in the treatment of Marfan syndrome and possibly of other aortic aneurysm syndromes, only surgery is able to modify the natural course of the disease.

## INDICATIONS FOR SURGERY

Due to clinical heterogeneity, individualized management of children with aortic root aneurysms is paramount. In particular, differentiated size criteria for operative intervention among the various syndromes is key, and its importance can never be overemphasized (Table 82-2).

In children with Marfan syndrome, Elhers–Danlos type IV, or with bicuspid aortic valve, timing for aortic repair is mostly based on the absolute size of the aneurysm and surgery is recommended when the diameter reaches 5 cm.[5,11,33–36] Aneurysm growth rate exceeding 1 cm/year, progressive aortic insufficiency and familial history of premature aortic dissection warrants earlier intervention (Table 82-2).[5,11,33–35] In children younger than 12 years of age, indications for surgical intervention are the finding of "giant aneurysms" (those that satisfy the adult criterion for intervention), rapid enlargement (>1 cm/year), and progressive aortic insufficiency (Table 82-2). In these young patients, we do not utilize *z*-scores as indicators for surgery, as dissection is rare irrespective of aortic dilation.[6,7,9,11,12]

Given their propensity to dissect even at small aortic diameters, patients with Loeys–Dietz syndrome require a completely different treatment algorithm. The algorithm currently in use at the Johns Hopkins Hospital is reported in Table 82-2.[37] In young children, surgery should be considered when aortic size exceeds the 99th percentile or when a diameter of 3 to 3.5 cm is associated with severe craniofacial deformity. However, every effort should be made to stabilize aneurysms with medical therapy and defer surgery until the aortic annulus is greater than 18 mm, which will allow the use of a large enough graft or prosthesis to accommodate growth into adulthood. Yet a different clinical approach is used for adolescents, who fall under the same algorithm utilized for adults.

## SURGICAL INTERVENTIONS

Surgical options available for the treatment of aortic root aneurysms in the pediatric population are manifold: composite valved tube graft (mechanical vs biological), aortic homograft, and aortic valve-sparing root replacement (AVSRR).

At present, valve-sparing procedures should be considered as the first-line choice in children with an aortic annulus greater than 18 mm, undamaged valvular leaflets, no evidence of acute aortic dissection and no need for mechanical mitral valve replacement. If simultaneous mitral valve

**TABLE 82-2: Surgical Indications for Pediatric Patients with Aortic Aneurysm Syndromes**

| | Children (<12 years) | Adolescents |

Progressive aortic insufficiency (AR > mild)<br>3. Family history of premature aortic dissection (<5 cm)<br>4. Large root at the time of intervention on the mitral valve | Same as children |
| Loeys–Dietz syndrome | Severe craniofacial features:<br>1. Aortic root *z*-score <3.0<br>2. Rapidly expanding (>0.5 cm/year)<br>3. Annulus ≥1.8 cm (if possible)<br>Mild craniofacial features:<br>1. Aortic root *z*-score >4.0<br>2. Rapidly expanding (>0.5 cm/year) | 1. Aortic root diameter >4.0 cm<br>2. Rapidly expanding (>0.5 cm/year) |
| Ehler–Danlos syndrome | Similar to Marfan syndrome | Same as children |
| Bicuspid aortic valve | Aortic root/ascending aorta >5.0 cm<br>Aortic root/ascending aorta <5.0 cm if<br>1. Rapidly expanding (>1 cm/year)<br>2. Need for aortic valve surgery (aortic diameter >4.5 cm) | Same as children |

repair is needed, it is standard practice to commence repair with the mitral valve. If the mitral valve needs to be replaced, then a Bentall procedure is a more sound option. Also, valve-sparing surgery in the setting of acute aortic dissection is not unreasonable, although technically more challenging challenging. However, the acuity of the clinical picture along with the many variables that may severely impact surgical outcome (coagulopathy, malperfusion, hypothermia) raise the question as to whether this operation is advisable in such a context. Finally, the presence of a congenitally bicuspid aortic valve is not a contraindication to a valve-sparing operation unless leaflet stress lesions, calcification, or severe and asymmetric prolapse make the leaflets unrepairable.

A composite mechanical-valve graft is favored in the presence of acute aortic dissection, aortic leaflets with unrepairable stress lesions (elongation/fenestration) or grossly asymmetric valve prolapse. A composite tissue–valve graft is indicated in young patients unsuitable for valve-sparing procedures, who cannot undergo anticoagulation or wish to become pregnant.

Homografts are still used in the setting of a small annulus (<18 mm) if the aortic valve cannot be preserved (Table 82-3), but durability is disappointing and therefore their use is becoming obsolete.

Although intuitive, it is worth mentioning that pulmonary valve autotransplantation (Ross procedure, see Chapter 78) is formally contraindicated in the setting of connective tissue disorders due to the intrinsic weakness of the pulmonary root.

Composite valve graft aortic root replacement is described in detail elsewhere in this textbook; we detail to follow the surgical technique currently in use at the Johns Hopkins Hospital for AVSRR as it is applied to pediatric patients with aortic root aneurysms.

## AORTIC VALVE-SPARING ROOT REPLACEMENT

It is now generally accepted that, in the setting of connective tissue disorders, aortic valve reimplantation techniques (David-type procedures) offer superior long-term anatomic and functional results when compared with remodeling of the aortic root (Yacoub operation). We therefore preferentially perform aortic valve reimplantation when AVSRR is indicated in pediatric patients. The Valsalva Gelwave graft is o ur graft of choice in pediatric patients in whom a graft of diameter equal or greater than 24 mm is chosen. Criticism against grafts with prefabbricated pseudosinuses has focused on the inability to tailor the prosthesis to individual patient anatomic variability; however, we have found these grafts are easy to use and adequately suit the needs of the vast majority of our pediatric patients.[38,39] Furthermore, most pediatric patients with connective tissue disorders will present for surgical intervention with annular diameter similar to that of an adult. This is important, as the fallback option in these patients is a mechanical prosthesis, available in diameter of greater than 18 mm.

After induction of general anesthesia, anatomy and function of the aortic root and ascending aorta are reviewed via transesophageal echocardiogram. Diameters of aortic annulus, sinuses, sinotubular junction, and ascending aorta are remeasured and the function of the aortic valve reassessed.

Access is obtained via median sternotomy and the pericardium is opened longitudinally. After systemic heparinization, the aorta is cannulated at the most distal part of its ascending segment and bicaval cannulation performed. Myocardial protection is obtained by means of cold blood cardioplegia infusion and topical ice-cold saline. Also, the left ventricle is vented through the right superior pulmonary vein. To prevent air embolism, the surgical field is flooded with carbon dioxide.

Before accessing the aortic lumen, the right atrium is routinely opened and the presence of a patent foramen ovale ruled out. The ascending aorta is then transected just above the sinotubular junction and dissected free from the pulmonary artery first and then down to the level of the annulus (Fig. 82-3A).

The aortic valve is inspected and the aortic annulus meticulously sized. Particular attention is paid to pliability and integrity of the cusps as well as the anatomic position of the coronary arteries.

We simplify the choice of the aortic graft by determining the optimal sinotubular junction diameter (the one that allows proper leaflet coaptation). Stay sutures are placed at each commissure to retract the aortic valve apparatus and obtain adequate leaflet coaptation. Valve continence is repetitively tested until the size of the sinotubular junction that

AVSRR, aortic valve-sparing root replacement.

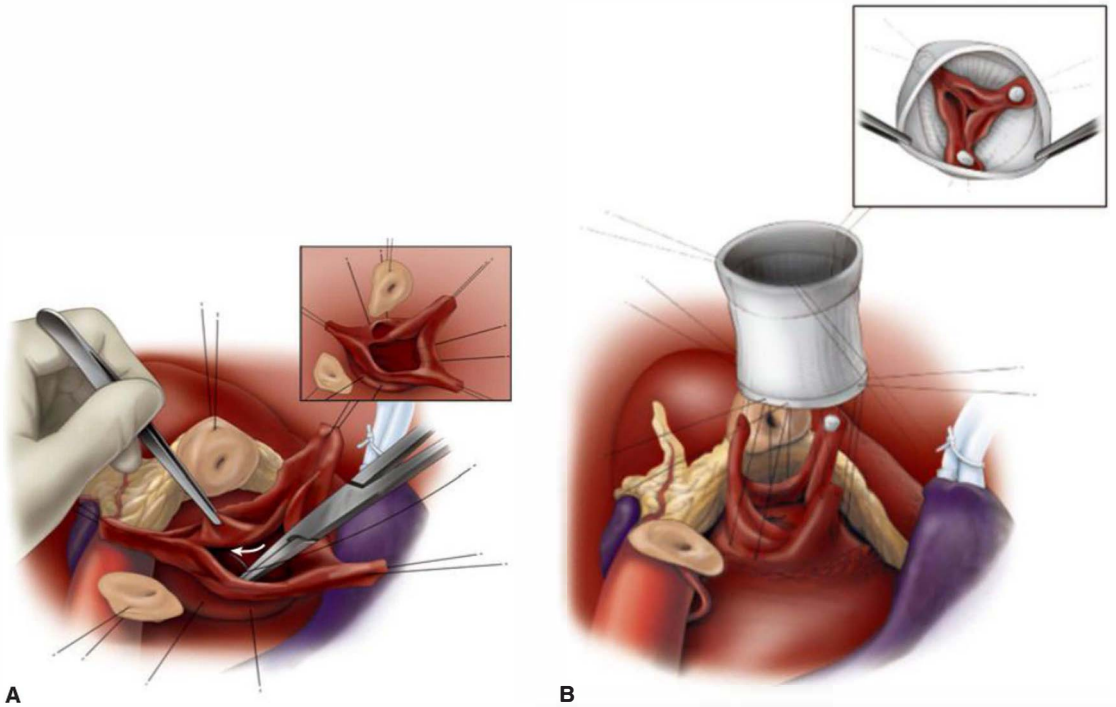

**FIGURE 82-3** **A.** Aortic valve-sparing root replacement (AVSRR). The aortic root is prepared by excision of all three sinuses of Valsalva, leaving 4 to 5 mm of sinus tissue for reimplantation. The coronary arteries are fully mobilized and three mattress sutures are placed below the nadir of the sinuses. (Courtesy of Dr. Duke Cameron, The Johns Hopkins University.) **B.** Johns Hopkins technique for AVSRR: The graft is anchored to a level below the nadir of the aortic annulus by three pledgetted braided sutures, while the commissures are resuspended within the Dacron prosthesis at three equidistant points. The remnants of the sinuses of Valsalva are reimplanted within the prosthesis with running monofilament sutures. (Courtesy of Dr. Duke Cameron, The Johns Hopkins University.)

allows for satisfactory leaflet apposition is found. The size of the graft is then upsized by 2 to 4 mm, to account for the thickness of the aortic wall.

To follow, stay sutures are placed above the takeoff of the coronary arteries, the sinuses are excised and trimmed 4 to 5 mm from the annulus, and the coronary arteries are dissected free from the surrounding tissue.

Single, pledgeted 2-0 Tevdek horizontal stay sutures are placed below the nadir of the annulus in each sinus to anchor the tubular graft at a subannular level.

The commisures are then secured to the sinotubular junction of the graft with pledgeted 5-0 Prolene sutures (Fig. 82-3B). At this point, appropriate positioning of the valve inside the new root is verified and a hemostatic suture between the graft and the aortic wall remnant at the aortic annulus is performed with a running 5-0 Prolene.

The coronary arteries are then reimplanted and their suture lines are reinforced with Teflon felt strips to enhance hemostasis and avert the development of pseudoaneurysms.

The aortic valve is then saline-tested and, if competent, repair is completed by performing the distal aortic suture line, which should be carried out as distal as possible. Replacement of the aortic arch should only be performed in case of dilatation or dissection, and not prophylactically.

The left ventricle is de-aired and the aortic clamp is released. During rewarming of the ventricles, function of the aortic valve is assessed by transesophageal echocardiography. The acceptable amount of residual regurgitation depends on the mechanism. Mild central aortic regurgitation secondary to thickened nodules of Arantius is usually not a cause of progressive aortic valve insufficiency and therefore acceptable. However, any instance of aortic insufficiency greater than mild is considered unacceptable, as is the presence of substantial prolapse. In these cases, the valvular apparatus is likely unstable and its function is bound to eventually deteriorate. Leaflet prolapse (often brought about by graft undersizing) should therefore be promptly addressed.

At the end of the intervention, patients with pectus excavatum may undergo concomitant repair with a Nuss procedure.

## SURGICAL OUTCOMES

Because of earlier diagnosis, an increasing number of patients with syndromic aortic root aneurysms are undergoing surgery during childhood. However, prophylactic aortic root replacement in pediatric patients is still a relatively

novel concept, as both the size of patient population and the length of cumulative follow-up are limited. In addition, identification of new clinical syndromes and the introduction of recent surgical techniques further fragments the study population in multiple, small cohorts. These features account for the little knowledge on treatment outcomes in children with congenital aortopathies.

In absence of long-term data on event-free survival following AVSRR surgery, the Bentall procedure remains as the gold standard for aortic root replacement.[40,41] However, aortic valve preservation offers intuitive advantages over valve replacement, making patients virtually free from infective endocarditis and lifelong anticoagulation. Therefore, and particularly in pediatric patients and young adults, there is widespread interest in performing valve-sparing operations even though long-term durability of such procedures has yet to be ascertained. In particular, aortic valve reimplantation techniques are now the default approach whenever the root anatomy is permissive. As for adults, remodeling techniques should now be considered obsolete in the pediatric population since late aortic root instability and clinically significant aortic valve insufficiency have been reported.[42]

Marfan syndrome is considered the prototype of connective tissue disorders and the one most studied. Yet, only a handful of studies are specifically dedicated to surgical results of children affected by this syndrome, with none of these exclusively focused on aortic root replacement.[40–43] Regardless, these studies demonstrate that aortic root replacement can be accomplished with minimal operative mortality and excellent long-term survival as shown by Kaplan–Meier estimates of 10-year survival that approach 80 percent.[40,41] However, 10-year freedom from operation is as low as 41 percent with the main cause of late reintervention being distal aortic pathology and need for mitral valve repair or replacement.[41] When compared with adults with Marfan syndrome, children have a greater risk of undergoing aortic reoperation; this is intuitive, considering the longer course of the disease and the fact that catastrophic aortic complications are exceedingly rare in children. This, combined with the knowledge that late mortality is primarily attributable to cardiovascular causes, highlights the importance of clinical and radiological surveillance for successful management of these patients, as current prophylactic treatment on the aortic root does not completely eliminate late cardiovascular morbidity.

Early surgical results in patients with Loeys–Dietz syndrome (either type I or type II) are encouraging. In an initial surgical series of 21 patients treated at the Johns Hopkins Hospital, there were no operative deaths or early reoperations. Early aortic valve function was excellent among the valve-sparing group and composite valve graft surgery was reserved for patients deemed not suitable for aortic valve preservation. No hemorrhagic event or infectious endocarditis were observed.[22] However, the main cause of late morbidity and mortality was dissection at sites remote from the previously operated aorta (7 percent of the surgical cohort) due to poor elastic properties of the arteries.[44]

In patients affected by vascular-type Ehlers–Danlos syndrome surgical mortality appears to be greater (10 percent) than in patients with similar connective tissue disorders mostly due to graft-related complications.[25] The most relevant feature of vascular type Ehlers–Danlos syndrome is in fact the extreme fragility of the arterial wall that makes vessels very little tolerant to intraoperative manipulation. Arterial friability is the main reason for the high prevalence of significant postoperative bleeding (46 percent) and late anastomotic complications such as disruption and pseudoaneurysm (40 percent) reported in the literature.[25] Long-term survival after surgery appears nevertheless satisfactory, although below that of the age-matched general population (68 percent at age 50 years).[25] Prevalent causes of late death are associated with anastomotic complications (pseudoaneurysms) and dissection at sites distant from prior vascular surgery. However, to the best of our knowledge no study exclusively dedicated to a pediatric population of Ehlers–Danlos patients has been published at this time.

## CARDIAC SURGICAL INTERVENTION IN PEDIATRIC PATIENTS WITH CONNECTIVE TISSUE DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 82)

1. Which is correct regarding pathophysiology of connective tissue disorders?
   A. Marfan syndrome is caused by deficiency of fibrillin-2.
   B. Ehlers–Danlos vascular type is associated with alteration of type I collagen.
   C. Bicuspid aortic valve aneurysms are caused by altered elastin production.
   D. Increased TGF-β signaling leads to decreased collagen synthesis.
   E. Molecular events in the adventitia may have a role in aneurysm formation.

2. Which is not a clinical feature of Marfan syndrome?
   A. In 25 percent of patients, the disease presents de novo.
   B. The infantile form is dominated by mitral valve disease.
   C. Rupture of an enlarged root is the leading cause of death in older adolescents.
   D. Aortic regurgitation is common once the root reaches 4 cm in diameter.
   E. Dissection is more common if the root expands at a rate of more than 15 mm/year.

3. Which is not an indication for surgery in patients with connective tissue disorders?
   A. Marfan syndrome and aortic root size 5 cm
   B. Bicuspid aortic valve and aneurysm growth rate 12 mm during the last year
   C. Progressive aortic insufficiency
   D. Family history of premature aortic dissection
   E. Eight-year old patient with *z*-score over 3

4. Which of the following would not be a suitable patient for valve-sparing root replacement?
   A. Acute aortic dissection
   B. Asymmetric valve prolapse
   C. Annulus size 20 mm
   D. Bicuspid aortic valve
   E. Simultaneous mitral valve repair
5. Which of the following is true for outcomes after operative for patients with connective tissue disorders?
   A. Remodeling techniques should be considered obsolete for pediatric patients.
   B. Ten-year survival for root replacement in children with Marfan syndrome is approximately 60 percent.
   C. The main cause for late reintervention in aortic regurgitation
   D. Prophylactic root replacement eliminates late cardiovascular morbidity.
   E. Surgical mortality for patients with Ehlers–Danlos syndrome is similar to other connective tissue disorders.

## ANSWERS

1. **Answer: E.** Recent studies on aneurysm progression emphasize molecular events in the adventitia. Marfan syndrome is caused by deficiency of fibrillin-1. Ehlers–Danlos vascular type is associated with alteration of type III collagen. Bicuspid aortic valve aneurysms are caused by altered collagen production. Increased TGF-β signaling has been observed in various forms of aneurysms and leads to increased collagen synthesis, loss of elastin content, and elastic fiber disarray.
2. **Answer: D.** Aortic regurgitation is rare if the root is less than 6 cm in diameter. The disease presents de novo in 25 percent of individuals. The infantile form is clinically aggressive and is dominated by mitral valve disease. The leading cause of death in older adolescents is aortic root rupture. Dissection is more common if the root expands at a rate exceeding 15 mm/year.
3. **Answer: E.** Z-score is not utilized for young patients with aortic dilation. Accepted indications for surgery include aortic root size of 5 cm, growth rate over 1 cm/year, progressive aortic regurgitation, and family history of premature dissection.
4. **Answer: B.** A grossly abnormal valve with asymmetric leaflet prolapse is generally not suitable for a valve-sparing procedure. Valve-sparing root replacement can be safely and effectively performed in acute dissection and bicuspid aortic valve if the leaflets are normal and competent. Annulus size greater than 18 mm and simultaneous mitral valve repair are also suitable patients.
5. **Answer: A.** Reimplantation techniques are superior to remodeling techniques in children. Ten-year survival for root replacement in children with Marfan syndrome is approximately 80 percent. The main causes for late reintervention are distal aortic pathology and mitral valve disease. Prophylactic root replacement does not completely eliminate late cardiovascular morbidity. Surgical mortality for patients with Ehlers–Danlos syndrome is greater than other forms of connective tissue disorders.

# Surgery for Congenital Coronary Artery Anomalies

*Julie A. Brothers*
*J. William Gaynor*

## INTRODUCTION

This chapter focuses on the management of coronary artery anomalies in patients without other hemodynamically significant heart defects. Although most coronary artery anomalies are of intellectual interest only, there are a few that are clinically significant as they may result in myocardial ischemia, left ventricular dysfunction, and sudden death. The clinically significant anomalies that we will discuss in this chapter are: anomalous origin of a coronary artery from the pulmonary artery, anomalous coronary artery that courses between the aorta and the pulmonary artery, and coronary artery fistulae.

Normally, two coronary arteries arise from separate ostia in the right and left aortic sinuses of Valsalva. The left main coronary artery (LMCA) originates from the left sinus and usually bifurcates into the left anterior descending (LAD) coronary artery and left circumflex coronary artery. The LAD courses in the anterior interventricular groove while the left circumflex coronary artery runs in the left atrioventricular groove. The right coronary artery (RCA) originates anteriorly from the right aortic sinus, runs along the right atrioventricular groove, and usually terminates as the posterior descending artery.

The coronary artery ostia are usually centrally located in the appropriate sinus of Valsalva. However, the ostium may be eccentrically located in some individuals, with the ostium arising close to a valve commissure. The coronary ostia may have a "high takeoff" from the tubular aorta above the sinotubular junction, which is usually benign. It is important to be aware of this anomaly if one needs an aortic valve replacement or requires an aortotomy for another reason, as the coronary artery can be transected if not recognized prior to surgery. When both coronary arteries arise from the same aortic sinus with either a single ostium or two separate ostia (Table 83-1), the anomaly is usually benign if the anomalous vessel courses posterior to the aorta or anterior to the pulmonary artery. However, if either the anomalous LMCA or RCA courses between the two great vessels, this may lead to myocardial ischemia and sudden death.

## ANOMALOUS ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of a coronary artery from the pulmonary artery is a rare congenital coronary anomaly that almost always results in early death if not diagnosed and treated promptly.[1,2] Anomalous origin of the LMCA from the pulmonary artery (ALCAPA) is the most common of this class of coronary anomalies and is associated with myocardial ischemia and left ventricular dysfunction. Much less frequently, the RCA may arise from the pulmonary artery in isolation. In extremely rare and usually fatal circumstances, the LAD, the circumflex, or both the LMCA and RCA may arise aberrantly from the pulmonary artery.

ALCAPA is otherwise known as the Bland-White-Garland syndrome after Bland and colleagues reported in 1933 on the clinical and autopsy findings of an infant with this anomaly.[3] The incidence of ALCAPA ranges from 1 in 30,000 to 1 in 300,000 individuals. In childhood, this anomaly is the most common cause of myocardial infarction and, if not treated, is associated with a 90 percent mortality rate by age 1 year.

### Anatomy

In ALCAPA, the LMCA generally arises from the main pulmonary artery (MPA), although it may arise from the right pulmonary artery. The LMCA most often originates from the rightward aspect of the posterior (facing) sinus of the

**TABLE 83-1: Origin of Both Coronary Arteries from One Sinus**

1. Left main coronary artery originates from right sinus of Valsalva (either from right coronary artery or separate ostia).
   - Left main coronary artery courses anterior to pulmonary artery.
   - Left main coronary artery courses through interventricular septum.
   - Left main coronary artery courses between aorta and pulmonary artery.
   - Left main coronary artery courses posterior to aorta.
   - Rarely the left anterior descending coronary or left circumflex coronary artery alone may originate from the right sinus.
2. Single left main coronary artery arises from the left sinus and bifurcates into the left anterior descending coronary and left circumflex coronary arteries. The left circumflex coronary artery crosses the crux and continues as the right coronary artery.
3. Single right coronary artery from right sinus, which crosses crux, continues as left anterior descending coronary artery and left circumflex coronary artery.
4. Right coronary artery originates from left sinus of Valsalva (either from left main coronary artery or as separate ostium).
   - Right coronary artery courses posterior to aorta.
   - Right coronary artery courses anterior to pulmonary artery.
   - Right coronary artery courses between aorta and pulmonary artery.

MPA (Figs. 83-1 and 83-2A–C). Other locations it may originate from are the leftward aspect of the posterior (facing) sinus and, rarely, the anterior (nonfacing) sinus of the MPA (Fig. 83-2C). In the case of an anomalous RCA, the most common location is originating from the anterior portion of the pulmonary artery.

Other associated defects with ALCAPA may include patent ductus arteriosus (PDA), ventricular septal defect (VSD), coarctation of the aorta, and tetralogy of Fallot.

## Pathophysiology

During fetal life, the systemic and pulmonary circulation pressures are similar; therefore, in children with ALCAPA, myocardial perfusion remains intact since the pulmonary arterial pressure is systemic. After birth but before ductal closure, the pulmonary artery pressure remains elevated, thus allowing adequate perfusion of the anomalous coronary artery. Because of this, diagnosis of ALCAPA in the first few days of life is rare. Children with ALCAPA will usually develop symptoms after ductal closure and the subsequent fall in the pulmonary vascular resistance. However, the clinical course after ductal closure varies and is largely dependent on the presence or absence of collaterals from the RCA to the left coronary system. If the collateral circulation has not been well established, myocardial ischemia and ventricular dysfunction rapidly occur due to inadequate myocardial perfusion.[4] Because the pulmonary artery pressure is lower than the systemic pressure, the left ventricle is being perfused with desaturated blood. If there is a PDA or VSD, the pulmonary artery pressure may be elevated, so that the left ventricular perfusion pressure may be adequate and ischemia may not occur. If ALCAPA is not diagnosed prior to closure of these defects, it will become apparent shortly thereafter when the pulmonary arterial pressure drops; the outcome is usually fatal.

If adequate collateralization has been established, then perfusion of the left coronary system is maintained. However, as the pulmonary vascular resistance falls, a shunt develops from the RCA to the pulmonary artery. The RCA and left coronary artery systems progressively dilate with flow reversal in the left coronary leading to a pulmonary-coronary steal. Although the overall shunt is relatively small related to cardiac output, it is significant with regards to coronary blood flow. Children with an extensive collateral system may survive past infancy; however, progressive left

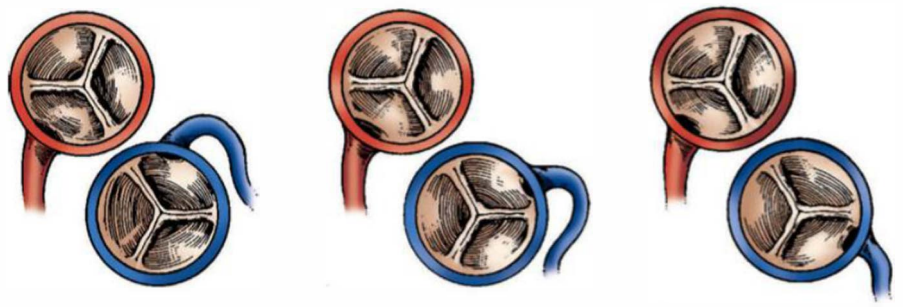

**FIGURE 83-2** **A.** Anomalous origin of left main coronary artery from the rightward aspect of the posterior facing sinus of the pulmonary artery. **B.** Anomalous origin of the left main coronary artery from the leftward aspect of the posterior facing sinus. **C.** Anomalous origin of the left main coronary artery from the nonfacing sinus of the pulmonary artery. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

ventricular dysfunction will predictably ensue.[5] In a small number of patients, the collateral vessels are enough to maintain adequate myocardial perfusion at rest and sometimes even during exertion. Because of this, these patients may not be diagnosed until adulthood.[6] This is rare, however, and most children have severe mitral regurgitation (MR) due to infarction of the posterior leaflet of the mitral valve and subsequent poor movement of the leaflet as well as ventricular dilation; fibrosis and fibroelastosis of the papillary muscle may also be present.

## Clinical Presentation

Clinical presentation is usually between 4 and 6 weeks of age when the pulmonary vascular resistance has dropped[7]; however, sometimes infants are not diagnosed until 2 to 3 months of age when symptoms have increased in severity. Presenting signs and symptoms are those of congestive heart failure, including sweating and discomfort with feeding, tachypnea, poor weight gain, and pallor. The apparent discomfort with feeding is thought to represent myocardial ischemia. Those not identified as infants are usually diagnosed at several months of age due to a loud MR murmur. Those not diagnosed during infancy may remain asymptomatic, while others may present with exertional chest pain, presyncope, or syncope. Furthermore, there have been reports of exertional sudden death in older patients. Patients with anomalous origin of the RCA from the pulmonary artery tend to have symptoms to ALCAPA but they may be less severe; however, myocardial ischemia and sudden death can still occur.

On physical examination, an infant with ALCAPA may demonstrate signs of congestive heart failure, including tachypnea, tachycardia, and hepatomegaly. Distinguishing left ventricular dysfunction secondary to ALCAPA from dilated cardiomyopathy can be difficult. Cardiac examination may demonstrate a gallop rhythm and a systolic murmur of MR at the apex. If pulmonary hypertension is present due to left ventricular failure, there may be evidence of right heart enlargement and an accentuated pulmonary component of the second heart sound on examination.

Chest radiography in infants with ALCAPA generally demonstrates an enlarged cardiac silhouette, mainly due to the enlarged left atrium and left ventricle. In those with congestive heart failure, electrocardiogram (ECG) can be a useful diagnostic clue. Classically, there is evidence of lateral or anterolateral wall infarction with Q waves and ST segment elevation in leads I, aVL, and V4-V6. While these electrocardiographic abnormalities can be found in other causes of myocardial infarction or cardiomyopathy, if they are seen in an infant in congestive heart failure, the diagnosis of ALCAPA needs to be strongly considered. Indeed, any infant with dilated cardiomyopathy must be extensively evaluated to rule out ALCAPA. This diagnosis must also be entertained in older children and adolescents with dilated cardiomyopathy since there are patients who survive past infancy.

## Diagnostic Imaging

Echocardiography with Doppler color flow usually shows a dilated left ventricle with some degree of MR. An enlarged RCA is almost always noted and should increase suspicion of this diagnosis. Visualization of the origin of both coronary arteries is necessary with the objective of demonstrating the origin of the LMCA from the pulmonary artery. If visualization of the anomalous vessel is difficult, color flow Doppler may be used to show retrograde flow from the LMCA into the pulmonary artery. Nevertheless, if any questions remain about location of both coronary ostia, then cardiac catheterization is mandatory to rule out ALCAPA.

Cardiac catheterization with angiography is the gold standard in diagnosing ALCAPA. In infants with ALCAPA, hemodynamic data may demonstrate elevated filling and pulmonary arterial pressures and a low cardiac output. In older

asymptomatic patients, hemodynamic data may show only slightly elevated pulmonary arterial pressures with normal filling pressures and a normal cardiac output. Catheterization data may show a small left-to-right shunt. On aortic root injection, a single, dilated RCA will arise normally from the aorta. If there are significant collaterals, aortic root angiography will demonstrate the collateral blood flow providing late, retrograde filling of the LMCA and a blush of contrast subsequently filling the MPA. Furthermore, if there are significant collaterals with a resultant large left–right shunt, a step-up in oxygen saturation may be noted in the MPA. If the diagnosis remains in doubt, a distal balloon occlusion of the MPA with proximal injection should demonstrate the anomalous LCA.[8]

Magnetic resonance imaging (MRI) has emerged as a useful noninvasive diagnostic tool for delineating congenital coronary anomalies.[9,10] Studies have shown that magnetic resonance angiography has a similar sensitivity and specificity compared to coronary angiography and may be particularly useful in delineating the proximal course of anomalous coronary arteries. Further data are needed before recommending MRI instead of cardiac catheterization. In adults, computed tomography (CT) scan has been used extensively for coronary artery delineation. Although CT scan may be useful in the older patients diagnosed with ALCAPA, exposure to radiation and the need for a slower heart rate with ECG gating generally excludes its use in infants.

## Surgical Management

### INDICATIONS

Surgical repair is necessary in all patients with ALCAPA. Even in infants who present in congestive heart failure, surgery should occur shortly following diagnosis, as the risk of further myocardial ischemia and subsequent death is high.[11] In older asymptomatic patients, surgery can be performed electively. If an infant presents in significant heart failure, surgery will likely need to be delayed for at least 24 hours to stabilize the patient using mechanical ventilation, inotropic support, and vasodilators, when necessary. As reported by Del Nido and colleagues, even the sickest infants can withstand surgical repair if left ventricular assist devices (LVAD) are utilized postoperatively.[12] Other critically ill infants may need extracorporeal membrane oxygenation (ECMO). It is important that centers performing ALCAPA surgery have the capability to provide mechanical assistance if necessary; if not, the child should be transferred to a hospital where these services are available.

Restoring a two-coronary system is the surgical goal. Simple ligation of the anomalous coronary should not be performed.[13] Furthermore, because significant recovery of heart function usually occurs postoperatively, infants presenting with severe left ventricular dysfunction and mitral insufficiency should not be excluded from revascularization. Even if severe MR is present at diagnosis, left ventricular aneurysmectomy and mitral valve repair or replacement are rarely indicated at the time of initial procedure because the severity of MR almost always diminishes after revascularization.

### SURGICAL TECHNIQUES

The first successful operation for ALCAPA consisted of ligation of the anomalous vessel at the pulmonary artery, thus preventing the left-to-right shunt. This procedure allowed perfusion of the left ventricle through collaterals from the RCA. However, there was significant operative mortality and risk of late sudden death with this procedure, so a variety of alternative techniques were developed to create a dual coronary artery system. These included coronary artery bypass grafting, creation of an aortopulmonary window, and direct coronary reimplantation.

Coronary artery bypass grafts utilized the left subclavian artery, the internal mammary artery (IMA), and saphenous vein. The first successful left subclavian artery-to-left coronary bypass was first reported in 1968[14]; however, the results of bypass grafting, notably with saphenous vein grafts, have been disappointing. The creation of an aortopulmonary window and intrapulmonary artery baffle using a pulmonary artery flap to direct blood flow from the aorta to the anomalous coronary artery was first described by Takeuchi and associates.[15] As experience with the arterial switch operation for transposition of the great vessels has increased, the procedure of choice currently utilized in most institutions is direct reimplantation of the anomalous coronary into the aorta.[16,17]

***Coronary Artery Bypass Grafting.*** Coronary artery bypass grafting is rarely utilized in patients with ALCAPA. If necessary, it is typically used as a way to create a dual coronary artery system after previous ligation or due to stenosis or occlusion after a previous attempt at repair. In these cases, the IMA is the conduit of choice and can be successfully used even in neonates and infants. There is some evidence for growth of the IMA after bypass grafting[18–20] in pediatric patients. Grafts using the saphenous vein are not recommended due to the risk of occlusion and poor long-term results,[21] and should only be utilized if no other option is available. Similarly, left subclavian-to-left coronary artery anastomosis is not frequently utilized due to the risk of stenosis or occlusion.[22,23]

***Direct Reimplantation.*** Direct reimplantation of the anomalous coronary artery onto the aorta can be performed in most patients with ALCAPA (Figs. 83-3–83-6).[24,25] The procedure is fairly straightforward when the anomalous coronary ostium is in the posterior-facing sinus. Even if the ostium is located in the non-facing sinus, direct implantation is possible by excising a large button of pulmonary artery to extend the coronary artery.

A median sternotomy is performed after induction of anesthesia and placement of monitoring lines. The thymus is resected. The pericardium is opened and suspended in stay sutures. Contact with the myocardium should be kept at a minimum until the patient is placed on cardiopulmonary bypass due to the risk of ventricular fibrillation from

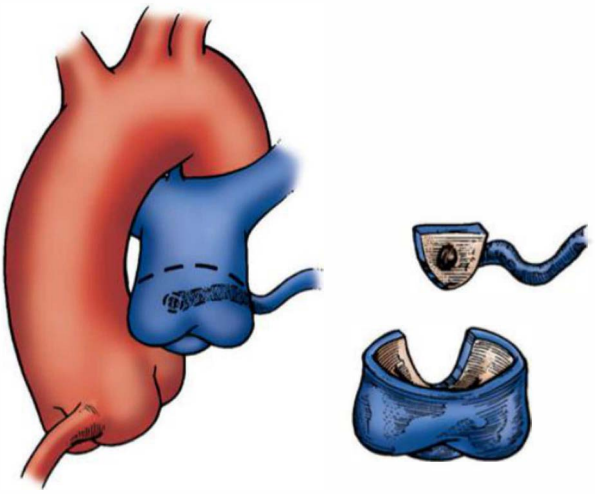

**FIGURE 83-3** After institution of cardiopulmonary bypass and induction of cardioplegia, the pulmonary artery is transected above the sinotubular junction and the anomalous coronary ostium excised with a generous button of pulmonary artery wall. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

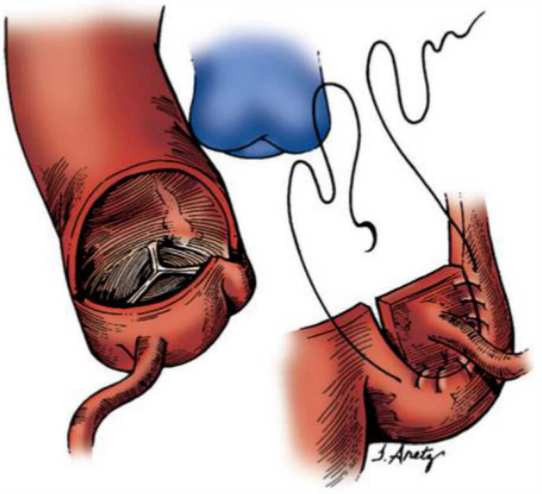

**FIGURE 83-5** After the anomalous coronary artery is mobilized, the aorta is opened transversely above the sinotubular junction and a vertical incision is made in the left posterior sinus to accept the reimplanted coronary. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

myocardial ischemia and left ventricular dysfunction. This operation may be performed using either continuous low-flow bypass with moderate hypothermia (25–28°C) or deep hypothermic circulatory arrest (18°C) in very small infants. An aortic purse-string suture is placed distally near the innominate artery and another is placed in the right atrial appendage for a single venous cannula prior to cannulation. Heparin is administered, the aortic and right atrial cannulae are inserted, and cardiopulmonary bypass is established. Decompression of the left ventricle should be performed by placing a left ventricular vent via the right superior pulmonary vein. Although on bypass, the pulmonary artery and

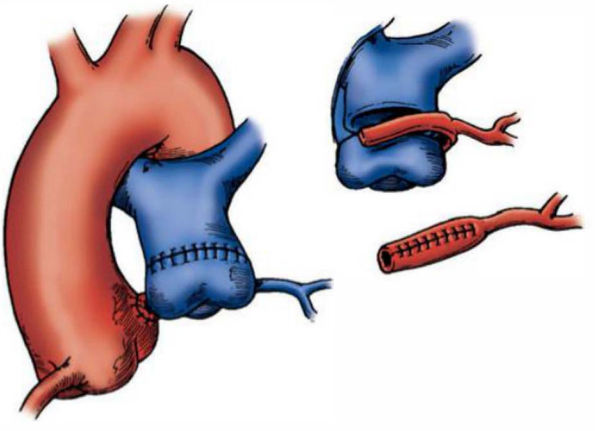

**FIGURE 83-4** Occasionally when the coronary artery arises from the leftward or anterior aspect of the pulmonary artery, direct reimplantation may not be possible. In these situations, a tube can be constructed from a segment of pulmonary artery to lengthen the coronary and allow reimplantation on the aorta. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

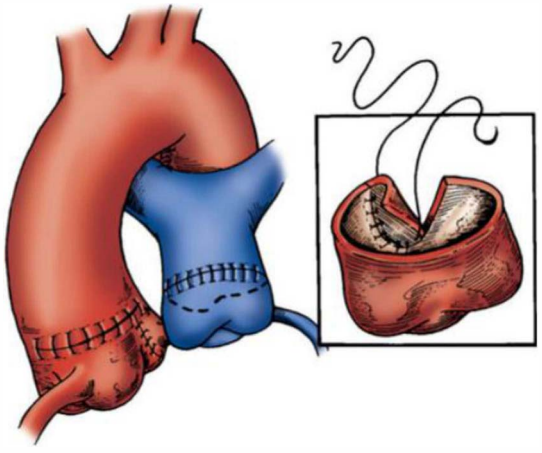

**FIGURE 83-6** After the coronary is reimplanted, the aorta is closed primarily. The pulmonary artery may frequently be closed primarily. Ligation and division of the ligamentum arteriosus improves mobility of pulmonary artery. Occasionally, patch repair of the defect in the pulmonary artery with autologous pericardium may be necessary (inset). (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

epicardial course of the left coronary artery are visualized. Direct reimplantation may not be possible if the anomalous left coronary originates far leftward in the posterior-facing sinus or on the anterior non-facing sinus.

The aorta and both pulmonary arteries are fully mobilized. The ductus (or ligamentum) arteriosus is ligated to improve mobility of the pulmonary artery. Tourniquets are placed around both the right and left branch pulmonary arteries to occlude the branch pulmonary arteries and prevent run-off of cardioplegia solution into the lungs. Another way to prevent run-off is to compress the coronary artery origin from the pulmonary artery during administration of cardioplegia solution. A cannula is inserted in the ascending aorta for administration of cardioplegia solution, the aorta is cross-clamped, and cold cardioplegia is administered via the aortic root. If circulatory arrest is utilized, the head vessels are then occluded with tourniquets, the circulation is arrested, venous blood is drained into the reservoir, and the cannulae are removed.

After adequate arrest, the pulmonary artery is opened transversely just above the sinotubular junction (Fig. 83-3) and the anomalous coronary orifice is noted. Similar to the procedure used for the arterial switch operation, the pulmonary artery is divided and the coronary ostium is excised from the posterior aspect of the pulmonary artery using a generous button of arterial wall. The excised segment of the pulmonary wall extends the proximal end of the coronary artery, thereby allowing for the aortic anastomosis to be accomplished without tension. The pulmonary commissure may need to be taken down if the coronary ostium is located near a commissure. Alternatively, if the coronary arises anteriorly from the pulmonary artery or from a branch pulmonary artery and above the commissures, one can extend the coronary artery by using a tube constructed from pulmonary artery wall to allow reimplantation (Fig. 83-4). The proximal portion of the coronary artery is mobilized using cautery, exercising caution to avoid any small branches. Just as in the arterial switch operation, the aorta is then opened transversely directly above the sinotubular junction and the incision is carried posteriorly over the left posterior-facing sinus (Fig. 83-5). The sinus is then incised vertically to accept the coronary button. The coronary button is carefully aligned with the aortic incision to avoid twisting or kinking. Using a continuous suture of 7-0 polypropylene (Prolene), the anastomosis is begun at the most inferior aspect of the coronary button, which is attached to the most inferior aspect of the incision in the sinus. The suture line is carried to the top of the incision anteriorly and posteriorly. The aorta is closed using a continuous suture of 7-0 Prolene, which is tied to the coronary button suture as the anastomosis is completed (Fig. 83-5). After aortic closure, cardioplegia solution is administered and the anastomotic site is inspected for adequate filling of the coronary as well as for hemostasis.

In most cases, the pulmonary artery can be repaired using a continuous suture of 7-0 Prolene. Division of the ductus will improve mobility of the pulmonary artery confluence and allow reconstruction without tension. If there is tension or narrowing, or if the defect left by excision of the coronary artery button is sizeable, the pulmonary artery should be repaired with a patch of autologous pericardium (Fig. 83-6). If a commissure was taken down during excision of the coronary button, the pulmonary artery should be reconstructed with pericardium and the commissure resuspended.

The patient is then rewarmed and the aortic cross-clamp is removed. Alternatively, the cross-clamp may be removed before the pulmonary artery reconstruction to minimize ischemic time. The left ventricle is inspected to assess for adequacy of perfusion, and suture lines are inspected for hemostasis. Right and left atrial lines are placed to adequately monitor pressure and for drug administration. Atrial and ventricular pacing wires are also placed. The patient is separated from cardiopulmonary bypass after complete rewarming.

The ECG should be monitored closely for evidence of ischemia during reperfusion and after separation from bypass. Inotropic support may be temporarily necessary due to preoperative left ventricular dysfunction.

***Modified Takeuchi Operation.*** The Takeuchi operation, or intrapulmonary artery tunnel, is an alternative surgical strategy for repair of ALCAPA. Takeuchi and colleagues first described the creation of an aortopulmonary window using a portion of the anterior pulmonary artery wall to create a baffle which would direct blood from the aorta to the anomalously located left coronary artery ostium.[15] In the modified repair, a polytetrafluoroethylene (PTFE, Gore-Tex) patch is used to construct the baffle. However, creating a baffle may not be possible if the ostium is located near a commissure or arises from a branch pulmonary artery.

The procedure may be performed with either continuous low-flow cardiopulmonary bypass (25–28°C) or deep hypothermic circulatory arrest (18°C). Cannulation is performed as described above for direct reimplantation. After induction of cardioplegic arrest, a longitudinal incision is made in the anterior portion of the pulmonary artery (Fig. 83-7) and the ostium of the anomalous coronary is identified. Using a punch, a 5-mm diameter opening is made on the leftward aspect of the aorta above the sinotubular junction (Fig. 83-8). If there is any question regarding placement of the aortic opening, an anterior aortotomy should be performed and the incision visualized directly to avoid damage to the aortic valve. By creating the aortopulmonary window above the sinotubular junction, this allows a downward angle of the baffle into the sinus if the ostium is located deep within a sinus. After a similar incision is made in the pulmonary artery directly opposite to the aortic opening, these are anastomosed using a continuous suture of 7-0 Prolene creating an aortopulmonary window (Fig. 83-8). A 4-mm PTFE tube graft is split longitudinally and customized to an appropriate length (Fig. 83-9). This graft functions as an intrapulmonary artery tunnel, baffling blood from the aortopulmonary window to the anomalous coronary ostium. The suture line starts at the anomalous coronary and is continued inferiorly along the pulmonary artery wall to the aortopulmonary window. The suture line then returns to the coronary artery to complete the superior aspect of the baffle.

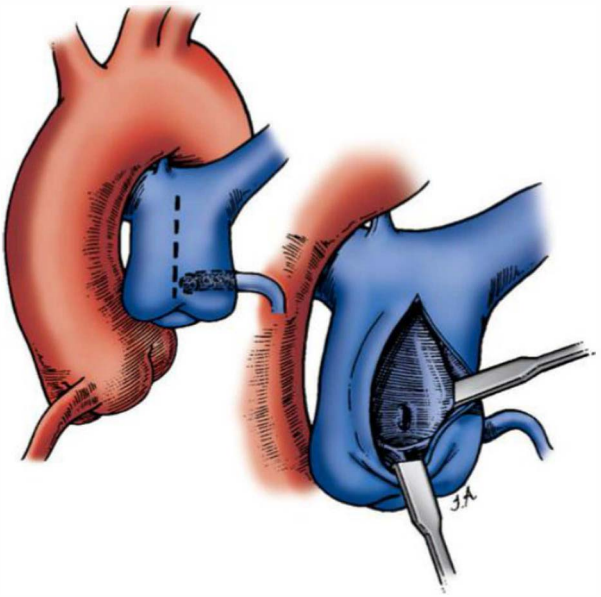

**FIGURE 83-7** After institution of cardiopulmonary bypass and induction of cardioplegia, a longitudinal incision is made in the main pulmonary artery, and the ostium of the abnormal coronary is identified. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

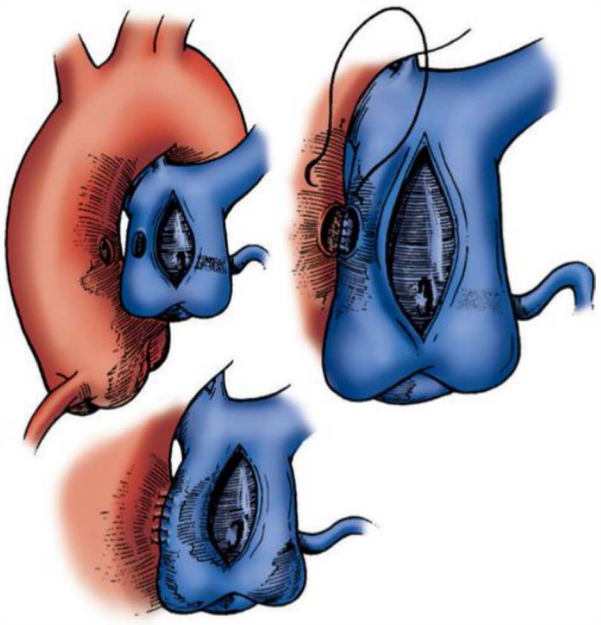

**FIGURE 83-8** Using a punch, a 5-mm opening is made in the aorta on the leftward aspect above the sinotubular junction. A similar opening is made in the pulmonary artery at the same level, and these are anastomosed to create an aortopulmonary window. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

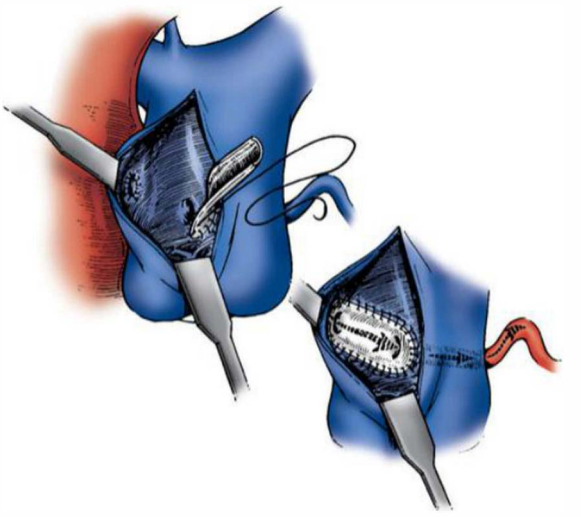

**FIGURE 83-9** A segment of 4-mm polytetrafluoroethylene (Gore-Tex) graft is opened longitudinally and used to fashion a baffle that directs blood flow from the aortopulmonary window to the anomalous coronary ostium. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

After the baffle is created, repair of the pulmonary artery is performed using a prosthetic patch or autologous pericardium to avoid supravalvar pulmonary artery obstruction (Fig. 83-10). The most common complications of the modified Takeuchi operation include baffle leak, baffle occlusion, and supravalvar pulmonary artery obstruction.

## Postoperative Management

Regardless of which surgical technique was utilized, the most common postoperative issues are those related to the infant's preoperative state: low cardiac output, left ventricular dysfunction, and hypotension. Optimizing the patient's hemoglobin, electrolytes, acid-base and fluid status, and providing adequate inotropic support are extremely important. LVAD or ECMO support may be temporarily necessary in infants and children with severe preoperative cardiac dysfunction. Bleeding is also a common postoperative issue and is more frequently encountered in small infants and those who require mechanical support. Platelets and fresh frozen plasma should be used aggressively to replace ongoing losses. Patients with low cardiac output and/or bleeding issues may be candidates for delayed sternal closure.

## Results

Although simple ligation of ALCAPA has unacceptable early and late mortality rates, survival after establishment of a dual coronary system is generally excellent.[13,26] Bunton and

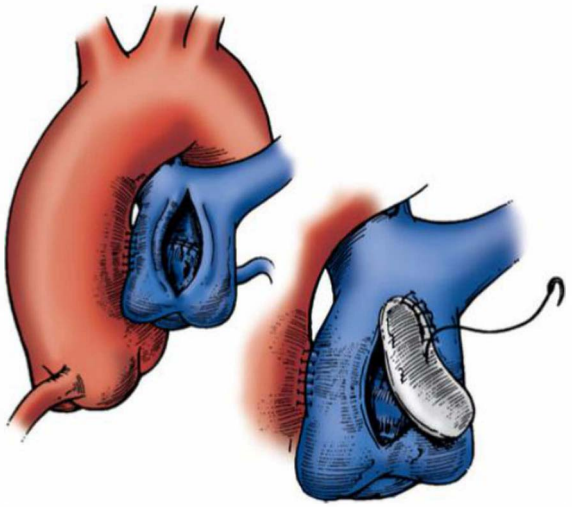

**FIGURE 83-10** After the baffle is completed, the pulmonary arteriotomy is repaired with a patch to avoid creation of supravalvar right ventricular outflow tract obstruction. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

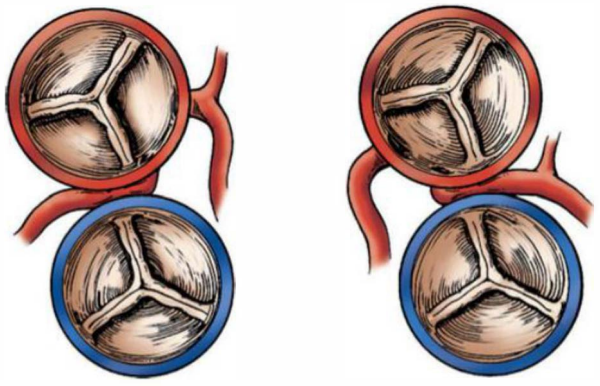
colleagues reported in 1987 on 24 patients with ALCAPA: 11 had coronary ligation or ostial closure, 11 underwent a Takeuchi repair, and 2 had other procedures.[27] Over an average 10.5-year follow-up period, those who underwent coronary ligation or ostial closure had a 27 percent early mortality and a 25 percent late mortality rate. On the other hand, there were no early or late deaths over an 18.5-month follow-up period in those who underwent the Takeuchi procedure. After Takeuchi repair, two patients developed right ventricular outflow tract obstruction and one patient had baffle occlusion. Backer and colleagues reported the follow-up surgical results of 20 patients with ALCAPA who underwent different procedures.[28] There were two early deaths and one late death out of nine patients who underwent ligation, but there were no deaths among the 10 patients who underwent creation of a dual coronary artery system or the 1 patient who had cardiac transplantation. Of five patients who had left subclavian-to-left coronary anastomosis, two developed significant anastomotic stenosis. Vouhe and associates from Paris reported on coronary reimplantation in 31 consecutive children.[29] Within the first 3 months, there were three hospital deaths and two additional deaths, but no late deaths. The only risk factor identified for early mortality was poor cardiac function. The survivors were studied for more than 1 year after repair and all had normal left ventricular function. In five of seven patients who had severe MR preoperatively, the severity had decreased to mild or no regurgitation. The reimplanted coronary artery was patent in all patients. Lange and colleagues recently reviewed the long-term results of 56 patients with ALCAPA who underwent either subclavian artery anastomosis or coronary artery transfer.[30] Patients who had a Takeuchi procedure or a left IMA graft were excluded. Both surgical groups had similar early mortality rates of 14 percent but no mortality in those undergoing repair in the last 13 years. There was one late death in each surgical group. At final follow-up (mean 14.5 years for subclavian artery group and 8.7 years for coronary transfer group), 95 percent of patients had normal left ventricular function and 84 percent had only mild MR. Although the prospect of functional recovery is excellent, cardiac transplantation may be indicated if left ventricular function does not improve following the revascularization procedure.

## Special Considerations

### MITRAL REGURGITATION

The management of MR during the initial surgery is controversial.[31] In general, at least a moderate degree of MR is present initially in most patients. Even in patients with severe MR, there are several reports of significant improvement after coronary reperfusion alone. This is likely due to improved left ventricular function and a decrease in left ventricular size postoperatively. Valve repair at the time of initial surgery can result in longer ischemic times and can be technically more difficult to perform in an infant heart compared to an older child. However, some advocate routine annuloplasty at the time of initial repair whereas others recommend annuloplasty or mitral valve replacement only with severe MR.[32] In summary, early surgical repair of the mitral valve is generally not necessary. If valve repair due to severe MR is needed later, it is likely to be more successful and easier to do technically. If severe MR persists late postoperatively, possible causes of ongoing myocardial ischemia should be investigated.



### LATE PRESENTATION IN THE ADULT

As discussed previously, adults who present with ALCAPA are rare but do occur. Surgery is indicated in all cases but can generally be done electively. In adults, the surgical choice is coronary bypass grafting using the left internal thoracic artery in association with ligation of the proximal vessel; this is generally a low-risk procedure that all adult cardiothoracic surgeons can perform with a low mortality rate.

# ANOMALOUS CORONARY ARTERY COURSE BETWEEN AORTA AND PULMONARY ARTERY

## Anatomy

An anomalous coronary artery that courses between the two great vessels is associated with an increased risk of myocardial ischemia and sudden death, notably in children and young adults. When there are two separate ostia in the same

A B

**FIGURE 83-11** **A.** Anomalous origin of the right coronary artery from the left aortic sinus with abnormal coursing of the right coronary artery between the aorta and pulmonary artery. **B.** Abnormal origin of the left main coronary artery from the right aortic sinus with abnormal coursing of the left main coronary artery between the aorta and pulmonary artery. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds): Mastery of cardiothoracic surgery. Philadelphia: Lippincott-Raven, 2007).

sinus of Valsalva, either the aberrant RCA or LMCA may subsequently run intramurally between the great vessels (Fig. 83-11).[33] When the two ostia arise from the same sinus, the anomalous coronary ostium is usually small and slit-like with an acute-angle takeoff from the aorta.[34] Another potential high-risk situation occurs when a single coronary artery arises from the right aortic sinus and the LMCA or LAD runs intramurally between the aorta and pulmonary artery, or if the single coronary arises from the left aortic sinus and the RCA courses intramurally between the great vessels.[35–38]

## Pathophysiology

When the aberrant vessel courses intramurally in the aortic wall between the two great vessels, this anatomy is associated with increased incidence of sudden death.[39–45] Both anomalous LMCA from the right sinus and RCA from the left sinus are associated with sudden death, but the former carries a higher risk. Based on autopsy studies of anomalous coronary artery patients, sudden cardiac death is thought to occur from decreased anomalous coronary blood flow resulting in myocardial ischemia and/or ventricular tachyarrhythmias. This diminished blood flow is likely due to an anatomical malformation of the anomalous vessel, including the narrow slit-like orifice as well as the systolic lateral compression of the anomalous vessel as it courses intramurally. The greatest risk of ischemia and sudden death is during or just after completing vigorous exercise when myocardial oxygen demand and cardiac output are greatest.[46–48]

## Clinical Presentation

The true prevalence of this anomaly is unknown because there is no denominator; however, estimates range from 0.1 to 0.3 percent of the general population.[49–51] What makes this diagnosis especially challenging is that there are no characteristic physical findings. Indeed, the physical examination is almost always normal. What often prompts the referral to a cardiologist is an innocent heart murmur: A carefully performed echocardiogram will then lead to the diagnosis. Many patients with this anomaly are asymptomatic and the initial presentation is sudden death.[49,52] When symptoms are present, they most commonly include chest pain, palpitations, presyncope or syncope during or just following exertion.[33,42,53–55] This diagnosis must be considered in any young patient with exercise-induced complaints suggestive of myocardial ischemia, or in those presenting with aborted sudden death or sudden death.[56] Screening first-degree relatives using echocardiography has recently been suggested due to the potential familial link with this anomaly.[53]

## Diagnostic Imaging

Anyone presenting with presyncope, syncope or chest pain during or just after exertion requires attention and further clinical evaluation. A resting ECG should be obtained to evaluate for ventricular hypertrophy, arrhythmias, and evidence of previous myocardial infarction.

Transthoracic echocardiography with color Doppler is necessary to document normal intracardiac anatomy and to evaluate heart function, especially focusing on areas of abnormal wall motion as clue of possible ischemia.[53,54,57] Close attention should be paid to the coronary artery origins and proximal coronary anatomy. Improvements in two-dimensional echocardiography have made the identification of both coronary artery origins possible in many patients. However, when using traditional two-dimensional imaging alone, the anomalous vessel may appear to arise normally where it exits the aorta. Color Doppler imaging can be quite useful in demonstrating the direction of blood flow within the aortic wall, thus helping to differentiate an anomalous vessel from one that arises normally.

Other noninvasive techniques, such as MRI or CT scan, may be used when the coronary artery origins cannot be adequately delineated and/or to confirm the diagnosis.[58,59] Occasionally cardiac catheterization with angiography or transesophageal echocardiography will be utilized to visualize the coronary anatomy; however, these are more invasive options and are generally not the first choice in children. Indeed, although cardiac catheterization with coronary angiography still remains the gold standard for detecting anomalous coronary arteries, it is being replaced by noninvasive imaging as described above. Coronary angiography may be necessary in adult patients to delineate associated coronary atherosclerotic disease prior to undergoing surgical intervention.[60]

Most patients who are asymptomatic will undergo further evaluation for myocardial ischemia. This usually includes an

exercise stress test with an imaging study, such as a nuclear perfusion scan or stress echocardiography. However, basing management decisions on a single exercise test is not recommended since ischemia is intermittent with this anomaly. In a study by Brothers and colleagues, of nine children who presented with cardiovascular symptoms and who also had a preoperative exercise test, only one demonstrated an abnormality during maximal exercise testing.[33] Furthermore, sudden death has been extensively reported in patients negative results on previous stress-testing.

## Surgical Management

### INDICATIONS FOR SURGERY

Surgical intervention is indicated in any patient with anomalous coronary artery with an interarterial and intramural course who has signs and/or symptoms of myocardial ischemia or ventricular arrhythmias. Most would also agree that surgery is indicated in asymptomatic patients with anomalous origin and course of the LMCA because of the high risk of sudden death observed in this subgroup of patients. The management of asymptomatic patients with anomalous RCA remains controversial.

### UNROOFING PROCEDURE

The unroofing procedure has become the procedure of choice for patients with anomalous coronary artery with an interarterial and intramural course.[33,54,61,62] After a median sternotomy is performed, the pericardium is opened and the anatomy is inspected. Aortic cannulation occurs near the innominate artery and a two-stage venous cannula is inserted via the right atrial appendage. After cardiopulmonary bypass with moderate hypothermia is established, a left ventricular vent is placed via the right superior pulmonary vein. The ascending aorta is cannulated for administration of cardioplegia solution. The aorta is cross-clamped and cardioplegia solution is administered. A transverse aortotomy is performed after adequate arrest is achieved and the coronary ostia are identified. If the anomalous coronary ostium is located near the aortic valve commissure, take down of the commissure may be needed (Fig. 83-12). The anomalous ostium is opened longitudinally starting at the anomalous coronary os and continuing into the correct sinus (Fig. 83-13). A segment of the common wall between the aorta and coronary is excised and the intimal surfaces are approximated with interrupted sutures using 8-0 Prolene. If the commissure was taken down, it is resuspended with a pledgeted suture (Fig. 83-14). The aortotomy is then repaired and the cross-clamp is removed after de-airing. As the patient is rewarmed, close attention should be paid to the ECG to evaluate for signs of myocardial ischemia.

### CREATION OF A NEO-OSTIUM

The creation of a neo-ostium in the correct sinus is an alternate technique that may be used when the anomalous

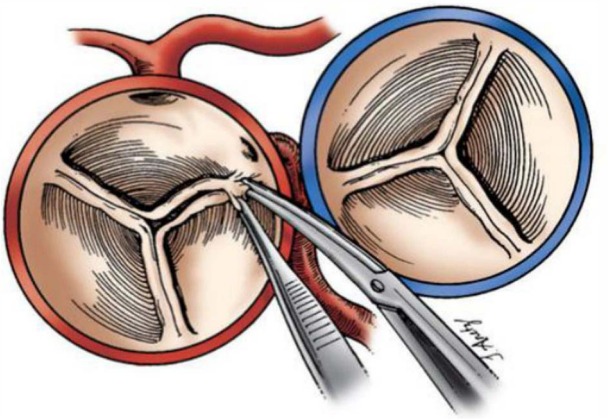


**FIGURE 83-12** When the coronary arises anomalously from the opposite sinus of Valsalva and courses between the pulmonary artery, the ostium is frequently abnormal. Repair may be undertaken by remodeling of the ostium. The abnormal ostium is usually located near a commissure and this commissure must be initially taken down to allow remodeling of the ostium. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

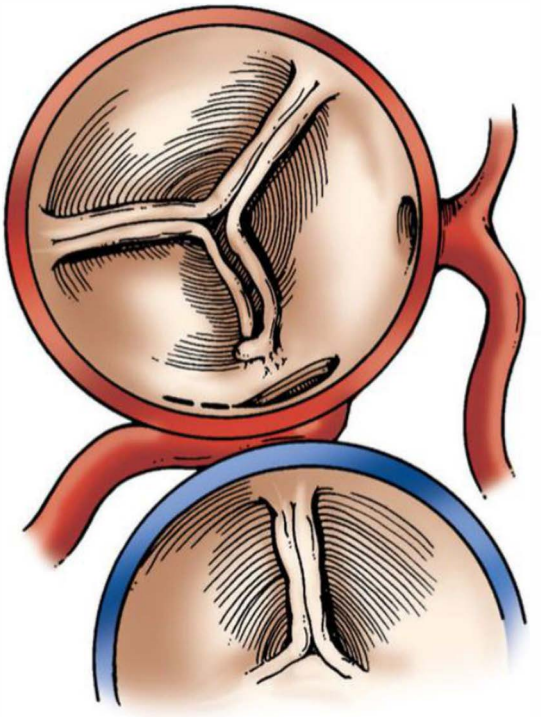

**FIGURE 83-13** After the commissure is detached, the abnormal coronary is incised longitudinally beginning at the abnormal ostium and this incision is carried into the right aortic sinus. A portion of the common wall between the aorta and coronary is excised. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

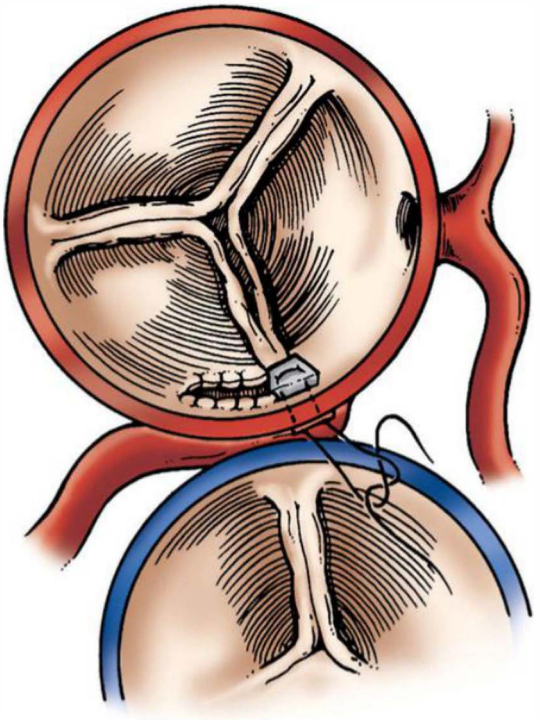

**FIGURE 83-14** The walls of the coronary artery and aorta are anastomosed with interrupted sutures of 8-0 polypropylene (Prolene), enlarging the ostium and preventing compression by the great vessels. The commissure of the aortic valve is resuspended with a pledgetted suture. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 1998.)

coronary passes intramurally below the aortic valve commissure. A probe is passed through the intramural segment of the anomalous coronary into the correct sinus. The coronary artery is opened where it exits the aorta and a neo-ostium is created. The intima is sewn to the aortic wall with interrupted sutures. This technique avoids the takedown and resuspension of the commissure.[51]

### OTHER TECHNIQUES

When there are two separate coronary ostia with an interarterial but not an intramural course, coronary artery translocation with reimplantation has been advocated.[62] This is similar to reimplantation done for the arterial switch procedure as described above for the ALCAPA repair. The coronary artery is excised with a button of aortic tissue and usually reimplanted above the commissure in the correct sinus. Since some believe that myocardial ischemia is due to coronary artery compression between the two great vessels, one technique that may be utilized when the anomalous coronary course is not intramural but the ostia are close together is pulmonary artery translocation. This technique has been used to possibly prevent the compression of the anomalous coronary artery is translocation of the MPA to the left pulmonary artery. This technique leaves the coronary circulation intact.[63] Combining coronary artery patch angioplasty using pericardium in addition to translocating the MPA to the left pulmonary artery has also recently been proposed.[64] Coronary artery bypass grafting utilizing saphenous vein or IMA grafts may be appropriate in the older adult; however, due to issues with long-term graft patency, this surgical option in children and young adults is generally not utilized.

## Surgical Results

No data exist regarding long-term neo-ostia patency rates in the unroofing procedure. However, short-to-mid-term results have overall been reassuring with no reports of ostial stenosis by echocardiography. In a study by Romp and colleagues, one patient developed severe aortic insufficiency requiring aortic valve replacement 44 months after the initial operation.[55] One study by Brothers and colleagues evaluated children in the short-to-mid-term following the unroofing procedure. They found subclinical evidence of myocardial ischemia in one-half of the patients with anomalous RCA and one of eight patients with anomalous left coronary artery, being asymptomatic during testing and having patent neo-coronary ostia by echocardiography.[33] The long-term clinical implications of these findings are unknown and further evaluation is needed over the next several years.

Although coronary artery reimplantation has been utilized by some, one study by Rinaldi and colleagues reported that two patients required subsequent emergency bypass grafting.[65] As this is an analogous procedure utilized for transposition of the great arteries, concern regarding long-term coronary patency may be warranted. A recent report by Pedra and associates evaluating children after repair of transposition of the great arteries demonstrated proximal eccentric intimal thickening by intravascular ultrasound in a majority of patients seen at least 5 years after the original surgery.[66] The long-term success of pulmonary artery translocation procedures is not known.

# CORONARY ARTERY FISTULA

A coronary artery fistula is an abnormal communication between a coronary artery and either a cardiac chamber or any of the great vessels, such as the coronary sinus, vena cavae, pulmonary artery, or a pulmonary vein.[67,68] Fistulas that end in right-sided structures, such as the right atrium, right ventricle, or pulmonary artery are termed arteriovenous fistulas while those that terminate in left-sided structures are described as arterioarterial fistulas.

Although coronary arterial fistulas comprise only 0.2 to 0.4 percent of congenital heart defects, they make up nearly half of all congenital coronary anomalies. They can be found in isolation, or in association with other forms of congenital

heart disease. Those that are acquired are the generally due to cardiac surgery, cardiac catheterization, or as a complication from Kawasaki disease.[69]

## Anatomy

Coronary artery fistulas may arise from either the right or the left coronary artery; occasionally both coronary arteries are affected.[70] The majority arises from an otherwise normal coronary artery. The fistulous connection may begin in the midportion of a coronary artery with a normal-sized vessel continuing beyond the fistula origin or the connection may arise as an end artery at the termination of the vessel. Proximal to the fistula, the coronary will be dilated and elongated proportionally to the size of the shunt across the fistulous connection. Distal to the fistula, the portion of the vessel usually returns to a normal diameter.

The right ventricle and the right atrium are the most common termination sites. In a review by Fernandes and colleagues, a single fistula was present in 83 patients and 10 had multiple fistulas.[71] The RCA was the most common site of origin and the right ventricle was the most common drainage site. Coronary fistulas were noted in 56 patients with otherwise normal cardiac anatomy while the others had additional cardiac lesions. Lowe and colleagues reviewed 286 patients and found the RCA to be the site of origin in approximately half of the patients and the left coronary artery system in nearly one-third.[72] Right-sided structures were the most common drainage sites (right ventricle 39 percent, right atrium 33 percent, and pulmonary artery 20 percent) with the left atrium or left ventricle in the remaining 8 percent.

## Pathophysiology

Coronary fistulas result in either a left-to-right or left-to-left shunt. The shunt is usually small to moderate when the fistula drains to the right side of the circulation; however, when the fistula drains into a left-sided chamber (i.e., left-to-left shunt), the result is an aortic runoff with similar physiology as aortic regurgitation. The shunt size is related to the amount of blood flow draining from the fistula to the chamber, as well as the chamber into which the fistula drains. Shunt size may also be affected by myocardial ischemia occurring from "steal" from the coronary circulation.

## Clinical Presentation

Patients with coronary artery fistula are usually asymptomatic and are rarely diagnosed in infancy or childhood. Many patients are diagnosed due to a murmur auscultated on exam that leads to an echocardiogram. The most common complaints if symptomatic are exertional dyspnea and fatigue. Angina is rare, even when coronary steal is present. Occasionally, a patient may present with ventricular dysfunction and congestive heart failure but this is more commonly seen in the adult. An older patient may present in atrial fibrillation due to right atrial enlargement caused by a coronary artery fistula to the right atrium.

On physical examination a continuous murmur is often heard. The murmur may be mistaken for a PDA but is heard lower on the sternal border, which is not the usual location for a PDA. In large left-to-left shunts a wide pulse pressure may be appreciated similar to aortic regurgitation.

### NATURAL HISTORY

In congenital coronary arterial fistulas, the fistula is present early in life and, over several years, gradually increases in size. Despite progressive enlargement of the coronary arteries, spontaneous rupture is rare. When rupture does occur, it is usually because of aneurysmal dilatation with weakening of the vessel wall due to a congenital defect or atherosclerosis. Bacterial endocarditis is possible due to the turbulent flow. Small fistulas may spontaneously close.

## Diagnostic Imaging

The ECG is commonly normal. However, it may demonstrate evidence of ventricular volume overload or atrial fibrillation, which may be seen in adult patients who have right atrial fistulous connections with subsequent chronic volume overload. Evidence of myocardial ischemia in the affected region may be noted if coronary steal is present. Chest radiography is usually normal but may show cardiomegaly or evidence of congestive heart failure. Giant aneurysms, if present, may also be noted. Two-dimensional echocardiography can show the fistulous origin, the chamber into which it drains, and any cardiac chamber enlargement and/or hypertrophy. Color Doppler should be used to demonstrate the fistula itself. MRI has become an excellent non-invasive imaging modality to diagnose and provide detailed anatomy of the coronary arterial fistula. Although it may replace cardiac catheterization, it currently is still used as an adjunctive imaging modality.

Cardiac catheterization with selective coronary angiography remains the gold standard. It is used in defining the coronary anatomy and the hemodynamic consequences of the fistula. An experienced interventional cardiologist may choose to coil embolize the fistula, alleviating the morbidities associated with cardiopulmonary bypass and sternotomy (Fig. 83-15).[73] However, the indications for coil embolization have not been well-defined in the pediatric population; therefore, the preferred treatment in most patients is surgical closure.[74]

## Surgical Management

### INDICATIONS FOR SURGERY

All patients with symptomatic coronary artery fistulas should undergo closure. Those who have very small fistulas may not require surgical closure; however, the natural progression of the fistula is to enlarge (Fig. 83-16), requiring close follow-up over time.[75] Asymptomatic patients with moderate-to-large fistulas should undergo elective surgical closure.

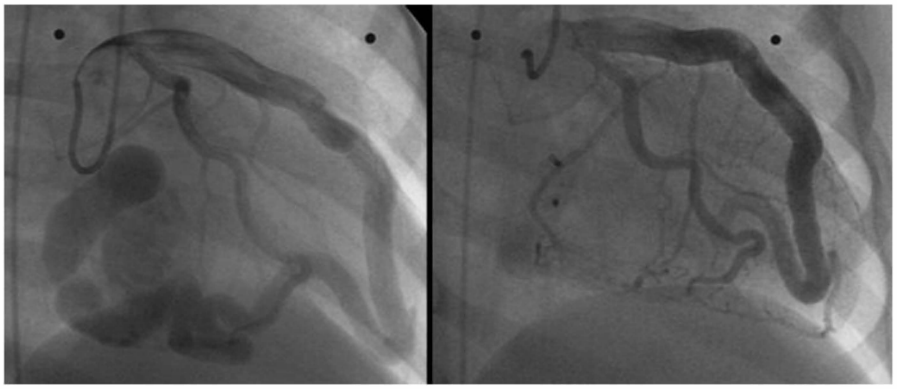

**FIGURE 83-15** Endovascular approach to large right coronary artery arteriovenous fistula (left). The fistulous tract was occluded percutaneously (right). (Courtesy of Dr. Richard Ringel, Division of Pediatric Cardiology, the Johns Hopkins Hospital.)

## SURGICAL TECHNIQUES

Coronary artery anatomy must be clearly defined, usually by coronary angiography, prior to surgical closure. Each operation should be individualized based on the anatomy. Often the fistula can be ligated or oversewn at its origin or termination without cardiopulmonary bypass; however, cardiopulmonary bypass should always be available.

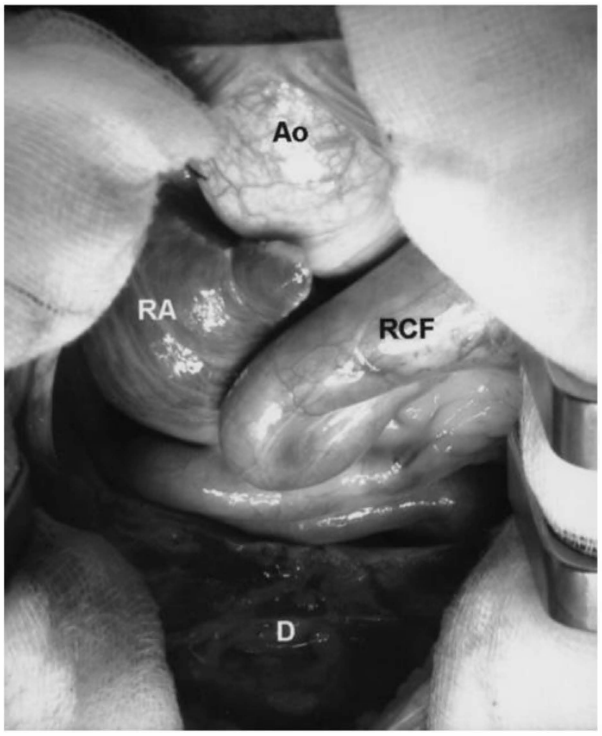

**FIGURE 83-16** Intraoperative photograph of giant right coronary artery arteriovenous fistula. The fistulous tract was ligated distally, before entrance in the right atrium. Ao, aorta; D, diaphragm; RA, right atrium; RCF, right coronary fistula. (Courtesy of Mr. Victor Tsang and Sir Magdi Yacoub, Cardiac Unit, Great Ormond Street Hospital for Children NHS trust, London.)

Through a median sternotomy the coronary anatomy is visualized and carefully inspected, noting the site of the enlarged vessel. When the fistula is located at the distal end of the coronary artery without viable myocardium distal to the fistula, it may be ligated without the use of cardiopulmonary bypass (Fig. 83-17). A ligature is placed around the coronary artery immediately proximal to the fistula, thus temporarily occluding the fistula. The heart is observed for signs of ischemia and the ECG is monitored closely. The ligature is tied if there is no evidence of ischemia and there is adequate myocardial perfusion. A second suture ligature should also be placed to ensure complete closure. Intraoperative transesophageal echocardiography may be useful to verify complete fistula closure.

Cardiopulmonary bypass is indicated under several conditions, including: the fistula originates from the middle of a coronary artery, the fistula is inaccessible, another cardiac lesion needs to be repaired during the operation, and/or the complete coronary course cannot be adequately delineated. The aorta and both cavae are cannulated and bypass is initiated. If cardioplegic arrest is necessary, the fistula should be temporarily compressed during administration of the cardioplegia to prevent runoff through the fistula into the heart. If adequate arrest is not possible due to flow through the fistula, it may be necessary to administer cardioplegia in a retrograde fashion.

Closing the fistula can be accomplished using a variety of techniques. If the fistula terminates in the middle of the LAD, the fistulous communication can be closed by placing multiple pledgeted sutures beneath the coronary artery, making sure to avoid compromising distal perfusion (Fig. 83-17). Coronary bypass grafting may be necessary if distal perfusion of the coronary bed is affected after closure of the fistula. Alternatively, when the fistula arises from the middle of the coronary artery, the latter can be opened longitudinally on the epicardial surface, oversewing the origin of the fistula from within the coronary arterial lumen (Fig. 83-18). The coronary artery can then be closed primarily.

If the right atrium or right ventricle is the site of the fistulous termination, it may be closed directly from within

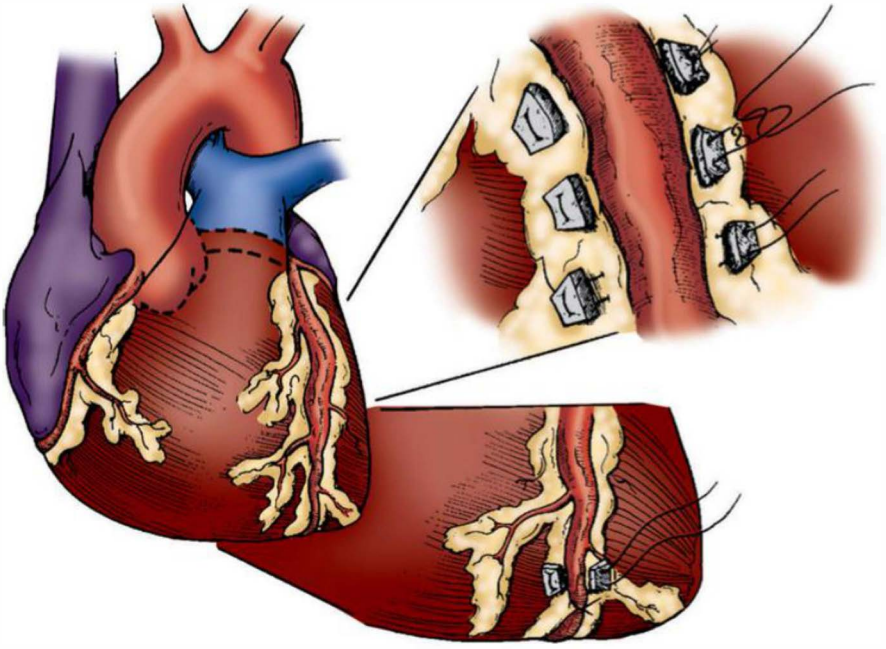

**FIGURE 83-17** If the termination site of the fistula is at the distal aspect of the coronary and no significant myocardium is in jeopardy, the coronary may be ligated proximal to the termination site. If the fistula terminates in the midportion of the left anterior descending coronary artery, the fistulous communication may be closed with multiple pledgetted sutures placed underneath the coronary artery so as not to impair distal perfusion. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

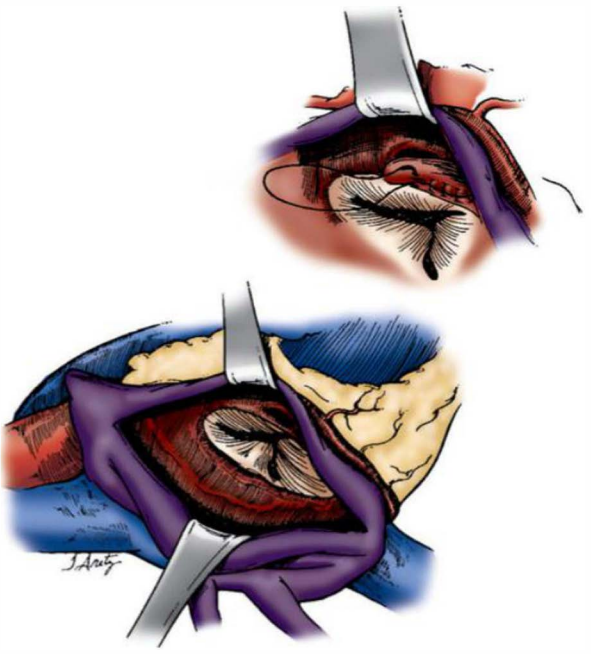

**FIGURE 83-20** After institution of cardiopulmonary bypass and induction of cardioplegia, the right atrium is opened and the termination site of the fistula identified from within the right atrium. This may be dosed primarily or with a patch of pericardium. (Reprinted with permission from: Gaynor JW. Coronary artery anomalies in children. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 2007.)

the cardiac chamber (Fig. 83-19). After institution of cardiopulmonary bypass, a right atriotomy is performed and the termination site is noted from within the chamber. Cardioplegia may be useful for localization. The termination site may be closed primarily or with a pericardial patch (Fig. 83-20).

### SURGICAL RESULTS

The operative mortality for coronary artery fistula repair is very low and late results are excellent, with very few patients experiencing a recurrence.[52,70] In a report by Lowe and colleagues, 22 patients underwent surgical closure of coronary artery fistulas and four patients had the fistula closed using sutures without cardiopulmonary bypass.[72] In six patients, the fistula terminated within a cardiac chamber and was closed using cardiopulmonary bypass; in the remaining two patients, saphenous vein bypass grafts were necessary to maintain distal perfusion after fistula closure. There were no deaths at an average follow-up time of 10 years. One patient had a small residual fistula but there were no recurrences. Fernandes and colleagues reported no early or late mortality in 56 patients who had closure of isolated coronary artery fistula; however, two patients experienced a perioperative myocardial infarctions.[71] Finally, in a report by Mavroudis and colleagues on 17 pediatric patients (average age of 5.5 years), all had complete closure without recurrences or deaths.[74]

## SURGERY FOR CONGENITAL CORONARY ANOMALIES BOARD REVIEW QUESTIONS (CHAPTER 83)

1. Which is correct regarding anomalous origin of a coronary artery from the pulmonary artery (ALCAPA)?
   A. The most common form is the right coronary artery arising from the pulmonary artery
   B. It is the most common cause of myocardial infarction in childhood
   C. An anomalous left main coronary artery typically arises from the anterior sinus of the main pulmonary artery
   D. Diagnosis is usually evident at birth
   E. A shunt will develop, resulting in coronary-pulmonary steal

2. Which is true for surgical repair of ALCAPA?
   A. Surgery should be delayed for 4–6 weeks to allow for myocardial recovery
   B. Infants with severe LV dysfunction and mitral insufficiency should be considered for cardiac transplantation
   C. Mitral valve repair with or without LV aneurysmectomy is indicated for concomitant severe mitral insufficiency
   D. Left internal mammary artery bypass grafting is the gold standard for children
   E. The classic Takeuchi operation uses a portion of the anterior wall of the pulmonary artery for coronary baffling

3. Which is true regarding outcomes after surgical repair of ALCAPA?
   A. Coronary ligation is associated with a 25% late mortality rate
   B. Left ventricular function is normal in 75% of patients after coronary transfer
   C. Over 50% of patients will have moderate or greater mitral insufficiency at late follow-up
   D. In adults, the preferred technique has become direct coronary reimplantation
   E. Early surgical repair of mitral insufficiency is generally necessary, as late repair is more difficult and less likely to be successful in a child

4. Which of the following is not an appropriate operation for anomalous coronary artery between the aorta and pulmonary artery diagnosed in a child?
   A. Unroofing procedure
   B. Creation of a neo-ostium
   C. Coronary artery translocation
   D. Pulmonary artery translocation
   E. Coronary artery bypass grafting
5. Which is true regarding coronary artery fistulas?
   A. The majority arise from a diseased artery
   B. The coronary artery will be dilated and elongated distal to the fistula
   C. The left ventricle and the right atrium are the most common termination sites
   D. A coronary fistula can cause either a right-to-left or a left-to-right shunt
   E. The most common presentation is angina

## ANSWERS

1. **Answer: B.** ALCAPA is the most common cause of myocardial infarction in childhood. The most common form is left main coronary artery arising from the pulmonary artery, originating from the posterior sinus of the main pulmonary artery. Diagnosis usually is not made until after ductal closure and pulmonary resistance falls, resulting in a pulmonary-coronary steal.
2. **Answer: E.** The classic Takeuchi operation uses a portion of the anterior wall of the pulmonary artery for coronary baffling. Surgery should be performed promptly to prevent further myocardial ischemia. Significant myocardial recovery will occur; therefore, transplantation and mitral operations are rarely indicated. Coronary artery bypass grafting is rarely used for this condition in children.
3. **Answer: A.** Coronary ligation is associated with a 25% late mortality rate. LV function is normal is about 90% of patients after coronary transfer, and nearly 85% have only mild mitral insufficiency. In adults, the preferred technique is coronary artery bypass grafting. Early surgical repair of mitral insufficiency is generally not necessary, as late repair is technically simpler and more likely to be successful in a child.
4. **Answer: E.** Coronary artery bypass grafting is generally not indicated in children, as long-term patency may be unsatisfactory. The remaining operations have all been demonstrated to achieve excellent results.
5. **Answer: D.** A coronary fistula can cause either a right-to-left or a left-to-right shunt, depending on drainage patterns. The majority arise from an otherwise normal coronary artery. The coronary artery will be dilated and elongated proximal to the fistula. The right ventricle and the left atrium are the most common termination sites. Most patients are asymptomatic on presentation and are diagnosed with a murmur.

# Vascular Rings and Pulmonary Artery Sling

*Carl Lewis Backer*
*Michael C. Mongé*
*Hyde M. Russell*

**KEY CONCEPTS**

- Epidemiology
  - Vascular rings and pulmonary artery sling (PAS) represent 1 to 3 percent of all congenital cardiac malformations. The most frequent type of vascular ring is aberrant left subclavian artery, whereas the most rare condition is the PAS.
- Morphology
  - Of the over 100 variations in morphology that have been described, 6 are most commonly observed: (1) anomalous left subclavian artery with left aortic arch, (2) double aortic arch (DAA), (3) right aortic arch with left ligamentum, (4) right aortic arch with aberrant left subclavian artery, (5) tracheal compression by the innominate artery, and (6) PAS. Cardiac malformations (tetralogy of Fallot, ventricular septal defect, atrial septal defect, and aortic coarctation) are seen in 15 to 20 percent of cases.
- Pathophysiology
  - Structural obstruction of the aerodigestive tract
- Clinical features
  - Most vascular rings are symptomatic. Compression by the complete or partial ring of the esophagus, trachea, or both dictates the mode of presentation. Patients with an aberrant left subclavian artery are often asymptomatic, whereas pulmonary artery sling and complete rings are almost uniformly clinically significant.
- Diagnosis
  - Chest x-ray is rarely diagnostic. Barium esophagography is usually able to point to the presence of a vascular ring with reasonable specificity. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in defining the anatomy and are currently more routinely utilized. Bronchoscopy is important in the diagnosis of both innominate artery compression and PAS and in assessing the degree of tracheobronchomalacia.
- Treatment
  - Treatment is indicated in all symptomatic patients. With the exception of DAA with dominant left component, almost all cases (left aortic arch with right ligamentum, PAS, and innominate artery compression) are approached through a left thoracotomy with division of the vascular ring.
- Outcomes
  - For the vast majority of vascular rings, morbidity and mortality are the same as seen in any simple thoracic procedure involving a thoracotomy. Mortality is much higher for patients with PAS. The degree of tracheobronchomalacia has a significant impact on long-term prognosis.

## INTRODUCTION AND DEFINITIONS

Vascular rings are congenital abnormalities of the aortic arch system that cause tracheal and esophageal compression. Patients with vascular rings have varying degrees of symptoms that range from subtle swallowing difficulties in the adolescent to severe respiratory distress in the neonate. The symptoms depend on the tightness of the vascular ring as it compresses the esophagus and/or trachea. The phrase "pulmonary artery sling (PAS)" refers to a particular anomaly where the left pulmonary artery (PA) originates from the right PA and compresses the distal trachea and right bronchus on its route to the left lung. The Congenital Heart Surgery Nomenclature and Database Project Committee has standardized the classification of vascular rings to include complete rings [double aortic arch (DAA), right aortic arch

with left ligamentum] and incomplete rings [pulmonary artery sling (PAS), innominate artery compression].[1] Each of these vascular rings can have different anatomic variations. Nearly all patients with complete vascular rings and PAS will eventually require surgical intervention. Although the literature now contains citations describing over 100 variations of vascular rings, in this chapter we will focus on the most common vascular rings. We will also address the issue of a Kommerell diverticulum and select rare vascular rings. We will review the historic surgical events in vascular ring surgery, the epidemiology, embryology, pathogenesis, the clinical presentations and diagnostic evaluations, the surgical management, and postoperative care and outcomes.

## HISTORY

The first vascular ring described in the medical literature involved a patient with a DAA described by Hommel in 1737.[2] The first surgical repair of a vascular ring was performed by Robert Gross on a patient with a DAA in 1945.[3] In his report, Gross coined the term "vascular ring." Gross also reported the first repair of a right aortic arch with left ligamentum, and innominate arteriopexy for innominate artery compression syndrome.[4] Willis J. Potts from Children's Memorial Hospital (Chicago) was the first to successfully repair a PAS in 1953.[5]

## EPIDEMIOLOGY

Because some patients with vascular rings fail to manifest symptoms, the exact prevalence of this anomaly is not truly known. In one comprehensive series, the estimate ranged from 0.04 to 0.5 percent of live births or approximately 1 to 3 percent of surgical congenital cardiovascular anomalies.[6] The most common vascular anomaly is left aortic arch with an aberrant (retroesophageal) right subclavian artery (not a complete vascular ring) with a prevalence of 0.5 percent.[7] In a comprehensive cardiovascular screening program using echocardiography in school-age children, Chen and colleagues reported the following incidence of vascular rings in 186,213 screened children: PA sling ($n = 11$, 0.006 percent), anatomically complete vascular ring (DAA, right aortic arch with left ligamentum, $n = 96$, 0.05 percent).[8,9]

## EMBRYOLOGY AND PATHOGENESIS

There is a fascinating and surgically important relationship between the embryology and clinical anatomy of vascular ring anomalies. The characterization of the embryonic arch system by Edwards is based on a hypothetical intermediate stage involving an initial DAA in all patients that progresses in most cases to a single arch system (Fig. 84-1).[10]

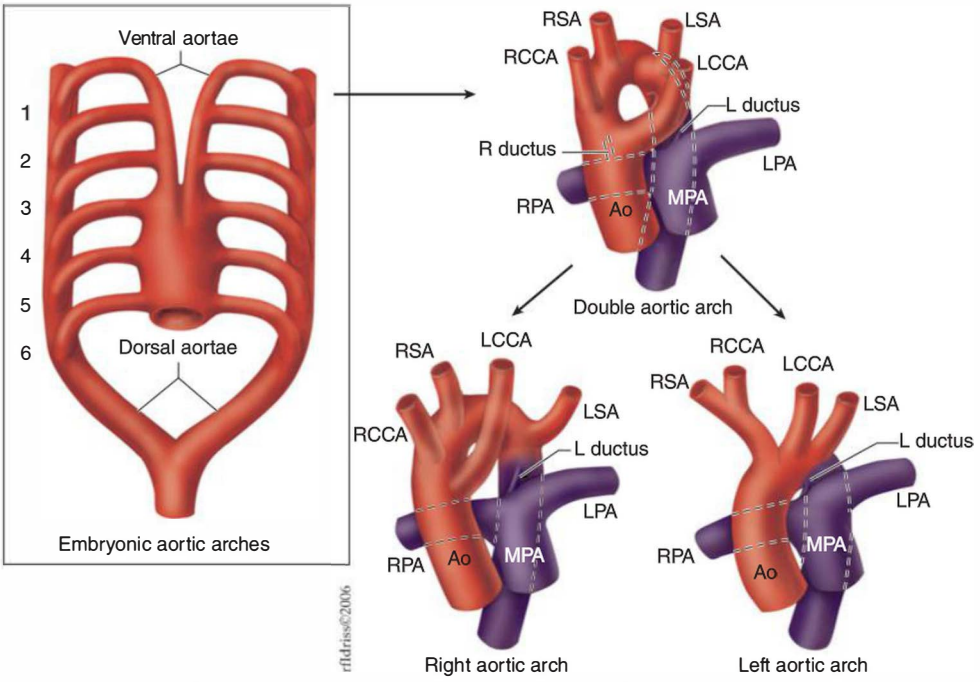

**FIGURE 84-1** Embryonic arotic arch development. Diagram of the embryonic aortic arches with six pairs of aortic arches originally developing between the dorsal and ventral aorta. During development, the first, second, and fifth arches regress. Preservation or deletion of different segments of the other arches results in either a double aortic arch, a right aortic arch, or the "normal" left aortic arch. Ao, aorta; CCA, common carotid artery; L, left; PA, pulmonary artery; R, right; SA, subclavian artery. (Reprinted with permission from Mavroudis C. *Pediatric Cardiac Surgery*, 3rd edition. Philadelphia: Mosby Elsevier, 2003.)

Initially, an aortic arch is located on either side of the trachea with a ductus arteriosus on each side. In this system, early in development six pairs of arches are present that connect the ventral and dorsal aorta. During further development, these arches variously mature, recede, fuse, and remodel to eventually form the typical left-sided aortic arch. Different vascular rings form when specific segments of the aortic arches either persist or resorb. During normal development, most of the first, second, and fifth arches regress, and the third arch persists to become the carotid artery. The right fourth arch forms the right brachiocephalic artery. The left fourth aortic arch becomes the ascending aorta and transverse aortic arch. The fifth aortic arch regresses on each side. In the typical left arch patient, the right dorsal portion of the sixth arch regresses, and on the left side it persists as the ductus arteriosus. The PA forms from a branch of the ventral bud of the sixth aortic arch which connects to the lung bud. The seventh intersegmental artery matures into the subclavian artery. The sidedness of the aortic arch is determined by which fourth arch persists which usually is the left. The anatomic definition of a left arch is that the apex of the aortic arch is to the left of the trachea. With reference to the center of the vertebral bodies, the descending aorta may be either right, left, or midline.

## DOUBLE AORTIC ARCH

A DAA forms when the ascending aorta arises normally from the heart but as it exits the pericardium, the right and left arches both persist and encircle the esophagus and trachea (Figs. 84-2 and 84-3). The left aortic arch passes anterior to the trachea and connects to the descending aorta at the level of the ligamentum arteriosum, while the right aortic arch courses posteriorly to the trachea and esophagus and then joins the descending aorta. The right arch typically gives rise to the right carotid and right subclavian arteries; the left subclavian and carotid arteries originate from the left aortic arch. In our series the right-sided (posterior) arch was dominant in 75 percent of patients with a DAA, the left-sided (anterior) arch was dominant in 18 percent of the patients, and the arches were equal in size in 7 percent of the patients.[11]

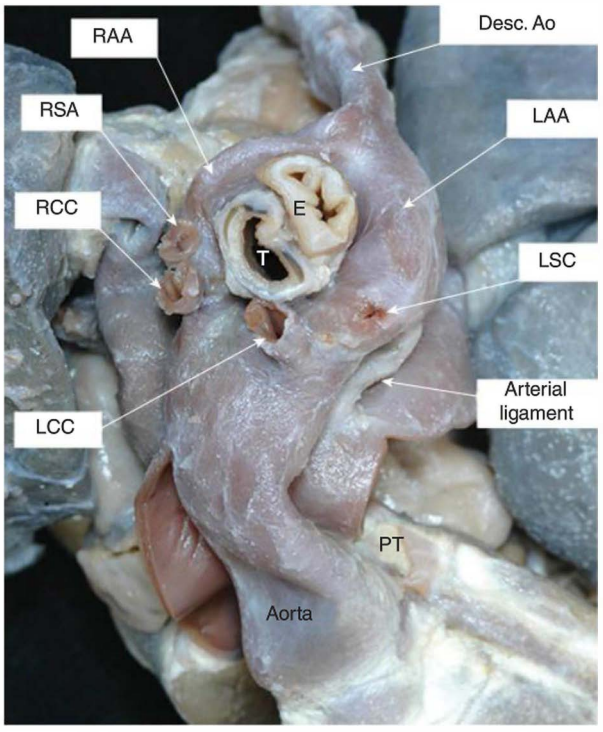

**FIGURE 84-2** Double aortic arch. Autopsy specimen of a child with a double aortic arch (left arch dominant). Desc. Ao, descending aorta; E, esophagus; LAA, left aortic arch; LCC, left common carotid; LSC, left subclavian; PT, pulmonary trunk; RAA, right aortic arch; RCC, right common carotid; RSA, right subclavian artery; T, trachea. (Courtesy of Diane Spicer from the F.S. Idriss Registry, Children's Memorial Hospital, Chicago, IL.)

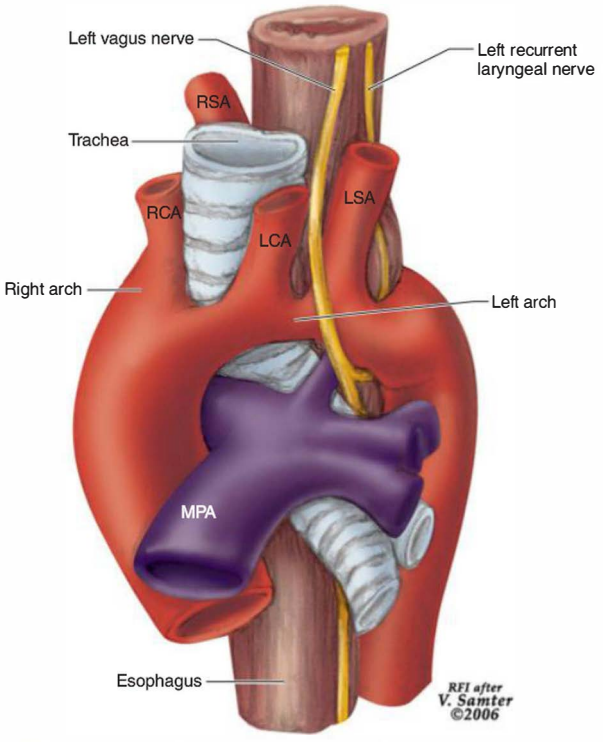

**FIGURE 84-3** Double aortic arch. This is an illustration of a dominant right arch with a smaller but patent left arch with separate origins of the right and left carotid and subclavian arteries. (RCA, right carotid artery, RSA, right subclavian artery, LCA, left carotid artery, LSA, left subclavian artery, MPA, main pulmonary artery.) (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery.* Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

## RIGHT AORTIC ARCH WITH LEFT LIGAMENTUM

A right aortic arch (RAA) occurs when the left fourth arch involutes and the right fourth arch persists. The two anatomic types of right aortic arch are classified based on the branching pattern of the arch vessel as: retroesophageal left subclavian artery (Fig. 84-4) and mirror-image branching (left brachiocephalic artery) (Fig. 84-5).[12] In our series this distribution was 66 percent retroesophageal left subclavian artery and 34 percent mirror-image branching.[11] A complete vascular ring occurs when the ligamentum arteriosum connects the descending thoracic aorta to the PA. The vascular ring configuration includes the right aortic arch, the PA, and the ligamentum. In the patient with a retroesophageal left subclavian artery, the ligamentum arteriosum nearly always comes from the descending aorta, completing the vascular ring. In the patient with mirror-image branching, the ligamentum arteriosum may arise either from the descending thoracic aorta or the anterior left brachiocephalic artery. If the ligamentum arises from the left brachiocephalic artery a vascular ring is not formed (Fig. 84-6). This is the common situation in patients with tetralogy of Fallot and truncus arteriosus.

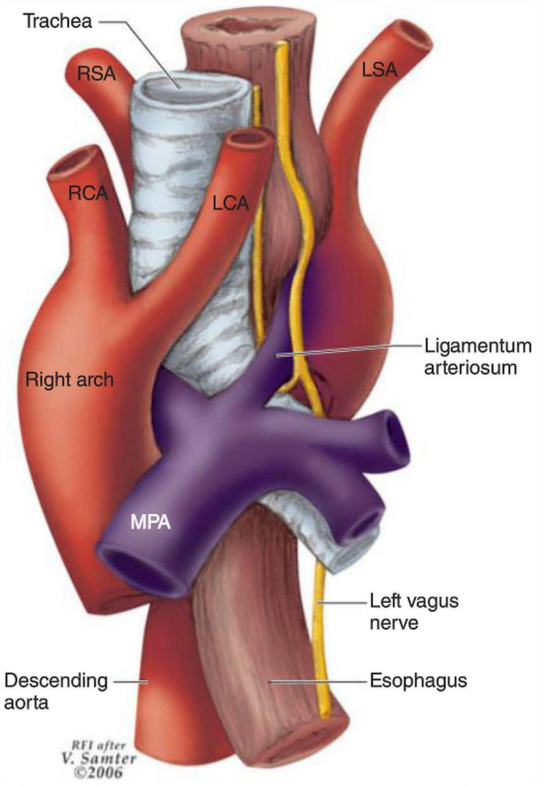

**FIGURE 84-4** Right aortic arch, left ligamentum, retroesophageal left subclavian artery. The vascular ring is formed by the right aortic arch, the main pulmonary artery, and the ligamentum arteriosum (RCA, right carotid artery; RSA, rigth subclavian artery; LCA, left carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery). (From: Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery*. Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

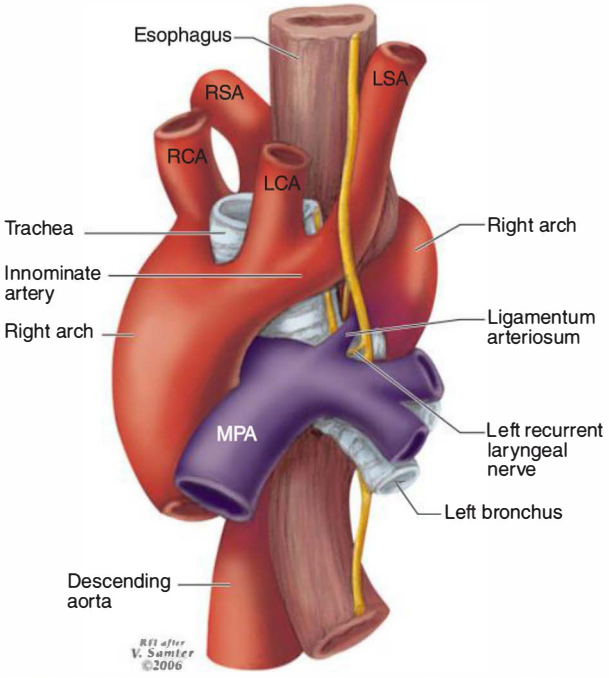

**FIGURE 84-5** Right aortic arch, left ligamentum, mirror-image branching (Note left innominate artery). The vascular ring is formed by the same components as in Figure 84-3, but the left subclavian artery has an anterior origin from the left innominate artery. (RCA, right carotid artery; RSA, right subclavian artery; LCA, left carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery; Innominate A, innominate artery.) (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery*. Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

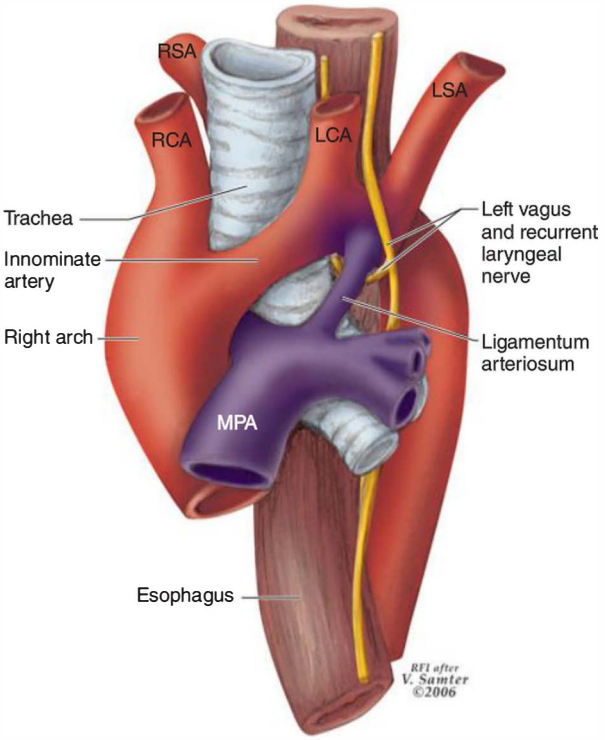
## INNOMINATE ARTERY COMPRESSION

Innominate artery compression results when the anterior trachea is depressed by the innominate artery as it travels from left to right within the superior mediastinum. The exact mechanism that causes the aortic compression in some patients is unknown but may involve a more distal takeoff of the innominate artery from the aorta or a predisposition to tracheomalacia. Figures 84-7–84-9 show by computed tomography (CT) imaging how the tracheal



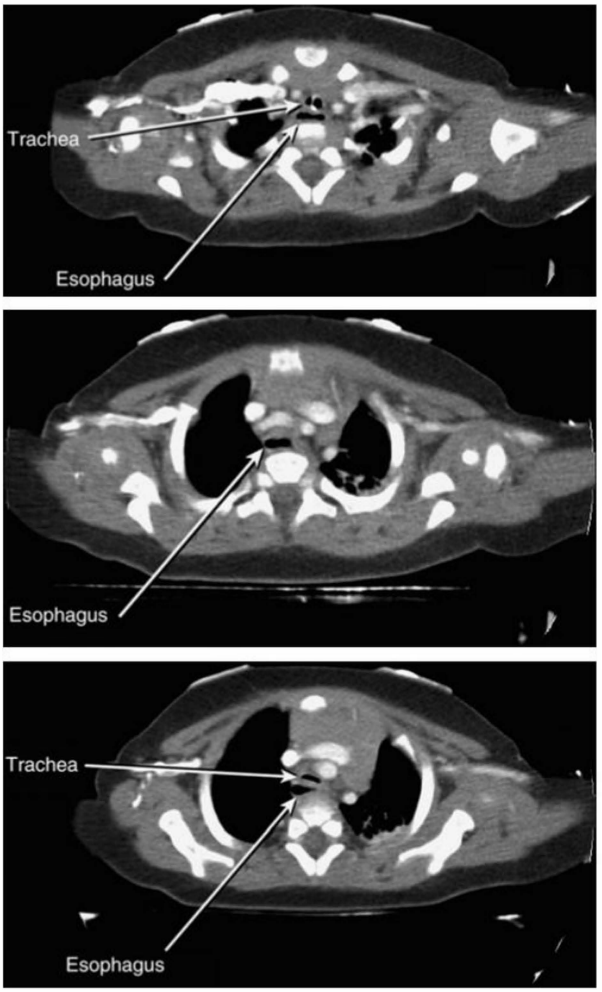


**FIGURE 84-6** Right arch, mirror-image branching with ligamentum from innominate artery. There is a space between the ligamentum and descending aorta and a vascular ring is *not* formed. (RCA, right carotid artery; RSA, right subclavian artery; LCA, left carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery; Innominate A, Innominate artery.) (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery.* Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

**FIGURES 84-7–84-9** Innominate Artery Compression Syndrome. Serial CT cuts in a 5-month-old infant with severe stridor. The tracheal lumen completely disappears in the second of the three images. By bronchoscopy the lumen was nearly occluded. The child responded very well to innominate arteriopexy. (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery.* Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

lumen can be compressed in a 5-month old with severe stridor from innominate artery compression syndrome.

## PULMONARY ARTERY SLING

PAS occurs when two embryologic abnormalities coexist at the same time. The left PA originates from the right sixth arch instead of the left sixth arch and the course of the left PA is posterior rather than anterior to the maturing tracheobronchial tree. The anatomic result is that the left PA originates from the posterior aspect of the right PA and not from the main PA (Fig. 84-10). The left PA then courses posteriorly over the right main stem bronchus and then between the trachea and esophagus which results in a sling compressing the right main stem bronchus and the posterior distal trachea. The ductus or ligamentum originates from the usual site on the main PA and connects to the aorta. A true vascular ring does not exist but the "sling" causes significant symptomatic compression. There is a strong association between PAS and complete cartilage tracheal rings causing tracheal stenosis.[13]

## ABERRANT RIGHT SUBCLAVIAN ARTERY WITH A LEFT AORTIC ARCH

This lesion is not a true vascular ring but is the most common vascular arch anomaly, occurring in 0.5 percent of all humans (Fig. 84-11).[7,14] In this anomaly the aortic arch and descending thoracic aorta are left-sided, and there is no right brachiocephalic artery present. The right subclavian artery

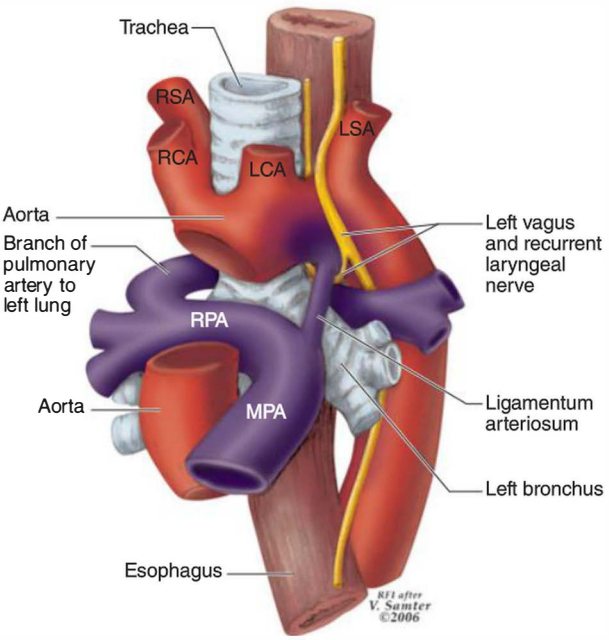

**FIGURE 84-10** Pulmonary artery sling. The aorta has been cut away to visualize the right pulmonary artery and the anomalous origin of the left pulmonary artery from the rigth pulmonary artery. The left pulmonary artery courses posterior to the trachea, anterior to the esophagus, and anterior to the descending thoracic aorta on its way to the left lung. (RCA, right carotid artery; RSA, right subclavian artery; RPA, right pulmonary artery; LCA, left carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery; Innominate A = Innominate artery.) (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery.* Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

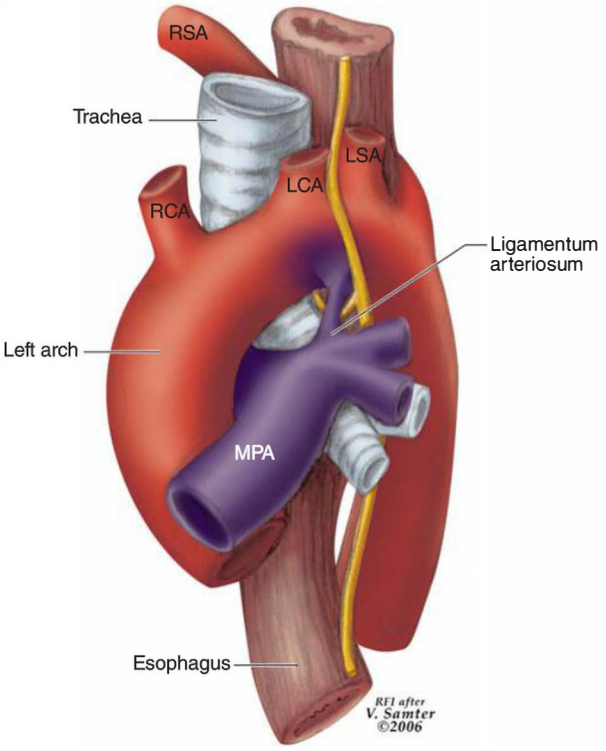

**FIGURE 84-11** Aberrant right subclavian artery. This illustration is a right subclavian artery originating from the descending thoracic aorta distal to the take-off of the left subclavian artery. This artery courses in the posterior mediastinum posterior to the esophagus as it travels to the rigth arm. (RCA, right carotid artery; RSA, rigth subclavian artery; LCA, left carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery.) (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery*. Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

arises independently from the descending thoracic aorta and traverses the mediastinum posterior to the esophagus en route to the right arm. This lesion in fact rarely (if ever) causes symptoms and surgical intervention for these patients is uncommon.[15] We have not operated on a patient with this diagnosis since 1973. What frequently occurs is that, during the evaluation of a patient with swallowing symptoms, an aberrant right subclavian artery is discovered and mistakenly considered as the etiology of the swallowing symptoms. That is why this is referred to as "dysphagia lusoria" which refers to difficulty in swallowing due to a "trick of nature."[15] The aberrant right subclavian artery and swallowing difficulties are "true, true, and unrelated." The exception to the usual recommendation of no surgical intervention is the older patient with aneurysmal dilation of the origin of the right subclavian artery, a Kommerell diverticulum.[16] These patients may indeed require Kommerell diverticulum resection and right subclavian artery reimplantation, usually in the older adult patient.[17]

## RARE VASCULAR RINGS

Since many embryonic variants may exist, there are numerous rare vascular ring anomalies that have been reported.[18–22] One rare vascular ring is created by a left aortic arch, right descending thoracic aorta, and a right ligamentum arteriousum.[21] A second rare vascular ring involves a right aortic arch, right ligamentum, and an absent left PA.[18] Another rare vascular ring is a circumflex aorta that consists of a right aortic arch, a left-sided descending thoracic aorta, and left ligamentum arteriosum.[22] In this lesion the problem is posterior compression of the trachea by the aorta crossing from right to left above the carina.

## ASSOCIATED ANOMALIES

The most commonly associated lesion in patients with vascular rings is congenital heart disease, occurring in 12 percent of patients with vascular rings.[11] The most common cardiac

lesions are ventricular septal defect and tetralogy of Fallot. The most commonly associated chromosomal abnormality is 22q.11 deletion, which occurs in 15 to 20 percent of patients with associated cardiac defects.[23] These additional anomalies can impact the operative strategy, the postoperative recovery period, and the long-term outcome for these patients.

## CLINICAL SYMPTOMS

The severity of symptoms from a vascular ring are directly correlated with the degree of compression of the trachea and esophagus. Clinical symptoms vary with the age of the patient. Symptoms in neonates primarily derive from tracheal compression, while dysphagia occurs later in life when the child is transitioning to solid food. The common symptoms from tracheal compression are a barky cough, stridor, wheezing, recurrent respiratory infections, respiratory distress, and apnea.[11] Patients with a DAA present earlier in life than patients with a right aortic arch because they have a tighter ring. Patients with innominate artery compression syndrome typically present in the first 3 to 6 months of life. PAS can present from newborn to adult, but most commonly in the first year of life. Since vascular rings are such a rare condition, patients are often initially misdiagnosed with more common etiologies of respiratory illnesses, such as asthma, croup, and reflux. The diagnosis is dependent on the clinician having a high index of suspicion.

As the infant transitions from liquids to solids, poor feeding may result with episodes of choking from compression of the esophagus. Other patients go for many years without swallowing issues despite severe compression and finally present for unknown reasons as adults. Each of the different vascular rings can cause certain symptoms due to their anatomical compression of the trachea or esophagus. For instance, PAS and innominate artery compression syndrome do not cause dysphagia, but can cause apnea.

## DIAGNOSIS

The diagnosis of a vascular ring initially starts with a detailed history and physical examination with careful attention being paid to potential symptoms related to the compression of the esophagus and trachea. A thorough history is sometimes needed to reveal the subtle clinical symptoms that occur with these patients. This is then followed with a diagnostic study to confirm the diagnosis. Possible diagnostic studies employed include: chest x-ray, barium esophagram, bronchoscopy, echocardiogram, CT, and magnetic resonance imaging (MRI). Barium swallow used to be the primary means of diagnosis but is now rarely used. Cardiac catheterization is no longer used as a diagnostic study for patients with vascular rings. Echocardiography is used mostly to rule out other congenital heart anomalies and not to establish a diagnosis of vascular ring, except in the situation of a PAS. The main studies we and others now recommend are either CT or MRI which clearly defines the anatomy of the vascular ring and allows operative planning.[11,24,25]

The first study is the chest x-ray which serves two purposes. First, it rules out other etiologies of respiratory problems such as pneumonia or an aspirated foreign body. Second, the chest x-ray defines the location of the aortic arch. The presence of an aortic "knob" on the right side compressing the lateral wall of the trachea lends strong suspicion to a DAA or right aortic arch. Although the barium esophagram may show indentations in the esophagus from the vascular ring, it does not give a precise diagnosis or surgical roadmap. However, a normal barium esophagram does rule out a DAA or a right aortic arch with a left ligamentum. PAS is the only vascular ring that causes anterior compression of the esophagus on a barium esophagram but this can sometimes be subtle and difficult to recognize. We have essentially abandoned barium esophagram in the diagnosis of vascular rings.[11]

If the suspicion for a vascular ring is high, a CT scan or MRI is the next preferred study. We prefer CT over MRI for several reasons. First, the CT scan using the new multislice, multidetector technology obtains the images in a faster period of time which is very useful in a patient with a compromised airway.[11] The CT scan may take 30 s to obtain in contrast to the MRI scan which may take 30 to 45 min. Small children and infants may find it difficult to stay still for this long which makes it challenging to obtain good images. CT also provides better evaluation of the central airways and lung parenchyma.[24] Lastly, three dimensional (3D) reconstructions from the CT scan images provide a detailed relationship of the vascular rings with the other mediastinal structures, necessary for operative planning.[25]

The CT scan has findings that are specific to each of the individual vascular rings. One typical sign is the "four artery sign" which may be seen on coronal sections superior to the aortic arch (Fig. 84-12). The four arteries are the two dorsal subclavian arteries and the two ventral carotid arteries that are symmetrically spaced around the trachea in a patient with a true complete vascular ring. This arrangement of the four

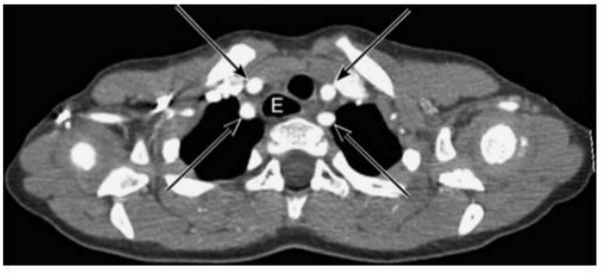

**FIGURE 84-12** "Four-artery" sign. CT scan of a 3-year-old child with a right aortic arch with left ligamentum. Note the four brachiocephalic vessels grouped symmetrically around the trachea. Also note the dilated proximal esophagus (E). (From Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: Vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds). *Pearson's Thoracic and Esophageal Surgery*. Philadelphia: Churchill Livingstone Elsevier, 2008:242–255.)

Lurie Children's Hospital of Chicago, Chicago, IL.)

arteries is seen in both DAA and in right aortic arch with a left ligamentum and retroesophageal left subclavian artery. The breakthrough from a surgical standpoint in imaging is the 3D reconstruction possible with CT and MRI. Examples are shown in Figures 84-13 and 84-14. The exquisite detail provided leaves little doubt about the most effective surgical approach and management. In patients with innominate artery compression syndrome, CT demonstrates anterior compression of the trachea (Figs. 84-7, 84-8, and 84-9). In patients with a PAS, CT shows the anatomic origin of the left PA from the right PA and its course between the trachea and esophagus (Figs. 84-15 and 84-16). It is also very useful to evaluate the trachea in these patients. One limitation of the CT scan and MRI is the inability to detect the ligamentum segment or nonpatent atretic arches. We recommend intraoperative bronchoscopy for all vascular ring patients. It confirms the presence or absence of tracheomalacia, bronchomalacia, complete tracheal rings, foreign bodies, and tracheal anomalies. These additional tracheal findings are important for surgical management and prognosis.

## SURGICAL APPROACHES

When patients develop clinical symptoms, surgical intervention is nearly always required, as medical treatment has no role in the treatment of these anomalies (see Fig. 84-25). Furthermore, unrepaired patients with vascular ring symptoms may develop severe upper respiratory infections and pneumonia requiring prolonged intubation. Adverse complications reported in unoperated patients include erosion of the esophagus into the tracheobronchial tree or aorta and aortic dissection.[26,27] The longer a symptomatic patient lives with an unoperated vascular ring, the more likely they will have a longer recovery related to more severe tracheobronchomalacia.

The more difficult situation is when the patient has a diagnosis of vascular ring made serendipitously when they have a scan for reasons unrelated to vascular ring symptoms. In these patients, careful, directed questioning may elicit symptoms that lead to a recommendation for surgery. In our experience all patients with a DAA and PAS have had symptoms and undergone repair. In contrast we have seen a number of patients with innominate artery compression

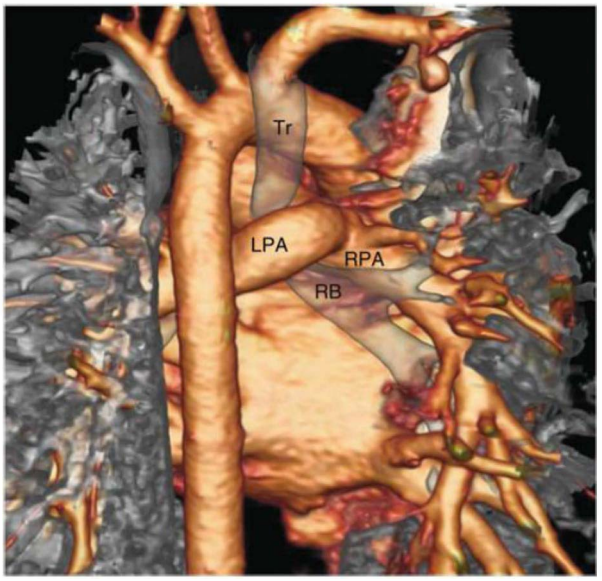

**FIGURE 84-15** Pulmonary artery sling. CTA Chest: 3D Reconstruction. The left pulmonary artery arises from the right pulmonary artery, courses over the right main bronchus, and then posterior to the trachea en route to the left lung. Lurie Children's Hospital of Chicago, Chicago, IL.)

syndrome and right arch and left ligamentum with no symptoms or very mild symptoms and we are carefully following them without an operation.

## SURGICAL PRINCIPLES

When approaching a patient with a vascular ring, several operative principles are used. First, we believe the preoperative CT scan is very important in determining the operative strategy, including the approach of either a left or right thoracotomy or midline sternotomy. Second, vascular clamps and fine prolene sutures are used to divide the vascular structures in order to avoid potential complications of crushing the vessel causing delayed hemorrhage. A third principle is that of not closing the pleura over the repair since adhesions in the area of the divided vascular ring can cause recurrent symptoms. Lastly, careful and adequate monitoring should be part of the routine, intraoperative practice. An arterial line is not usually required, but blood pressure cuff monitoring in upper and lower extremities is recommended. Pulse oximetry waveform on multiple extremities is a very helpful part of the monitoring process.

## DOUBLE AORTIC ARCH

The usual surgical approach for DAA repair is that of a thoracotomy opposite the location of the dominant aortic arch. For example, in a patient with a dominant right aortic arch (75 percent of patients), a left thoracotomy is the preferred approach and the smaller left arch is divided. In patients with a dominant left aortic arch, we prefer a right thoracotomy and the smaller right arch is divided. We would approach patients with balanced aortic arches and a left descending aorta through a left thoracotomy. In these particular patients we would recommend upper and lower extremity arterial line monitoring. A median sternotomy is used only when coexisting cardiac anomalies require repair.

The left thoracotomy is performed with a muscle-sparing technique through the fourth intercostal space. The lung is retracted anteriorly and the supreme intercostal vein is ligated and divided. The mediastinal pleura covering the aorta is incised superiorly and inferiorly while not extending anteriorly which may injure the vagus nerve, or posteriorly where the thoracic duct may be injured. The vascular ring is defined by first identifying the left subclavian artery and then determining the location of the posterior and anterior arches. The descending aorta is then dissected, but it may not be visible in situations where there is a right-sided descending aorta. In these cases the esophagus is prominently displayed. The ligamentum should also be identified. In the majority of cases, the left or anterior aortic arch is the smaller arch and is most commonly divided at the insertion to the descending aorta. In 34 percent of our cases, the left arch was atretic where it inserts into the descending aorta. This atretic area is an excellent site for arch division. Before dividing the

vascular structure, a test occlusion is performed to confirm no changes in the right or left upper extremity and carotid pulses. We then doubly clamp the arch between Potts ductus clamps, divide the arch, and the stumps are oversewn with two layers of running 5-0 or 6-0 polypropylene suture (Fig. 84-17A–C). In addition, the left ligamentum should also be divided. This prevents conversion of a DAA to a right aortic arch with left ligamentum. Once the arch is divided, any adhesive bands overlying the esophagus are divided. The left recurrent laryngeal nerve usually encircles the ligamentum arteriosum, and is carefully identified and avoided. The mediastinal pleura is left open to prevent adhesion formation. We do not routinely place chest tubes, but evacuate air in the thorax with a small suction catheter passed through the corner of the incision. Nearly all patients with a DAA can be extubated in the operating room and then admitted to the intensive care unit overnight. The next day the patient is usually transferred to the floor and they are often discharged home on the third day. In most patients the symptoms initially improve dramatically after surgery, but complete resolution of respiratory symptoms may take up to one year. It is helpful to inform parents of this preoperatively.

## RIGHT AORTIC ARCH WITH LEFT LIGAMENTUM

We approach these patients through a left thoracotomy. The only exception would involve associated cardiac anomalies that need simultaneous correction where median sternotomy is the preferred approach. In the unusual patient with situs inversus who has a left aortic arch with a right ligamentum;

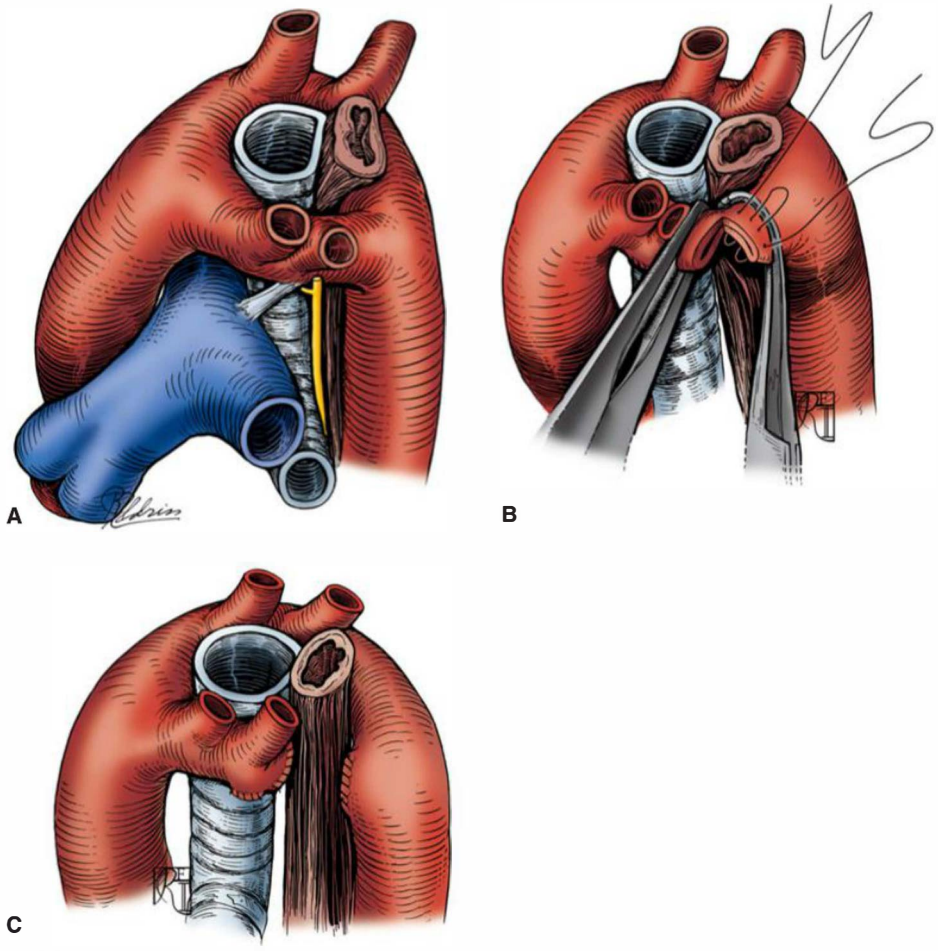

**FIGURE 84-17** Double aortic arch division. **A.** Double aortic arch, right arch dominant. The approach is via left thoracotomy. **B.** The left arch has been occluded proximally and distally with vascular clamps and partially divided. The stumps are oversewn with two layers of running Prolene suture. **C.** Left arch divided. The ligamentum has also been divided and oversewn. Ao, Aorta; L, left; LCCA, left carotid artery; RCCA, right carotid artery; LSA, left subclavian artery; RSA, right subclavian artery; PA, pulmonary artery; R, right. (Reprinted with permission from Backer CL, Mavroudis C. Vascular rings and pulmonary artery sling. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery*, 3rd ed. 2003:234–250.)

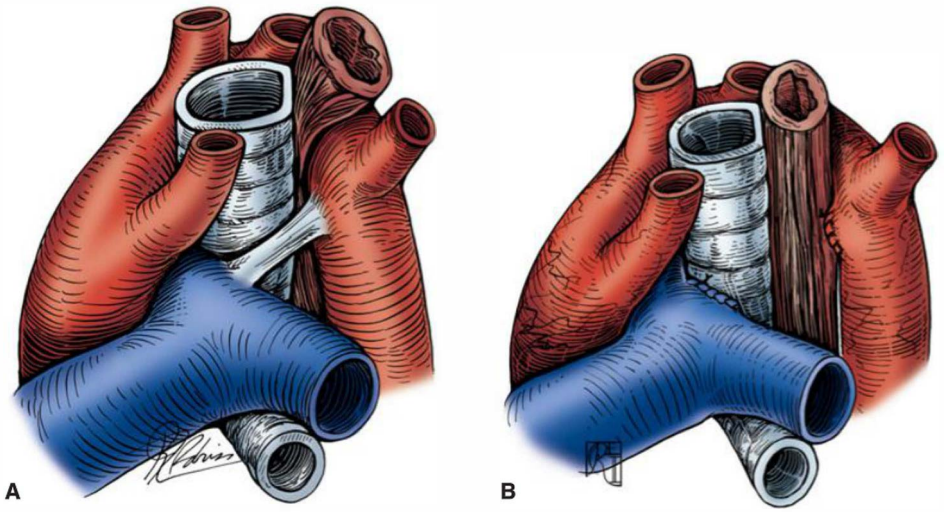

**FIGURE 84-18** Right aortic arch—division and oversewing of ligamentum arteriosum. **A.** Ligamentum completes the vascular ring. **B.** Ligamentum divided and oversewn. Ao, Aorta; LCCA, left common carotid artery; RCCA, right common carotid artery; LSA, left subclavian artery; RSA, right subclavian artery; MPA, main pulmonary artery. (Reprinted with permission from Backer CL, Mavroudis C. Vascular rings and pulmonary artery sling. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery* 3rd ed. 2003:234–250.)

a right thoracotomy is the preferred approach. The chest is entered with a muscle-sparing fourth intercostal space approach and the pleura covering the aorta is opened. The left subclavian artery arises from the descending aorta next to the origin of the ligamentum arteriosum in 66 percent of the cases. The ligamentum is dissected and doubly clamped with vascular clamps, divided, and the remnants are oversewn with running polypropylene suture (Fig. 84-18A and B). Because the ligamentum has no lumen, another surgical option is to doubly ligate with silk ties and reinforce with polypropylene sutures. The recurrent laryngeal nerve is carefully identified and preserved. Adhesive bands around the esophagus are divided and the pleura is left open. In patients with a preoperative diagnosis of right aortic arch and left ligamentum care must be taken to insure there is not a small atretic left arch connecting from anteriorly—an actual DAA. This can be a cause of residual symptoms after simple ligamentum division, and the atretic arch is not visible on CT or MRI.

An interesting subgroup of patients are those who present with the typical right aortic arch with left ligamentum but have aneurysmal dilation at the base of the retroesophageal left subclavian artery (Fig. 84-19). This is a Kommerell diverticulum which is the embryologic remnant of the left fourth arch.[16] With increasing growth of the aneurysm, the diverticulum may independently compress the esophagus and/or trachea. These patients often have had an initial surgical division of the ligamentum arteriosus but develop recurrence of their symptoms. Through the same left thoracotomy incision, the Kommerell diverticulum is excised, the base is oversewn, and the left subclavian artery is transferred to the left carotid artery (Figs. 84-20 and 84-21).[28] This procedure is also

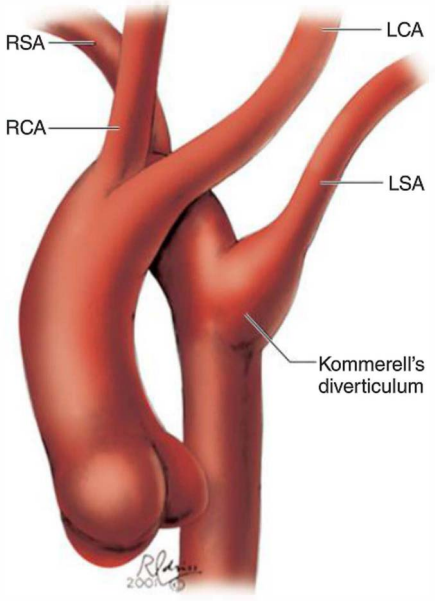

**FIGURE 84-19** Kommerell diverticulum. The origin of the left subclavian artery (LSA) in some patients with a right aortic arch is an aneurysmal embryologic remnant of the left fourth arch. This is called a Kommerell diverticulum. RCA, right carotid artery; RSA, right subclavian artery; LCA, left carotid artery. **FIGURE 84-21** Completed repair. The orifice at which the Kommerell diverticulum was resected is usually closed primarily. The orifice can also be patched with polytetrafluoroethylene if necessary (as shown in the inset). The left subclavian artery has been implanted into the side of the left common carotid artery with fine running polypropylene sutures. LCA, left carotid artery; RCA, right carotid artery; LSA, left subclavian artery; RSA, right subclavian artery. (Reprinted with permission from Backer CL, Hillman N, Mavroudis C, Holinger LD. Resection of Kommerell diverticulum and left subclavian artery transfer for recurrent symptoms after vascular ring division. *Eur J Cardiothorac Surg* 2002;22:64–69.)

preferred as a primary operation in the patients with a right arch, left ligamentum, and large Kommerell diverticulum.

## PULMONARY ARTERY SLING

A median sternotomy with cardiopulmonary bypass support is now the preferred approach for PAS repair.[29] Intraoperative bronchoscopy is critically important in determining the extent of tracheal compression and whether or not complete tracheal rings are present. If airway reconstruction is required, the intracardiac repair is performed first to avoid potential contamination from the tracheal reconstruction. Since 1985, we have used normothermic cardiopulmonary bypass with the heart beating for all PAS patients. The left PA is divided at its origin from the right PA. The right PA opening is closed primarily. The left PA is mobilized under the trachea and brought over to the left side of the mediastinum. It is then pulled anteriorly to the site on the main PA where the ligamentum has usually been divided. An opening is created in the main PA and the left PA is reimplanted at this site (Figs. 84-22 and 84-23). The patient is ventilated and weaned off cardiopulmonary bypass. If the airway requires repair the endotracheal tube is pulled up near the vocal chords. A tracheal resection is performed for a short segment stenosis (<6 rings) and a slide tracheoplasty is performed for long segment tracheal stenosis.[30] The reconstruction of the trachea follows general tracheal surgery principles which include extensive mobilization, preservation of the lateral blood vessels, and tension-free anastomosis. After reconstruction, the endotracheal tube is advanced beyond the site of an anastomosis which is externally marked with surgical clips that will help identify the reconstruction during the postoperative chest x-ray. For patients with unilateral agenesis of the right lung the PA sling can in some cases be repaired by translocation rather than reimplantation.[31,32]

## INNOMINATE ARTERY COMPRESSION

The repair of innominate artery compression syndrome is usually accomplished with suspension of the innominate artery to the sternum through a right anterior minithoracotomy. Through this limited incision, the right lobe of the thymus is excised. The pericardium is opened anterior to the phrenic nerve near the ascending aorta and the innominate artery. The aorta is pexed with three pledgetted permanent sutures, one at the junction of the ascending aorta with the innominate artery, a second on the proximal innominate artery, and a

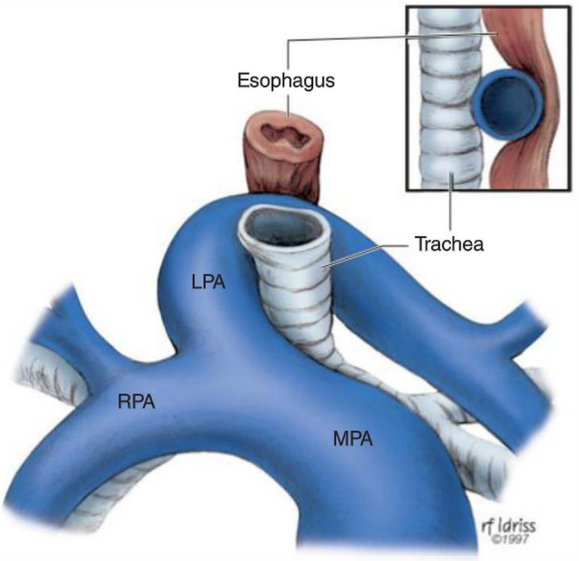

**FIGURE 84-22** Pulmonary artery sling. The left pulmonary artery (LPA) originates from the right pulmonary artery (RPA) and courses between the esophagus and trachea to reach the left lung. third on the ascending aorta (Fig. 84-24). Careful monitoring of the right arm blood pressure and pulse oximetry will prevent stenosis of the right subclavian artery. In addition, guidance by intraoperative bronchoscopy determines the extent of tracheal traction required to relieve the compression.

## VIDEO-ASSISTED TECHNIQUE OF MANAGEMENT OF VASCULAR RING

At some centers, VATS has become the preferred operative approach for selected vascular ring patients.[33,34] After single lung ventilation, the patient is positioned in a right lateral decubitus position. Four thoracostomy working ports are inserted which will admit a camera (usually a 5-mm port), lung retractor, grasping forceps, and cautery probe. The optimal positioning of the ports is dependent on the surgeon's preference but the camera is typically placed at the tip of the scapula and the remaining ports are placed inferiorly and laterally to allow adequate movement of the working ports. Of note, the small child's thoracic cavity makes the relative motion of the instruments more crowded and limited than in an adult. After the lung is retracted, the remaining part of the operation proceeds in the usual fashion as for an open approach, except that clips are used to ligate the vascular ring before the division of the ring is performed. The essential principles of adequate exposure and definition of the vascular ring is critical when working through limited access. The

ideal candidate for this surgical approach is the child with an atretic arch (nonpatent) or a ligamentum. We have not used VATS in our practice, given the risk of catastrophic bleeding from a slipped clip with a patent arch. In addition, the morbidity of a muscle-sparing thoracotomy is quite small.

## TRACHEOBRONCHOMALACIA

A major morbidity intrinsic to many vascular ring patients is dynamic airway collapse due to lack of structural support, termed tracheobronchomalacia. Severe malacia is present in approximately 5 to 10 percent of vascular ring patients. This problem will cause the child to continue to have noisy respiratory symptoms after surgery. The key is to look for steady clinical improvement in the postoperative period and to remember that there is no definite time period for all the symptoms to disappear. However, if the noisy breathing symptoms fail to improve or get worse, then bronchoscopy should be repeated to secure the diagnosis of tracheal or bronchial malacia. The timing of the bronchoscopy is a clinical decision. Some guiding principles for when to perform the bronchoscopy: (1) if after extubation, the patient maintains excessive work of breathing with failure to grow, and

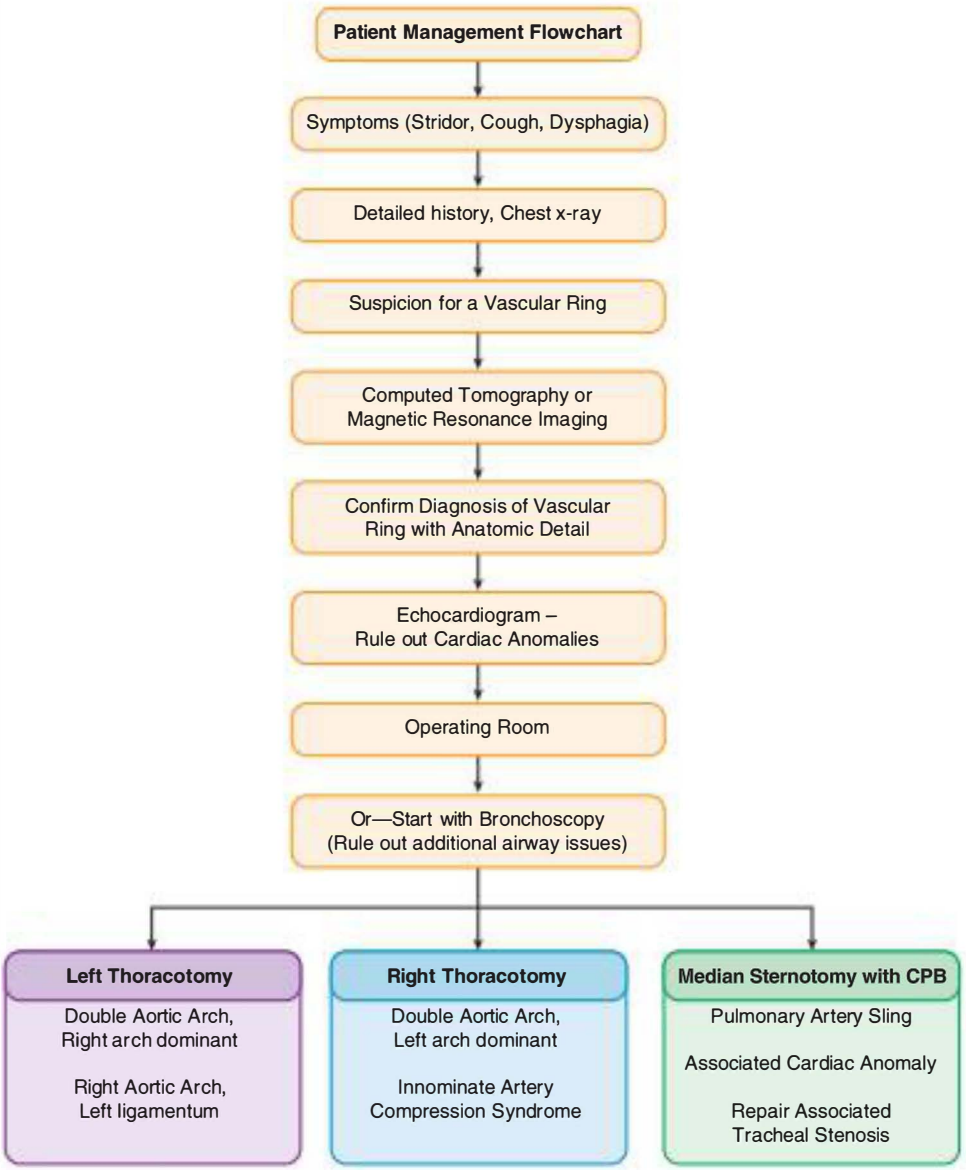

**FIGURE 84-25** Patient management flowchart.

(2) if the respiratory symptoms still persist with no improvement after 2 to 3 weeks postoperatively. A CT or MRI scan may provide additional or confirmatory anatomical detail of the trachea to determine whether a reoperation is warranted.

The management of tracheobronchomalacia appearing postoperatively is not straightforward, and varies from patient to patient. The first step in the management is to confirm with a CT scan that the vascular ring was successfully divided and no residual ring of tissue is present. Conservative management is the initial strategy, with surgical options including aortopexy, tracheostomy, external splinting, and internal stenting. We prefer aortopexy as a means of externally stenting the trachea, but in rare patients tracheostomy may be required to provide the necessary positive pressure support. Intramural stenting with thin-walled silicon stents or self-expandable metallic stents are additional options, although these stents are not ideal and have their own limitations, including mucus plugging, stent migration, and intrastent granulation tissue formation.[35] Furthermore, stents do not provide a permanent solution, as all stents need eventual removal. In summary, the management of tracheobronchomalacia is a rare but difficult postoperative morbidity that is usually treated conservatively.

## OUTCOMES

The overall outcome of patients with surgically treated vascular rings is extremely favorable. We reported our experience with 209 infants and children with vascular rings reported from 1946 to 2003.[11] No hospital deaths occurred after 1959. The primary preoperative study used for diagnosis has shifted from barium swallow to CT scan as the current practice. All patients in our practice undergo preoperative echocardiogram and pre- or intraoperative bronchoscopy. During this period, the mean hospital length of stay decreased to three days. Only four patients (2 percent) had persistent malacia that required aortopexy between 2 months and 4 years postoperatively. The results in patients with pulmonary sling are also quite good. We reported 16 patients operated on through a midline sternotomy using cardiopulmonary bypass in 1999.[29] No operative deaths were reported; however, one patient died from long term complications of tracheal surgery. We now have 34 patients who have undergone PAS repair using cardiopulmonary bypass and no operative mortality. Patients with vascular rings require a high index of suspicion to come to the diagnosis, but once the diagnosis is established, surgical repair can be accomplished with very low morbidity and essentially no mortality (Fig. 84-25).

## VASCULAR RINGS AND PULMONARY ARTERY SLING BOARD REVIEW QUESTIONS (CHAPTER 84)

1. Which of the following is an incomplete ring?
   A. Double aortic arch, right dominant
   B. Right arch with retroesophageal left subclavian artery
   C. Right arch with mirror imaging branching
   D. Double aortic arch, left dominant
   E. Left arch with aberrant right subclavian artery

2. Which is correct regarding clinical presentation and diagnosis of vascular anomalies?
   A. Neonates usually present with esophageal compression.
   B. Patients with a double aortic arch present later in life.
   C. Pulmonary artery sling usually presents during the first year of life.
   D. The "four artery sign" is seen in innominate artery compression.
   E. MRI easily detects the ligamentous segment.

3. Which is correct regarding operative technique for vascular anomalies?
   A. The usual approach for double aortic arch repair is on the same side as the dominant arch.
   B. A balanced double arch and left descending aorta should be approached through a right thoracotomy.
   C. A left thoracotomy is preferred for the patient with situs inversus and a left arch with a right ligamentum.
   D. For repair of a Kommerell diverticulum and vascular ring, the left subclavian artery should be transferred to the left carotid artery.
   E. Circulatory arrest is the preferred strategy for pulmonary artery sling.

4. Which of the following would not be a suitable solution for a patient with tracheobronchial malacia?
   A. Internal stenting
   B. Aortopexy
   C. External splinting
   D. Tracheal resection
   E. Tracheostomy

5. Which of the following is true for outcomes after surgery for vascular anomalies?
   A. Mean length of stay is 5 days.
   B. Surgery for tracheobronchial malacia is required in 5 to 10 percent of patients.
   C. Mortality for repair of pulmonary artery sling is zero.
   D. 10 to 20 percent of patients with vascular rings have severe tracheobronchial malacia.
   E. Video-assisted techniques are ideally suited for the patient with a double aortic arch.

## ANSWERS

1. **Answer: E.** A left aortic arch with an aberrant right subclavian artery does not form a complete vascular ring. Double aortic arch forms a complete vascular ring, as does a right arch with a ligamentum arteriosum.
2. **Answer: C.** Pulmonary artery sling usually presents during the first year of life. Neonates usually present with tracheal compression. Patients with double aortic arch usually present early in life and the "four artery sign" on CT is typical. MRI is unable to detect the ligamentous segment or nonpatent atretic arches.
3. **Answer: D.** A Kommerell diverticulum and vascular ring is repaired by translocating the left subclavian artery to the left carotid artery. The usual approach for a double aortic arch is on the opposite side from the dominant arch. A balanced double arch and left descending aorta should be approached through a left thoracotomy. A right thoracotomy is preferred for the patient with situs inversus and a left arch with a right ligamentum. Circulatory arrest is typically not required for repair of pulmonary artery sling.
4. **Answer: D.** Aortopexy, internal stenting, external splinting, and tracheostomy are all suitable options for the treatment of a patient with tracheobronchial malacia that is resistant to conservative therapy. Tracheal resection is not indicated.
5. **Answer: C.** Current surgical mortality for repair of pulmonary artery sling is zero. Mean length of stay is approximately 3 days, and surgery for tracheobronchial malacia is required in less than 5 percent of patients. Severe tracheobronchial malacia is present in 5 to 10 percent of vascular ring patients. Video-assisted techniques are best reserved for patients with nonpatent/atretic archs or ligamenta.

# Ebstein's Anomaly

*Viktor Hraška*
*Boulos Asfour*
*Joachim Photiadis*

## KEY CONCEPTS

- Epidemiology
  - Ebstein's anomaly occurs in 1 percent of all congenital heart defects and represents 0.3 to 0.8 percent of all cardiac malformations diagnosed during the first year of life.
- Pathophysiology
  - The degree of displacement and morphology of the tricuspid leaflets determine the degree of regurgitation. The attachments of the anterior leaflet to the right ventricular outflow tract may inhibit normal flow to the pulmonary artery, thus creating various degrees of outflow tract obstruction or functional/anatomical pulmonary atresia with duct-dependent pulmonary circulation. Diminishing forward output, with increasing backflow to the right atrium, leads to severe cyanosis due to right-to-left shunting at the atrial level. Right ventricular dilation can induce leftward bulging of the interventricular septum, thus compromising left ventricular function. Progressive cardiomegaly can affect the growth of the lungs, inducing lung hypoplasia.
- Clinical features
  - Clinical presentation can occur at any age. Newborns will often manifest cyanosis and congestive heart failure, accompanied by circulatory collapse. After infancy, the child may show limited cyanosis during exercise. With increasing age arrhythmias, cyanosis and limited exercise tolerance (with dyspnea and palpitations) become more prominent. Mild forms may not be symptomatic until adulthood.
- Diagnostics
  - Echocardiography is diagnostic. Cardiac catheterization is not routinely performed, unless the pulmonary artery pressure and vascular resistance require evaluation.
- Treatment
  - In neonates and young infants, the indications for surgery are ventilator dependence, severe cardiac failure, and severe tricuspid insufficiency with prostaglandin-dependent circulation.
  - In older patients, surgery is indicated due to symptoms of poor growth, decreased exercise tolerance, cyanosis, progressive cardiomegaly (cardiothoracic ratio >0.6), reduced left ventricular function, tachyarrhythmias, and the presence of significant associated lesions. Timely operation is warranted before cardiomegaly develops and the functional status deteriorates.
  - Surgical therapy should restore tricuspid valve competence and address the inadequacy of the inefficient right ventricle. In children, tricuspid valve plasty with biventricular correction should take preference over tricuspid valve replacement or single ventricle pathway. Surgical repair consists of (1) reconstruction of the tricuspid valve, (2) consideration of plication or resection of the atrialized right ventricle, (3) closure of the atrial communication and correction of any associated anomalies, (4) arrhythmia surgery, and (5) right reduction atrioplasty. In special situations, the concept of one and one-half ventricular repair or of the single ventricular pathway should be adopted.
- Outcomes/prognosis
  - With current surgical techniques, repair is feasible in the vast majority of patients and results in low early mortality (<5 percent); reintervention rate and survival is of >80 percent at 20 years. Newborns and small infants remain, however, still a challenge.

## INTRODUCTION

Ebstein's anomaly is a rare congenital heart malformation of the right ventricle and tricuspid valve. Failure of delamination of the tricuspid valve, especially of the posterior and septal leaflets from the underlying myocardium, results in variable degree of tricuspid valve and right ventricular deformity as first described by Wilhelm Ebstein,[1] a German pathologist.

The natural history of this malformation is influenced by a high rate of intrauterine and neonatal death, especially when the anomaly is associated with severe deformity of the tricuspid valve and cyanosis. At the other end of the spectrum, patients with mild dysfunction of the tricuspid valve may remain asymptomatic until late adult life.[2,3] Management, therefore, often requires a choice between a conservative approach and operative intervention. Currently available surgical techniques have demonstrated survival and functional benefit even for those patients in whom the malformation is severe.[4–7]

## DEFINITION AND MORPHOLOGICAL FEATURES

Ebstein's anomaly occurs relatively late in heart development, as the inner surfaces of the right atrium and ventricle are undermined distal to the atrioventricular sulcus. The anterior leaflet is formed earlier than the posterior and septal leaflets, during the third and fourth month of gestation, which may explain the differences in maturation.

The anomaly is characterized by the following (Fig. 85-1):

1. Tricuspid valve malformations
   a. The septal and posterior leaflets are displaced toward the apex of the right ventricle with a variable degree of adherence to the myocardium (spiral failure of delamination).
   b. The sail-like, redundant anterior leaflet has a normal attachment to the tricuspid valve annulus, but is frequently fenestrated, having chordal attachments to the ventricular wall and eventually also linear attachments (fibrous and muscular attachments) between the leaflet and the myocardium.
2. The right ventricle is malformed and consists of
   a. A thin-walled "atrialized" component, defined as a segment of the right ventricle, from the level of the "true" tricuspid annulus to the level of displacement of the septal and posterior leaflets;
   b. A thick-walled functional component ("true right ventricle cavity"), consisting of apical and outlet portions, often obstructed by chordal attachments of the anterior leaflet of the tricuspid valve. The inlet portion is small or nonexistent. The cavity of the functional right ventricle is usually smaller and, histologically contains fewer myocytes and more fibrous tissue than a normal right ventricle.

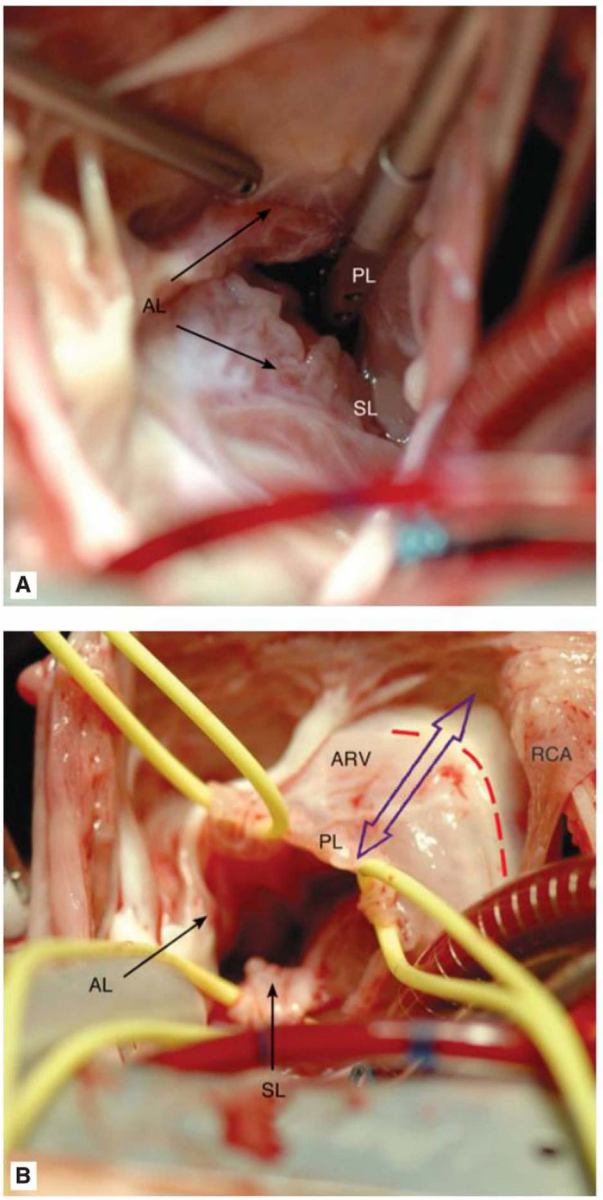

**FIGURE 85-1** Ebstein's anomaly in a 6-month-old patient. **A.** Note the severe displacement of the posterior and septal leaflets. **B.** Vessel loops surround the fibrous and muscular attachments of the leading edges of the leaflet to the underlying myocardium. Note the atrialized portion of the right ventricle and position of the right coronary artery. RCA, right coronary artery; AL, anterior leaflet; PL, posterior leaflet; SL, septal leaflet; ARV, atrialized right ventricle.

The most commonly associated anomaly is an atrial septal defect or persistent foramen ovale (in about 90 percent of the cases). Survival in symptomatic newborns with severe obstruction to pulmonary outflow depends on the presence of a patent ductus arteriosus in addition to atrial-level communication. The Wolff–Parkinson–White syndrome is

present in about 10 percent of the cases. Association with an atrioventricular septal defect, ventricular septal defect, tetralogy of Fallot, congenitally corrected transposition of the great arteries, aortic coarctation or other defects is rarely observed.

## ETIOLOGY

The majority of cases of Ebstein's anomaly are sporadic, but familial cases have been reported. Gestational exposure to lithium increases the relative risk of any malformation, including cardiac anomalies, by two to three times.

## PATHOPHYSIOLOGY

### Tricuspid Valve

The degree of displacement, hypoplasia, and tethering of the leaflets, as well as existing fenestrations and the dilation of the right atrioventricular junction, determine the degree of regurgitation. The large anterior leaflet with the linear attachments may divide the inlet from the muscular portion, mimicking tricuspid stenosis or even tricuspid atresia if there are no leaflet fenestrations. Attachments of the anterior leaflet to the right ventricular outflow tract can also inhibit the normal flow to the pulmonary artery, inducing the development of pulmonary atresia in about 10 percent of infants.

### Right Ventricle

The two parts of the right ventricle show a specific movement pattern affecting forward flow. During atrial systole, the atrialized component balloons out, which may significantly reduce forward flow into the functional component of the right ventricle. During ventricular systole, the atrialized component of the right ventricle contracts, pushing the blood backward to the right atrium, resulting in an increase in systemic venous pressure and subsequent right atrial dilatation, even in the absence of significant tricuspid valve regurgitation.

### Left Ventricle

Right ventricular dilation can induce the interventricular septum to bulge toward the left and thus significantly compromise left ventricular function (ventricular interdependence).

### Postnatal Hemodynamics

Depending on the severity of Ebstein's anomaly and the associated heart defects, postnatal hemodynamics can be extremely variable.

#### MILD DISPLACEMENT OF THE TRICUSPID VALVE

With mild displacement of the posterior and septal leaflets of the tricuspid valve and good function of the right ventricle, postnatal circulation will be normal, with only mild tricuspid regurgitation and sufficient antegrade pulmonary blood flow.

#### MODERATE DISPLACEMENT OF THE TRICUSPID VALVE

A higher degree of displacement results in a higher grade of tricuspid regurgitation, enhanced by the postnatally high pulmonary vascular resistance. Elevated right atrial pressure promotes right-to-left shunting on an atrial level with a variable degree of cyanosis, depending on the ductal flow. If the pulmonary outflow tract is patent, ductal flow increases the right ventricle afterload and has a negative impact on tricuspid valve function. Clinically tolerable closure of the duct with sufficient antegrade pulmonary blood flow is a positive prognostic factor in infants.[8] In the case of pulmonary atresia, the duct may be the only source of pulmonary blood flow.

#### SEVERE DISPLACEMENT OF THE TRICUSPID VALVE

Severe displacement of the posterior and septal leaflets results in severe tricuspid regurgitation and a large atrialized component of the right ventricle. If the duct is open, the right ventricle is usually not capable of opening the pulmonary valve, mimicking pulmonary atresia. Systemic venous return is shunted to the left ventricle across the atrial septal defect, and the resulting physiology is similar to that of tricuspid or pulmonary atresia.

### Hemodynamics Beyond Infancy

Children with minor tricuspid regurgitation and a functioning right ventricle come to clinical attention because of associated lesions. Volume overload of the right ventricle, due to a left-to-right shunt at the atrial level, might accelerate the development of important tricuspid regurgitation. With more prominent tricuspid regurgitation, cyanosis may occur on exertion, unmasking the limited capability to augment right ventricular output.

### Arrhythmias

Arrhythmias occur in 20 to 30 percent of all patients. Deficient fibrous development of the tricuspid valve annulus, with accessory muscular pathways across the atrioventricular junction, results in a high incidence of preexcitation (Wolf–Parkinson–White syndrome). A stretched, fibrotic and dysplastic right ventricular myocardium is a substrate for ventricular arrhythmias. Incomplete fibrous encasement

of the atrioventricular node and the bundle of His can cause reentry tachycardias. Rapid conduction of atrial arrhythmias or ventricular tachycardias accounts for 3 to 10 percent of sudden death.

## CLINICAL FEATURES

Patients may present at any age. Prenatally, the fetus may suffer from tachyarrhythmia, pulmonary parenchymal hypoplasia secondary to cardiomegaly, or hydrops. Newborns and young infants often present with cyanosis, tachypnea, enlarged liver, and other symptoms of cardiac failure. Neonates disclosing the most extreme forms of this anomaly will become critically ill immediately after birth, requiring intensive medical treatment and ventilatory support. Beyond infancy, the child may show limited cyanosis during exercise, but there is rarely failure to grow and development of congestive heart failure with cardiomegaly. With increasing age, cyanosis and limited exercise tolerance, with dyspnea and palpitations, will become more prominent. The dominant mode of clinical presentation in adolescents and young adults is arrhythmia and limited exercise tolerance. Mild forms of Ebstein's anomaly may not become symptomatic until adulthood.[3]

## DIAGNOSTIC MODALITIES

### Physical Examination

Prominence or asymmetry of the chest is linked to the dilated right heart. Cyanosis and digital clubbing are secondary to a chronic right-to-left shunt. Multiple abnormal sounds and murmurs are evident on cardiac auscultation. The first and the second heart sounds are widely split due to increased excursion of the anterosuperior leaflet, the delayed closure of the abnormal tricuspid valve, and the late closure of the pulmonary valve secondary to right bundle branch block. A systolic murmur usually suggests either some associated cardiac anomaly or tricuspid regurgitation.

#### CHEST X-RAY

Variable cardiomegaly, secondary to enlargement of the right atrium, is typical. Pulmonary vascular markings are normal or diminished, according to the degree of right ventricular outflow tract obstruction (Fig. 85-2).

#### ELECTROCARDIOGRAM

Characteristically, the ECG is abnormal, presenting with a right bundle branch block and prominent P-waves that reflect the enlargement of the right atrium. The P-R interval may be prolonged up to a first degree of AV block, and the occurrence of the Wolff-Parkinson-White syndrome is not infrequent. Atrial rhythm problems such as atrial fibrillation, atrioventricular nodal reentry tachycardia, focal atrial tachycardia, and atrial flutter are common in older patients. Holter monitoring should therefore be performed repeatedly, especially in the symptomatic patient.

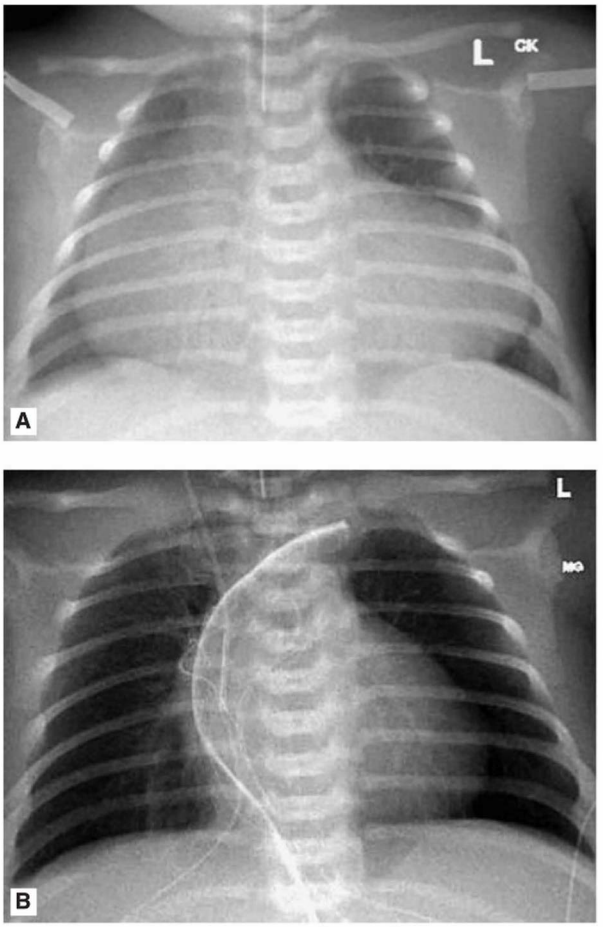

**FIGURE 85-2** Ebstein's anomaly. Chest x-ray of newborn before (**A**) and after corrective surgery (**B**).

#### ECHOCARDIOGRAPHY

Echocardiography is diagnostic, not only for outlining the morphology and physiology, but also for assessing the suitability for reconstructive surgery (Fig. 85-3). The evaluation should clarify:

1. The morphology of the tricuspid valve
   a. Displacement of the annular hingepoint of the septal and posterior leaflets
   b. Morphology of the anterior leaflet with elongation, tethering, chordal support, and mobility of the free leading edge
   c. Papillary muscle location and attachments

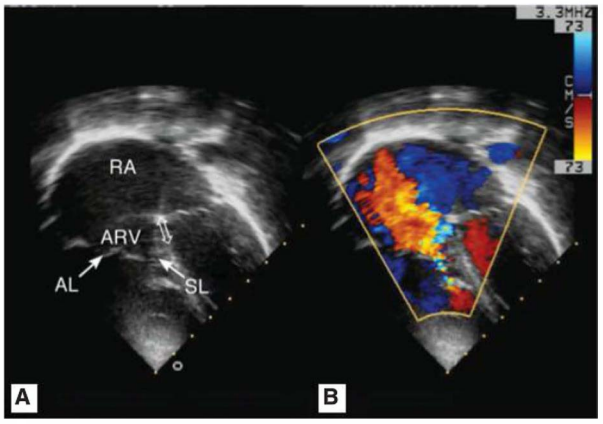

**FIGURE 85-3** Ebstein's anomaly. **A.** Echocardiography shows the displacement of the septal leaflet, the size and position of the anterior leaflet of the tricuspid valve. **B.** The Doppler echocardiogram shows moderate tricuspid regurgitation. RA, the right atrium; ARV, atrialized right ventricle; AL, anterior leaflet; SL, septal leaflet.

2. Function of the tricuspid valve
   a. Degree of regurgitation based on Doppler scanning of jet velocity and not on the quantity of regurgitation
   b. Number of regurgitant jets
   c. Function and mobility of the anterior, septal and posterior leaflets
3. The right ventricle
   a. Size and function
   b. Morphology of the outflow tract
      i. Degree of obstruction by the anterior leaflet
      ii. Function and morphology of the pulmonary valve
4. The left ventricle
   a. Systolic and diastolic function
   b. Presence of noncompaction
5. The size of the PDA, atrial septal defect, and shunt direction
6. Associated anomalies

Echocardiographic evaluation has several pitfalls: The severity of tricuspid regurgitation is frequently underestimated; therefore, surgical intervention might be inappropriately deferred. Proper evaluation of the right ventricular outflow tract, the proximity of the tricuspid valve tissue to the pulmonary valve (indicating severe displacement of the leaflet) and assessment of the effective capacity of the right ventricle below the point of coaptation are challenging.[9]

### MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging complements echocardiography in delineating apical displacement, mobility and function of the tricuspid valve. This modality is accurate in evaluating the size and the function of the atria, both ventricles and ventricular outflow tracts.

### EXERCISE TESTING

Exercise testing is used routinely to evaluate the patient before and after surgery, and aids in indicating the timing of surgical intervention.

### CATHETERIZATION

Diagnostic cardiac catheterization is not routinely performed, unless the pulmonary vascular resistance is to be evaluated before a planned bidirectional Glenn superior cavo-pulmonary anastomosis. A selective coronary angiogram is indicated in patients over 40 years of age or in those with a high risk of coronary artery disease. A preoperative invasive electrophysiological study with ablation is performed in patients with evidence of ventricular pre-excitation on ECG and in all patients with a history of recurrent supraventricular tachycardia, undefined wide-complex tachycardia, or syncope.[10]

## MEDICAL THERAPY

The main goal is to support newborns through the period of transition from fetal to neonatal circulation. All measures are therefore taken to lower pulmonary vascular resistance while preserving duct-dependent pulmonary circulation. The critically ill neonate requires mechanical ventilation, sedation, paralysis, hyperventilation, correction of metabolic acidosis, appropriate inotropic/volume management, and a prostaglandin $E_1$ infusion. After stabilization, when pulmonary vascular resistance begins to fall, the prostaglandin is stopped to allow ductal constriction. Subsequently, the true functional capability of the right ventricle in providing antegrade flow is evaluated. At this point, pulmonary vasodilator therapy may be useful.[11]

Older patients require either no treatment or treatment for symptoms of cardiac failure or arrhythmias. Oral anticoagulation should be considered in the case of paroxysmal or chronic atrial fibrillation or flutter.

## SURGICAL THERAPY

### Indication for Surgery

#### NEOANATES AND YOUNG INFANTS

Typically, the indications for surgery are ventilator dependence, severe cardiac failure, prostaglandin-dependent circulation, and gross cardiomegaly.[12]

#### OLDER CHILDREN AND ADULTS

Indications for operation include one or more of the following: poor growth, symptoms of dyspnea or decreased exercise tolerance (NYHA functional class III, IV), cyanosis (oxygen saturation <90 percent), paradoxical embolism, progressive cardiomegaly (cardiothoracic ratio >0.6), reduced left

ventricle function, tachyarrhythmias that are not controllable by medication or amenable to catheter-based intervention, and significant associated lesions (atrial septal defect, ventricular septal defects, pulmonary stenosis).[5,13,14] In asymptomatic patients, the indication for surgery remains controversial. The arguments in favor of earlier operation are[2]:

1. The natural history of patients who do not undergo operation is poor.
2. The surgical mortality of patients with late-stage complications is high.

A timely operation is therefore warranted before cardiomegaly develops and the functional status deteriorates. Currently, the operation can be considered in asymptomatic patients with low normal exercise tolerance, no right-to-left shunting, and only mild cardiomegaly (cardiothoracic ratio ≤0.6).[4,6] In children with mild symptoms but with significant enlargement of the right atrium due to massive tricuspid insufficiency, the risk of early rhythm disturbances is so high that surgery should be considered.[5]

# SURGICAL TECHNIQUES

## General Principles

Surgical therapy for Ebstein's anomaly should restore tricuspid valve competence and address the inadequacy of the inefficient RV. Especially in children, tricuspid valvuloplasty with biventricular correction should take preference over tricuspid valve replacement or a single ventricle pathway. Surgical repair consists of (a) reconstruction of the tricuspid valve, (b) consideration of plication or resection of the atrialized right ventricle (especially when it is thin-walled and moves paradoxically), (c) closure of the atrial communication and correction of any associated anomalies, (d) surgery for arrhythmia, and (e) right reduction atrioplasty. In special situations, the concept of one and one-half ventricular repair or of a single ventricular pathway should be considered. Heart transplantation is the last resort therapy. Reconstructive surgery is based either on the principle of anatomical repair[4,15,16] or monoleaflet repair.[13,17–19]

# ANATOMICAL REPAIR—CONE RECONSTRUCTION

## Principle

The cone reconstruction moves the new tricuspid valve orifice to the level of the true valve annulus, restoring the normal anatomical location of the tricuspid valve.[4,20]

## Advantages

The cone reconstruction restores the appearance of the normal tricuspid valve anatomy and its function, resulting in central diastolic blood flow and full coaptation of the leaflets. The normalization of the right ventricular volume and morphology is achieved by longitudinal plication of the atrialized right ventricle.

## Disadvantages

This technique raises concerns about tricuspid valve stenosis. However, the inclusion of the septal leaflet and the rotation of the cordless posterior leaflet tissue to enlarge the "cone" might minimize the risk of inflow obstruction.

## Technical Considerations

The important operative steps are as follows:

### "CORRECTION" OF FAILURE OF DELAMINATION

The anterior and posterior tricuspid valve leaflets are detached from the hingepoint. In a single piece, they are mobilized from their anomalous attachments in the right ventricle. The most important aspect of this surgical delamination is to incise all fibrous and muscular attachments between the body of the leaflet and the right ventricular myocardium, but to maintain all fibrous, or occasionally muscular, attachments of the leading edge of the leaflet to the underlying myocardium intact (Fig. 85-4). When a linear attachment is present, it is treated by making fenestrations in the distal aspect of the leaflet, thus creating the equivalent of "neochordae." Only the normal attachments of the anterior leaflet to the true tricuspid annulus and the proper subvalvular apparatus are left in place.

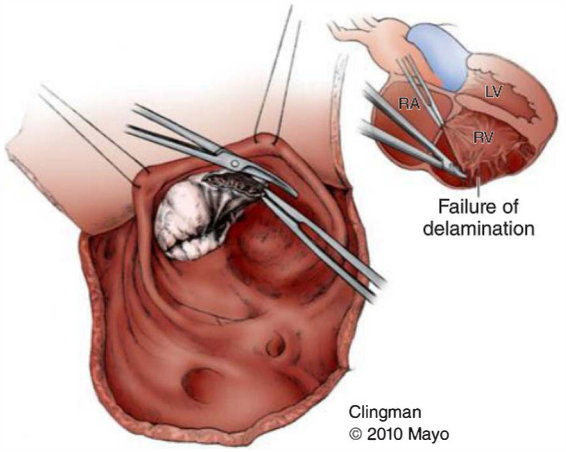

**FIGURE 85-4** Ebstein's anomaly and cone reconstruction. Detachment of the anterior leaflet and correction of failure of delamination. LV, left ventricle; RA, right atrium; RV, right ventricle. (Copyright and used with permission of Mayo Foundation for Medical Education and Research. All rights reserved)

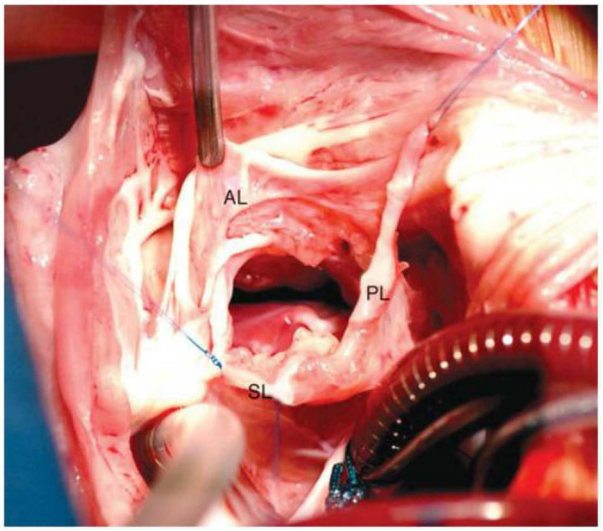

**FIGURE 85-5** Ebstein's anomaly and cone reconstruction in a 6-month-old patient. All fibrous and muscular attachments between the body of the leaflets and the right ventricular myocardium were incised. The cone reconstruction was completed by rotating the posterior leaflet clockwise to meet the proximal edge of the septal leaflet. AL, anterior leaflet; PL, posterior leaflet; SL, septal leaflet.

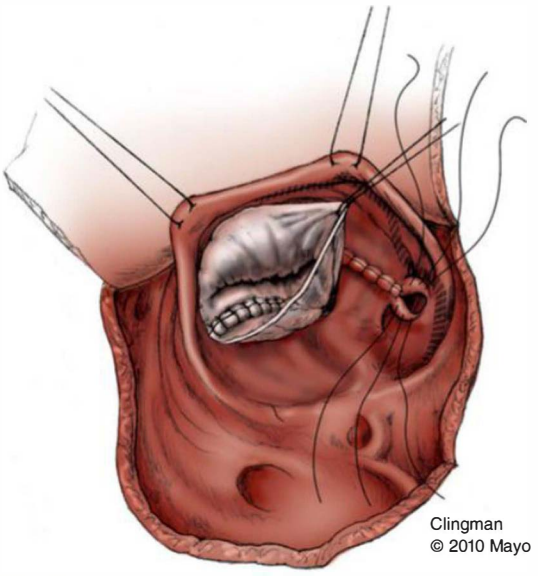

**FIGURE 85-6** Ebstein's anomaly and cone reconstruction. The suture line is advanced toward the atrioventricular groove, excluding the atrialized right ventricle. (Copyright and used with permission of Mayo Foundation for Medical Education and Research. All rights reserved)

## CREATING A CONE

The free edge of this valve complex is rotated clockwise for suture to the septal border of the anterior leaflet, thus creating a cone, the vertex of which remains fixed to the right ventricular apex. Additionally, the septal leaflet is extensively mobilized, in order to be incorporated into the cone wall wherever possible. Alternatively, fresh autologous pericardium is used to reconstruct the septal portion of the tricuspid valve.[16] This results in 360° of leaflet tissue that will make up the new tricuspid valve orifice (Fig. 85-5).

## EXCLUSION OF THE ATRIALIZED RIGHT VENTRICLE

The atrialized part of the right ventricle is then longitudinally plicated to exclude its thin part. Care is taken not to compromise the acute marginal branches of the right coronary artery (Fig. 85-6). Alternatively, the atrialized ventricular wall is excised longitudinally, restoring the right ventricular geometry.[16]

## ATTACHMENT OF THE TRICUSPID VALVE TO THE ANNULUS

The new valvular annulus is constructed (at the anatomically correct level) by means of plication of the true tricuspid annulus to match the proximal circumference of the cone-shaped valve. The base of the cone is sutured to the new valve annulus. The suture line is diverted slightly cephalad to the membranous septum and atrioventricular node to avoid heart block (Fig. 85-7).

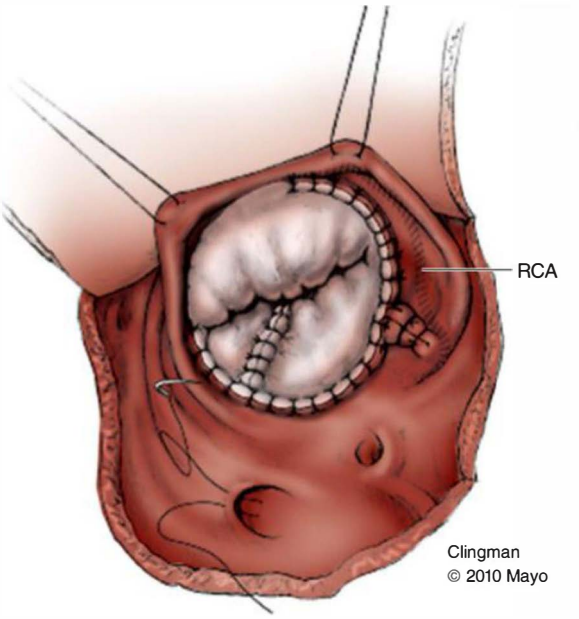

**FIGURE 85-7** Ebstein's anomaly and cone reconstruction. The base of the cone is sutured to the new valve annulus while the annulus is plicated. RCA, right coronary artery. (Copyright and used with permission of Mayo Foundation for Medical Education and Research. All rights reserved)

Additionally, the atrial septal defect is closed as a flap valve. The redundant right atrium is excised from each side of the atriotomy and then the atriotomy is closed.

## MONOLEAFLET REPAIR

### Principle

The repair is based on the use of the enlarged anterior leaflet, constructing a competent monoleaflet valve even though no usable septal or posterior leaflet tissue is present. The free leading edge of the anterior leaflet and at least 50 percent delamination of the anterior leaflet are required for successful reconstruction.[13]

### Advantages

If properly indicated and executed, the long-term functional outcome of the monolealfet valve is promising.

### Disadvantages

This type of reconstruction of the tricuspid valve generates an off-center diastolic blood flow.

## MONOLEAFLET APPROACH WITH TRANSVERSE PLICATION OF THE ATRIALIZED RIGHT VENTRICLE: DANIELSON TECHNIQUE[17]

### Technical Considerations

Transverse plication of the atrialized portion of the right ventricle brings the displaced valvular plane (posterior and septal leaflets) to the level of the "true" valvular plane. Because the spacing between each pledgetted mattress suture is wider at the annulus than at the valvular plane, the annulus is effectively downsized. The annulus may be further narrowed by plicating the free wall portion of the annulus to the septal portion. To improve the closing mechanism a posterior annuloplasty is added.

### Advantages

Internal transverse (apex to base) plication elevates the papillary muscle (thus facilitating the closure of the anterior leaflet against the septum in systole), obliterates the noncontractile portions of the atrialized right ventricle, and reduces the size of the annulus.

### Disadvantages

Transverse plication does not improve the volume and geometry of the right ventricle. There is a risk of myocardial ischemia and impairment of the right ventricular function due to torsion of the right coronary artery.

## MONOLEAFLET APPROACH WITH LONGITUDINAL PLICATION OF THE ATRIALIZED RIGHT VENTRICLE: CARPENTIER TECHNIQUE[18]

### Technical Considerations

The anterior leaflet is partially detached and the atrialized portion of the right ventricle is longitudinally plicated. After plication of the annulus, the anterior leaflet is partially rotated to reach the septal tricuspid region and is sutured to the anatomically correct level. In adult patients, the tricuspid annulus is remodeled and reinforced with a prosthetic ring.

### Advantages

Longitudinal plication of the atrialized right ventricle and attachment of the anterior leaflet to the normal level of the tricuspid annulus restores the right ventricular volume and provides better right ventricular morphology. In children, avoiding permanent fixation of the tricuspid annulus allows growth and flexibility of the annulus, which may contribute to the valve opening and closing mechanism.[21]

### Disadvantages

There is a risk of impairment of right ventricular function or of triggering ventricular arrhythmias due to interruption of some coronary arterial blood supply and/or of kinking of the right coronary artery. The stitches, therefore, have to be strictly endocardial and not penetrate the myocardium.

## MONOLEAFLET APPROACH WITHOUT PLICATION OF THE ATRIALIZED RIGHT VENTRICLE: SEBENING, AUGUSTIN AND DEARANI TECHNIQUE

### Technical Considerations

By using pledgetted horizontal mattress sutures placed through the dominant papillary muscles of the anterior leaflet and fixed to the interventricular septum, the anterior leaflet is "relocated." This keeps the free wall of the right ventricle and the anterior leaflet in apposition to the posterior aspect of the tricuspid annulus (Sebening stich). The posterior angle of the tricuspid orifice is plicated by bringing the right side of the anterior leaflet down to the septum[10,19] and a posterior annuloplasty is performed to narrow the diameter of the tricuspid annulus. To improve the stability of the annulus, an annuloplasty can be performed using a Teflon

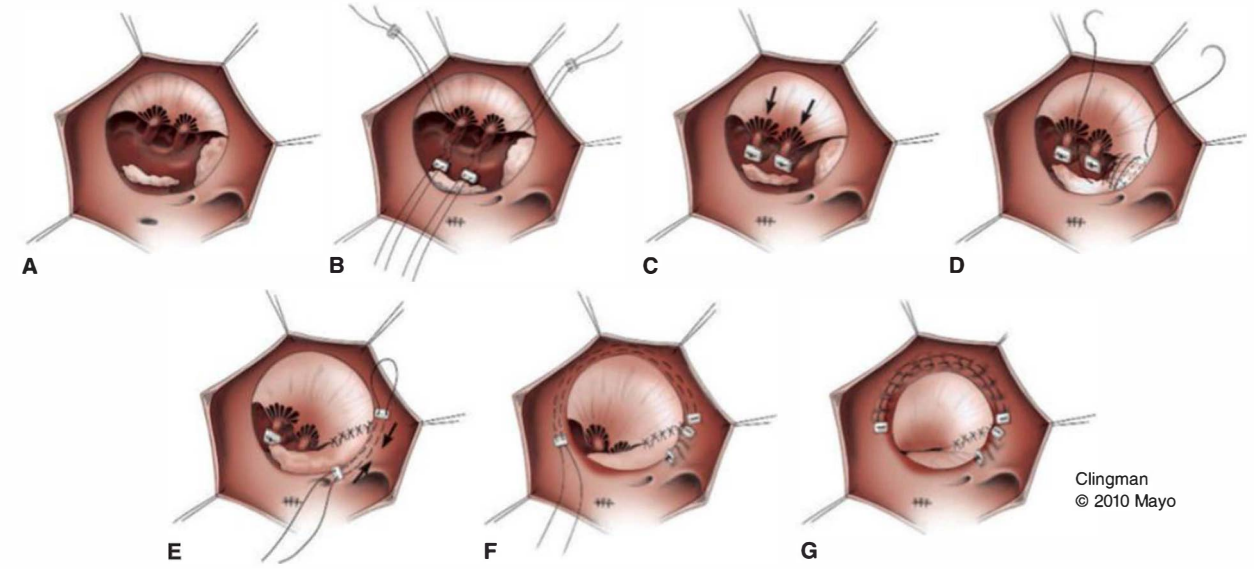

**FIGURE 85-8** Ebstein's morphology and Sebening/Dearani repair (**A**). The base of the papillary muscle is moved toward the ventricular septum (**B**, **C**). The posterior angle of the tricuspid orifice is closed by plication (**D**). A posterior annuloplasty (**E**) and a DeVega anterior purse-string annuloplasty (**F**, **G**). (Copyright and used with permission of Mayo Foundation for Medical Education and Research. All rights reserved)

strip.[6,19] An anterior purse-string annuloplasty (De Vega) should be considered if there is extensive dilatation of the anterior portion of the tricuspid annulus (Fig. 85-8).[10]

### Advantages

The base of the papillary muscle is brought toward the septum, improving geometry and function of the monoleaflet reconstruction. By avoiding plication, there is no risk of interrupting arterial blood supply of the right coronary artery. In some patients, the thin-walled, atrialized right ventricle maintains contractile, which may improve the function of the right ventricle.

### Disadvantages

By avoiding plication, the geometry and volume of the right ventricle are not altered. The nonfunctional portion (akinetic or dyskinetic) of the right ventricle is left in place.

## CORRECTIVE SURGERY FOR NEONATES AND YOUNG INFANTS

### Technical Considerations

A competent monocuspid valve is created using a variety of techniques, including the Sebening stitch, the longitudinal plication of the atrialized right ventricle, the posterior annuloplasty, the De Vega annuloplasty. The atrial septal defect is closed with a patch, leaving a 3-to-4-mm fenestration to unload the right heart and improve left ventricular cardiac output during the early postoperative period. If needed, the anterior leaflet can be taken down from the true annulus and enlarged with an autologous pericardial patch to create a large monocuspid valve. One might consider cone reconstruction as well. The management of associated pulmonary atresia depends on the adequacy of the tricuspid valve repair: If a competent tricuspid valve is achieved, a transannular pericardial patch is performed; otherwise a valved conduit is placed.[12,22]

### Advantages

The base of the papillary muscle is brought toward the septum, improving the geometry and function of the monoleaflet reconstruction. Longitudinal plication improves the geometry and function of the atrialized part of the right ventricle, providing more space for the lungs and reducing compression of the left ventricle, thus improving the left ventricular function.

### Disadvantages

This is high-risk surgery that is greatly dependent on the morphology of the anterior leaflet.

## UNIVENTRICULAR STRATEGY FOR NEONATES

If the tricuspid valve is not amenable to repair with highly laminated leaflet tissue, the tricuspid valve orifice is unguarded, the functional portion of the right ventricle is inadequate, or there is a right ventricular outflow tract obstruction that cannot be corrected reasonably, then the right ventricle is excluded (Starnes procedure) and a univentricular palliation strategy is undertaken.[23]

### Technical Considerations

Fenestrated (4 mm in ø) patching of the tricuspid valve is performed with a glutaraldehyde-fixed autologous pericardium sewn at the "anatomic" level of the tricuspid annulus, leaving the coronary sinus on the right atrial side. The atrial septum is resected and a reduction right atrioplasty is carried out. If the left ventricle is compressed, right ventricle plication or free wall resection[24] is performed. Care is taken to avoid kinking of the right coronary artery. If pulmonary regurgitation is present, the main pulmonary artery is ligated, creating iatrogenic pulmonary atresia. Pulmonary blood flow is provided by a modified Blalock-Taussig shunt.[23]

### Advantages

The procedure effectively decompresses the right side of the circulation, providing sufficient preload for the left ventricle.

### Disadvantages

The right ventricle exclusion procedure is a commitment to the single-ventricle pathway.

## TRICUSPID VALVE REPLACEMENT

### Technical Considerations

The abnormal leaflet tissue in the right ventricular outflow tract is excised in order to prevent obstruction. The valve suture line is diverted cephalad to the tricuspid annulus in the area of the membranous septum, AV node, and coronary sinus, to avoid injury of the conduction system and right coronary artery, leaving the coronary sinus to drain below the prosthesis.

Preferably, porcine bioprostheses are utilized due to their good durability; anticoagulants are not required, and access is permitted for catheterization, if necessary. A mechanical prosthesis is considered if the patient is already taking anticoagulants for another indication. The risk of thrombosis may increase even in the presence of effective anticoagulation, especially if significant right ventricular dysfunction is present.[25]

### Advantages

A competent valve.

### Disadvantages

Replacement should be used in older children or adults. Reoperation is inevitable due to structural failure of the valve. There are mechanical prosthesis-related complications if one is utilized.

## HEART TRANSPLANTATION

Orthotopic cardiac transplantation is considered as the first line of treatment only in the presence of severe biventricular dysfunction. Special consideration should be given to newborns with pulmonary atresia or stenosis and a thin-walled, poorly contractile right ventricle, which is most likely secondary to in utero severe tricuspid regurgitation. Ideally, these patients should be identified in utero and listed for transplant as soon as possible, otherwise, their prognosis is dismal.

## CONCOMITANT PROCEDURES

### "One and One-Half" Ventricle Repair

A bidirectional Glenn is an effective adjunctive procedure to any type of tricuspid valve reconstruction in patients with reduced function of the right ventricle, or when the tricuspid valve repair results in a small valvar orifice. This one and one-half ventricular repair provides unloading to an enlarged and dysfunctional myopathic right ventricle, with positive impact on tricuspid valve coaptation and preload of the left ventricle. By relieving the "pancake effect" of a massively dilated the right ventricle on the left ventricle, the compliance and diastolic function of the left ventricle improves. The significant reduction in mortality caused by right ventricular failure, the improvement in the function of the tricuspid valve, and decreasing risk of arrhythmias were demonstrated using the one and one-half ventricle repair technique.[26,27]

### Antiarrhythmic Treatment

Surgical treatment with intraoperative mapping and ablation are reserved for an unsuccessful percutaneous approach. Surgical ablation for accessory conduction pathways producing the Wolff–Parkinson–White syndrome and atrioventricular

nodal reentry tachycardia is highly successful, with nearly 100 percent freedom from recurrence. A concomitant maze procedure and cryoablation of the atrial isthmus for atrial flutter/fibrillation provide 75 percent freedom from recurrence.[28] Permanent pacing is required for <5 percent of the patients with Ebstein's anomaly, most commonly for atrioventricular block and rarely for sinus node dysfunction.[29] Epicardial placement of leads is preferable so as to not affect the function of the tricuspid valve.

## OUTCOMES

The unfavorable natural history[3] of patients with more severe forms of Ebstein's anomaly (worse functional status, cyanosis, severe tricuspid regurgitation, cardiothoracic ratio >0.6, right ventricular outflow tract obstruction, and early age at diagnosis) could be significantly improved with surgery. Reconstruction is feasible in the majority of patients, with low early mortality. The outcome, in terms of survival and freedom from reoperation in the long term is determined by the clinical state at the time of surgery. A timely operation is therefore warranted before cardiomegaly develops and the functional status deteriorates.[6] Excellent outcomes have been reported from various centers despite numerous types of repair (Table 85-1).

### Danielson and Dearani Techniques

Brown and coworkers[7] reported 5.9 percent early mortality for a cohort of 539 older patients (mean age 24 years) and 2.1 percent for patients operated after 2001. One hundred and eighty-two patients underwent tricuspid valve repair (either the Danielson or the Dearani technique was used) and 337 underwent tricuspid valve replacement. Late survival was 84.7 percent at 10 years and 71.2 percent at 20 years. Freedom from reoperation for valve repair and for valve replacement was 64 and 59 percent at 20 years, respectively. Tricuspid valve repair was associated with lower mortality and a lower reoperation rate, but patients who underwent valve replacement suffered more severely from the disease. In addition, significant residual tricuspid valve regurgitation persisted in 33 percent of patients who underwent valve repair, but only in 1 percent of patients who had undergone valve replacement.

### Carpentier Technique

Chauvaud[5] analyzed 269 operated patients (mean age 25 years) in whom 98 percent had undergone reconstructive surgery and 2 percent had had tricuspid valve replacement. The overall hospital mortality was 9 percent. A one and one-half ventricle repair was used in 107 patients, in whom the operative mortality decreased to 7 percent. Actuarial survival at 20 years was 80 percent. Eighty-four percent were classified as functional class I or II. Tricuspid valve insufficiency was nonexistent or trivial in 80 percent of patients, and reoperation was required in 9 percent of patients.

### Sebening and Augustin Techniques

Badiu and coworkers[6] reported 1.5 percent early mortality in 122 patients (mean age 23.8 years). In 110 (90.2 percent) patients primary tricuspid valve repair was feasible. Overall survival was 87.2, 85.1, and 81.2 percent at 10, 20 and 25 years, respectively. New York Heart Association functional class >II and cardiothoracic ratio of >0.6 were significant risk factors for mortality. Overall freedom from reoperation was 79.9, 61.9, and 58.0 at 10, 20 and 25 years, respectively. Age <12 years and a cardiothoracic ratio of >0.6 were significant risk factors for the need for reoperation.

### Cone Repair

Da Silva[4] reported 2.5 percent early mortality in 40 consecutive patients (mean age 16.8 years). Significant reduction in tricuspid regurgitation and good right ventricular morphology were demonstrated. No patient suffered from heart block. During the mean follow-up of 4 years, one patient died, two patients required late tricuspid valve re-repair, and exercise tolerance significantly improved in all patients. Similar results were reported by Wu[16]; there was no early or late death among 34 consecutive patients (mean age 17 years) who were operated on with the modified cone technique. Postoperative echocardiography showed no significant tricuspid incompetence in 29 patients and mild regurgitation in the remaining 5. The size of the right ventricle decreased significantly, accompanied by complete disappearance of the atrialized segment.

**TABLE 85-1: Outcomes of Repair of Ebstein's Anomaly**

| Author | Study Period | No. | Early Mortality (%) | Plasty (%) | 20-year Survival Rate (%) | OP-Technique |
|---|---|---|---|---|---|---|
| Brown et al. 2008[7] | 1972–2006 | 539 | 5.9 | 34 | 71 | Danielson & Dearani |
| Chauvaud et al. 2007[5] | 1980–2007 | 269 | 9 | 98 | 82 | Carpentier & Chauvaud 1½ ventricle |
| Badiu et al. 2010[6] | 1976–2007 | 122 | 1.5 | 90 | 85 | Sebening & Augustin |

## One and One-Half Ventricle Repair

Excellent functional midterm outcomes were reported by Malhotra and coworkers[27] in 57 nonneonatal symptomatic patients with Ebstein's anomaly. A modified monoleaflet approach with selective bidirectional Glenn for ventricular unloading was used. No early or late deaths occurred. At the initial repair, three patients received a prosthetic valve. Four patients required reoperation for severe tricuspid regurgitation. At follow-up, all patients were acyanotic and in NYHA class I. Tricuspid regurgitation was mild or less in 49 (86 percent) and moderate in 6 patients (11 percent).

## Neonatal Repair

Only a few institutions perform biventricular neonatal repair, therefore, the data are very limited. Knott-Craig and coworkers[12] reviewed their experience with a two-ventricle repair in 22 severely symptomatic neonates and 5 young infants. Twenty-three patients underwent tricuspid valve repair, two underwent valve replacement, and two received a shunt. Hospital survival was 74 percent, with no late death during a median follow-up period of 5.4 years. Three patients required tricuspid valve replacement during the follow-up period. Late arrhythmia requiring medication was present in one patient. All patients were in New York Heart Association functional class I.

## EBSTEIN'S ANOMALY BOARD REVIEW QUESTIONS (CHAPTER 85)

1. Which is correct regarding morphology of Ebstein's anomaly?
   A. The anterior and posterior leaflets are displaced toward the apex of the right ventricle.
   B. The redundant anterior leaflet has an abnormal attachment to the tricuspid annulus.
   C. There is a thin-walled atrialized component of the right ventricle.
   D. The functional component of the right ventricle consists of the apical and inlet portions.
   E. The outlet portion is small or even nonexistent.

2. Which is true regarding surgical management of subdivided atrium?
   A. Fifty percent of patients born with subdivided left atrium die in infancy without treatment.
   B. Urgent repair is indicated in older patients with chronic symptoms.

C. Hypothermic circulatory arrest is used in all patients with subdivided left atrium.
D. A left atrial approach is recommended for repair of subdivided left atrium in infants.
E. Percutaneous disruption of the obstructive membrane is the preferred approach in patients with subdivided right atrium.

3. Which is true regarding pathophysiology of Ebstein's anomaly?
   A. RV dilation can compromise LV function.
   B. Mild displacement of the tricuspid leaflets can obstruct pulmonary blood flow.
   C. Ductal flow increases RV afterload and has a positive impact on tricuspid valve function.
   D. Severe leaflet displacement results in functional tricuspid stenosis.
   E. Arrhythmias occur in 5 to 10 percent of patients.

4. Which is not a component of surgical repair of Ebstein's anomaly?
   A. Reconstruction of the tricuspid valve
   B. Plication of the atrialized right ventricle
   C. Enlargement of the interatrial septal defect
   D. Arrhythmia procedures
   E. Atrial reduction

5. Which is correct regarding outcomes after surgical repair of Ebstein's anomaly?
   A. Freedom from reoperation is less than 50 percent at 20 years after Danielson repair.
   B. Freedom from tricuspid insufficiency is 80 percent at 20 years after Carpentier repair.
   C. Freedom from reoperation is 70 percent at 20 years after Augustin repair.
   D. The right ventricular size does not decrease after the cone repair.
   E. Tricuspid insufficiency is mild or less in 50 percent of patients after one and one-half ventricle repair.

## ANSWERS

1. **Answer: C.** There is a thin-walled atrialized component of the right ventricle. The septal and posterior leaflets are displaced toward the apex of the right ventricle. The redundant anterior leaflet has a normal attachment to the tricuspid annulus. The functional component of the right ventricle consists of the apical and outlet portions, and the inlet portion is small or even nonexistent.
2. **Answer: B.** Urgent repair is indicated in an older patient with subdivided left atrium that presents with chronic symptoms. Up to 75 percent of patients will die without treatment during infancy. Hypothermic circulatory arrest is typically only used when there are associated complex anomalies. A right atrial approach is recommended for repair of subdivided left atrium in infants. A surgical repair remains the preferred approach for patients with subdivided right atrium.
3. **Answer: A.** RV dilation can displace the interventricular septum and compromise LV function. Mild displacement of the tricuspid leaflets does not adversely impact pulmonary blood flow, but severe displacement can cause severe valvular insufficiency. Ductal flow increases RV afterload and negatively impacts tricuspid valve function. Arrhythmias occur in 15 to 20 percent of patients.
4. **Answer: C.** The interatrial septal defect is closed, not enlarged. Other components of surgical repair include valve reconstruction, plication or resection of the right ventricle, procedures for control of arrhythmias, and reduction atrioplasty.
5. **Answer: B.** Freedom from tricuspid insufficiency is 80 percent at 20 years after Carpentier repair. Freedom from reoperation is 60 percent at 20 years after Danielson repair. Freedom from reoperation is 60 percent at 20 years after Augustin repair. The cone repair significantly reduces right ventricular size. Tricuspid insufficiency is mild or less in over 85 percent of patients after one and one-half ventricle repair.

# Congenital Anomalies of the Sinuses of Valsalva and Aortico–Left Ventricular Tunnel

*Torin P. Fitton*
*Christopher M. Sciortino*
*Luca A. Vricella*

## CONGENITAL ANOMALIES OF THE SINUSES OF VALSALVA

Initially described in 1839,[1] sinus of Valsalva (SoV) aneurysm is a rare condition incidentally found in 0.15 to 1 percent of patients undergoing cardiopulmonary bypass (CPB)[2,3] and five times more frequently in Asians.[4] In 1956, Morrow and Lillehei, using inflow inclusion and a membrane oxygenator, separately reported successful SoV aneurysm repair.[5,6] Since then, surgical repair has been established as the accepted standard of care.

Although acquired SoV aneurysms can occur in the setting of infection or trauma, they are most commonly congenital in origin and associated with many different connective tissue disorders, including rheumatoid arthritis, Ehlers–Danhlos syndrome, Marfan syndrome, Klippel–Feil syndrome, Turners syndrome, trisomies 13 and 15, Loeys–Dietz syndrome, arachnodactyly, and osteogenesis imperfecta. SoV aneurysms are frequently associated with other cardiac abnormalities, including ventricular septal defect (VSD) and aortic valve regurgitation.

SoV aneurysms most commonly originate from the right coronary sinus (RCS), followed by the noncoronary sinus (NCS),[7] reflecting the embryologic origin of the RCS and NCS from fusion of the bulbar septum and truncal ridges. Incomplete fusion of the bulbar septum can in fact result in aneurysm formation when the septum is subjected to long-standing systemic arterial pressure.[8] Aneurysms of the left coronary sinus are exceedingly rare and are usually an acquired phenomenon, as the left coronary cusp does not arise from the bulbar septum.

### Morphology

On histopathology, SoV aneurysms are characterized by separation of the sinus aortic media adjacent to the hinge point of the aortic valve cusp.[8] Normally, the sinuses are thinner than the tubular portion of the aorta and are limited inferiorly by the semicircular hinge point of the corresponding aortic valve cusp. In patients with SoV aneurysms, this otherwise normal characteristic is accentuated, and thinning of the aortic wall with disconnection of the media increases over time, resulting in aneurysm formation.[9]

The anatomic relationship between aortic root and adjacent cardiac structures predicts the clinical findings associated with gradual dilation and rupture of SoV aneurysms (Fig. 86-1). Aneurysms arising from the RCS most commonly involve the right atrium (RA) or right ventricular outflow tract (RVOT), while NCS aneurysms decompress either into the right or left atrium. Rare aneurysmal dilation of the left aortic sinus can eventually rupture into the left atrium. Although aortic root involvement is usually limited to a single sinus, enlargement of two sinuses or the entire aortic root occurs in rare cases. A concomitant VSD is found in up to 50 percent of congenital cases.[10,11]

### Clinical Features

SoV aneurysms produce symptoms by compression or direct rupture into an adjacent chamber and are often found incidentally. Onset of symptoms is gradual in 50 to 70 percent of patients and occurs most commonly between 20 and 30 years

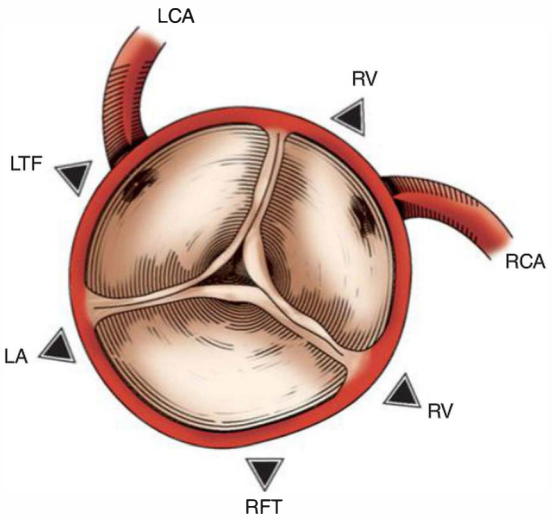

**FIGURE 86-1** Anatomic relationship between aortic root and adjacent cardiac structures as schematically viewed from the operating surgeon's perspective. LA, left atrium; LCA, left coronary artery; LFT, left fibrous trigone; RA, right atrium; RCA, right coronary artery; RV, right ventricle. (From Vricella LA, Cameron DE. Anomalies of the sinuses of Valsalva and aortico–left ventricular tunnel. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2006. With permission.)

of age but ranges in reported series from infancy to the seventh decade.[12–15] Aortic root rupture into either a neighboring cardiac chamber or within the pericardial cavity is rare in the first two decades of life.[16–18] Although clinical presentation is most commonly indolent, it can be acute depending on aneurysmal size, site of rupture (adjacent chamber versus pericardial sac), and the concomitant presence of a VSD or aortic insufficiency. In case of intracardiac rupture or fistulization, the most common presenting symptom is dyspnea, with nearly all patients exhibiting a continuous systolic–diastolic "machinery-like" murmur.[19] Numerous electrocardiographic findings have been described, including ST-segment depression, onset of Q waves, atrioventricular block, atrial fibrillation, and sudden death. Intrapericardial rupture typically presents with acute hemodynamic collapse and cardiac tamponade. A minority of patients (less than 20 percent) will present with evidence of sepsis associated with bacterial endocarditis.[20]

## Surgical Therapy

Urgent operative intervention is clearly indicated for symptomatic patients with rupture or compressive fistulas. SoV aneurysms that are asymptomatic but discovered at the time of CPB should be repaired because of the high likelihood of progressive increase in size, possibility of rupture, or symptom progression. Smaller, asymptomatic SoV aneurysms discovered incidentally during routine echocardiography can be safely followed over time unless progressive enlargement is noted or the patient develops symptoms. Surgical repair may be indicated earlier in patients with significant connective tissue disorder or family history of dissection or rupture.

After induction of general anesthesia, transesophageal echocardiography is routinely performed to confirm the preoperative findings, assess valvular competence, and rule out associated septation defects and endocarditic vegetations. Transesophageal echocardiography is also crucial in defining the course of the fistulous tract in case of intracardiac rupture. The surgical treatment of three-sinus enlargement of the aortic root is detailed elsewhere in this volume and entails either valve-sparing replacement[21,22] of the root or replacement with mechanical or biological prostheses.

Aortotomy is performed to assess the aortic root anatomy and an additional right atriotomy is performed to expose the distal site of rupture or protrusion, especially the "windsock" aneurysmal sac that projects toward the right-sided chambers. A transventricular approach can be utilized alternatively to expose a concomitant VSD. The aortic aspect of the defect is repaired with prosthetic material (Fig. 86-2) to prevent the high risk of aortic valve distortion and recurrence of primary closure. In case of diverticular extension into the RA or right ventricle (RV) (via a VSD), the distal aspect of the SoV aneurysm is corrected with similar technique.

In spite of several well-described repair techniques, the incidence of aortic regurgitation (AR) has been reported between 30 and 50 percent and is severe enough to warrant aortic valve replacement (AVR) in as many as 50 to 80 percent of affected patients.[23] AR commonly results from prolapse of the affected sinus cusp, which occurs secondary to involvement of the annulus, loss of infundibular support with a conal VSD, or a Venturi effect on the involved cusp.[18] The Ross procedure is considered a viable alternative to root replacement in selected cases.

## Results

Au and coworkers presented the long-term results of 53 patients treated for SoV aneurysms, reporting no operative mortality and a 15-year survival of 83 percent.[14] A retrospective review of 22 patients presenting with intracardiac rupture at the Johns Hopkins Hospital demonstrated an operative mortality of 5 percent, with late survival of 85 and 60 percent at 5 and 10 years, respectively.[19] This decrease in late survival likely reflects the noncongenital etiology of SoV aneurysm more frequently observed in western countries. Although factors such as bacterial endocarditis, need for AVR, and VSD closure do not appear to worsen survival, preoperative AR and VSD have been reported to decrease aortic valve-related freedom from reintervention, with a reported need for AVR of up to 25 percent in the decade following diagnosis and initial intervention.[13,14,24]

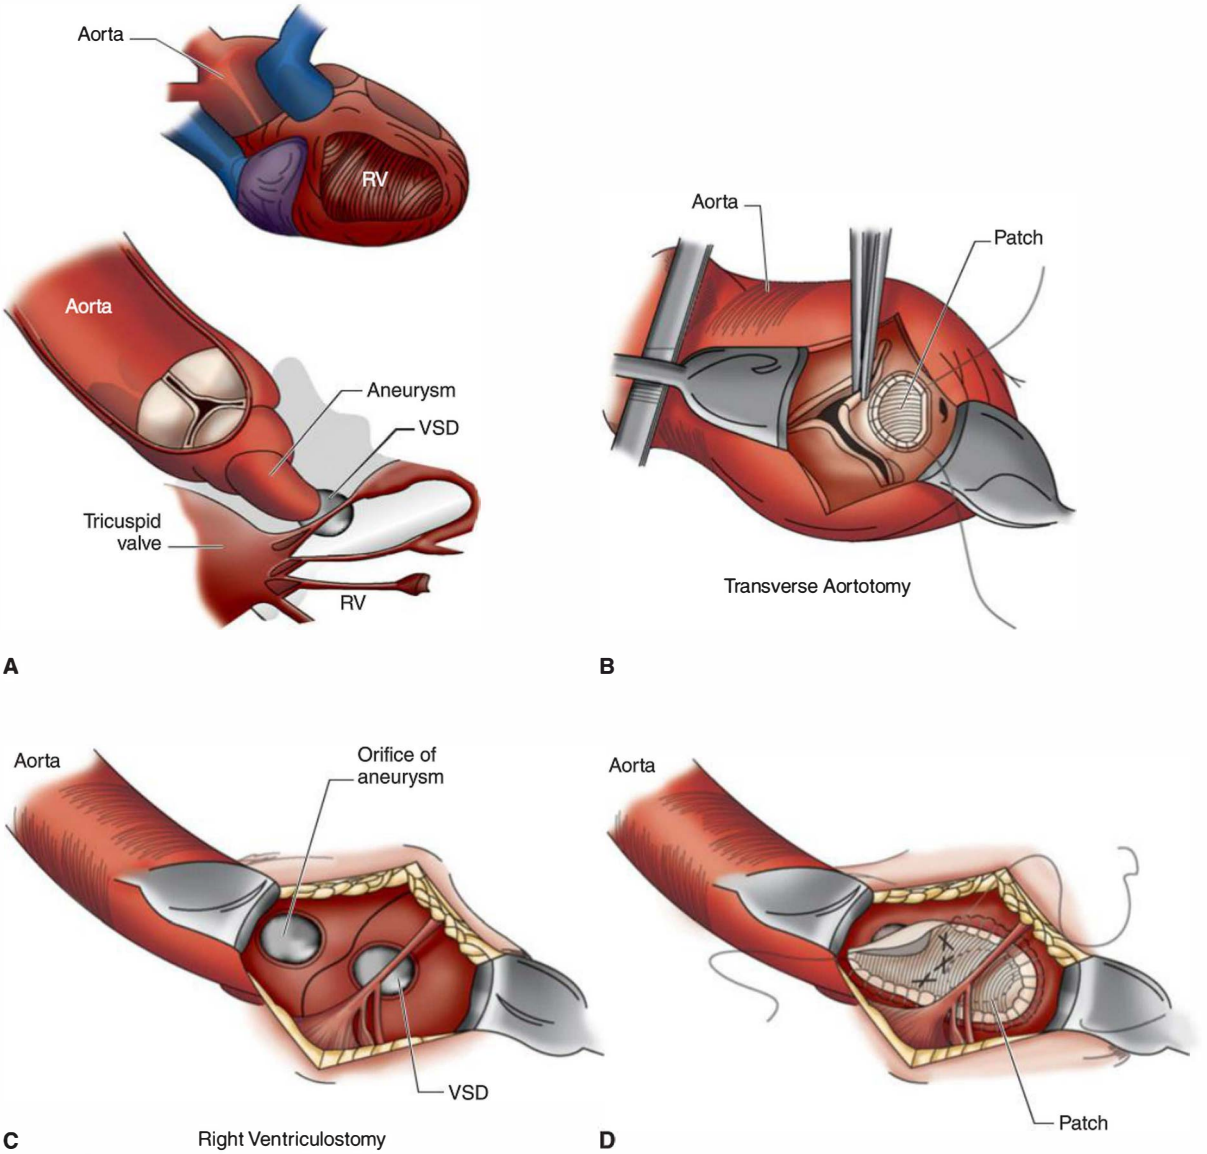

**FIGURE 86-2** Surgical repair of aneurysm of the sinus of Valsalva, originating from the right coronary sinus. **A.** Schematic view with aneurysm protruding through ventricular septal defect. **B.** The inlet to the aneurysm is closed with a patch of bovine or autologous pericardium. **C** and **D.** Transventricular repair of the inferior portion of the sinus of Valsalva aneurysm. The defect and the orifice of the aneurysm are closed with a single polyester patch. RV, right ventricle; VSD, ventricular septal defect. (From Vricella LA, Cameron DE. Anomalies of the sinuses of Valsalva and aortico–left ventricular tunnel. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2006. With permission.)

## AORTICO–LEFT VENTRICULAR TUNNEL

Aortico–left ventricular tunnel (ALVT) is an extremely rare developmental condition consisting of a paravalvular communication between the aortic root and left ventricular cavity. It represents only 0.001 percent of all congenital cardiac anomalies.

### Morphology

The lesion typically originates from the RCS around the coronary ostium and can be appreciated grossly as a palpable, pulsatile mass between aortic and pulmonary artery roots. The course of the aneurysm can be variable, but it usually terminates in the ventricular cavity below

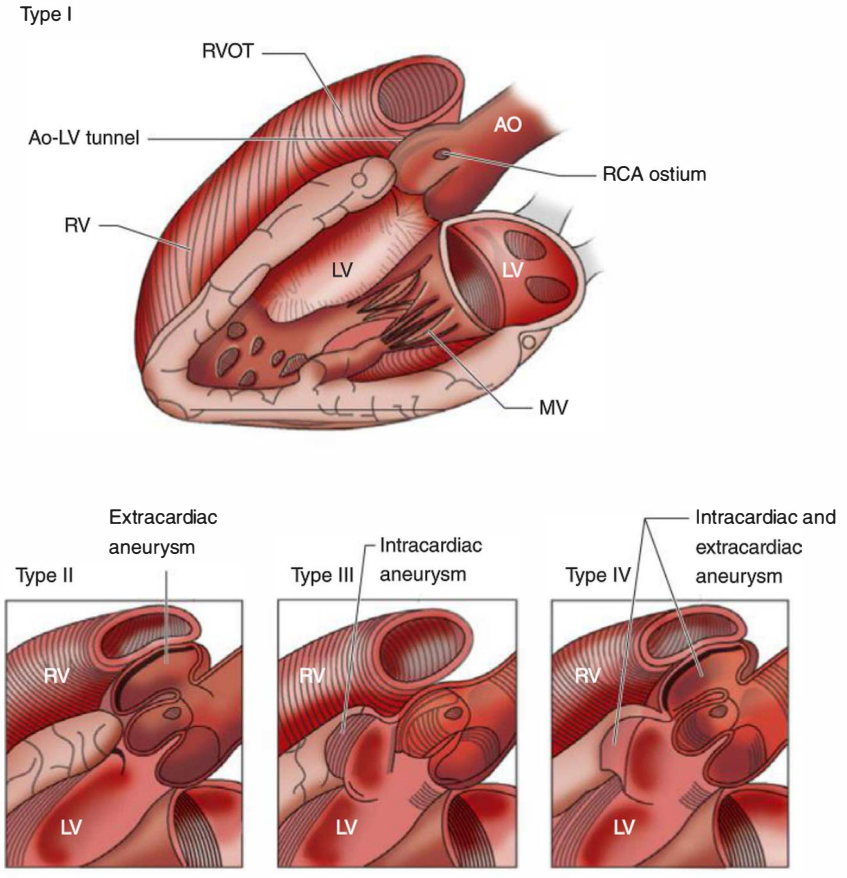

**FIGURE 86-3** Proposed morphologic classification of aortico–left ventricular (Ao-LV) tunnel. Type I: Simple tunnel with slit-like opening at aortic end, no aortic valve distortion. Type II: Large tunnel with oval aortic opening with or without aortic valve distortion. Type I II: Intracardiac aneurysm of the ventricular portion of the tunnel with or without right ventricular outflow tract obstruction. Type IV: Combination of types II and III. (From Shum-Tim D, Tchervenkov CI. Aortic–left ventricular tunnel. In: Mavroudis C, Backer CL (eds). *Pediatric Cardiac Surgery,* 3rd ed. Philadelphia: Mosby, 2003:576. With permission.)

the right coronary leaflet. The ventricular opening can be appreciated with retraction of the aortic valve cusps. The most frequently occurring anatomic variants are categorized in the Hovaguimian classification (Fig. 86-3).[25] Almost half of all patients will disclose associated defects (VSD, bicuspid aortic valve) on echocardiographic examination, although the aortic valve is usually competent. Coronary anomalies have been reported in up to one-third of patients.[6]

## Clinical Features

The clinical presentation is dependent on the size of the fistulous tract and the degree of associated AR. Although an ALVT is an uncommon cause of neonatal congestive heart failure, ALVT should be suspected in neonates with plethoric lung fields, cardiomegaly, a diastolic murmur, and widened pulse pressure. Like SoV aneurysms, large fistulous tracts can also lead to progressive right ventricular outflow tract obstruction and cyanosis.

The diagnostic modality of choice is transthoracic echocardiography, which readily demonstrates the classic "drop-out" of the interventricular septum inferior to the RCS. Cardiac catheterization and magnetic resonance imaging are rarely required.

## Therapy

The degree of valvular insufficiency and severity of congestive heart failure often mandate immediate operative intervention, but serial observation with echocardiography is acceptable, as spontaneous closure of small ALVT defects has been reported.

Intraoperatively, bicaval cannulation is employed only if a concomitant septal defect requires surgical correction. Cardiopulmonary bypass with moderate hypothermia

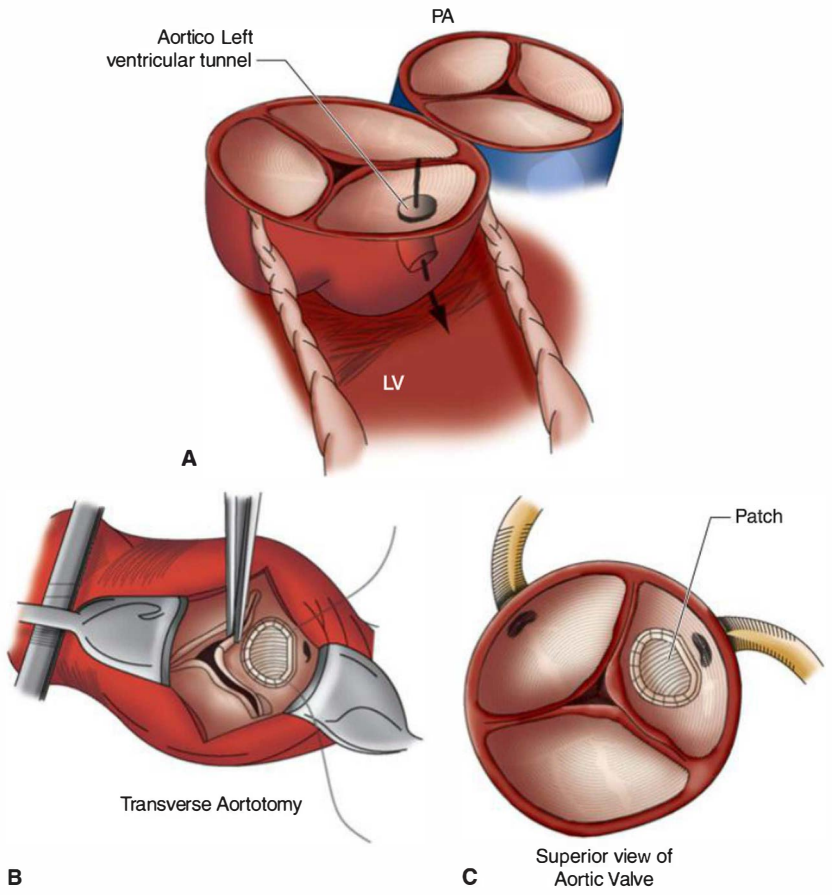

**FIGURE 86-4** Aortico–left ventricular tunnel with the inlet originating (**A**) in the right coronary sinus (most typical location). Through an aortotomy (**B** and **C**), the inlet orifice to the tunnel is closed with an autologous pericardial patch. The ventricular opening of the tunnel is closed through the aorta separately, either primarily or with an additional patch. (From Vricella LA, Cameron DE. Anomalies of the sinuses of Valsalva and aortico–left ventricular tunnel. In: Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2006. With permission.)

and the direct infusion of coronary ostial cardioplegia are employed. We favor closure of both inlet and outlet orifices of the tunnel in a manner similar as that described for SoV aneurysm (Fig. 86-4). Patch closure of both openings of the ALVT provides additional protection from late valvular regurgitation and recurrence of the fistulous tract. As an alternative approach, both orifices of the ALVT can be approached from within the ALVT (Fig. 86-5).

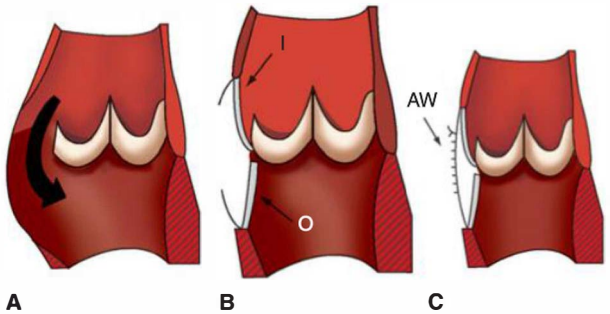

**FIGURE 86-5** Schematic representation of alternative approach for repair of aortico–left ventricular tunnel. **A.** Cross section of the aortic root with the tunnel indicated by the downward-pointing arrow. **B.** The tunnel is exposed *directly* through an aortotomy, and the inlet (I) an outlet (O) orifices are closed with separate patches. **C.** The aortic wall (AW) is closed primarily.

## Results

In contemporary series, operative mortality has been reported to be less than 10 percent, with need for reoperative intervention being the most significant determinant of late outcome. The most common early complications include atrioventricular heart block and aortic valve regurgitation. AR secondary to postrepair deformity or root dilation due to lack of annular support around the ALVT may result in need for late aortic valve or root replacement in up to 50 percent of patients, particularly if initial correction is delayed b eyond infancy.[26,27]

## INTRODUCTION

From the earliest days, advances in extracorporeal membrane oxygenation (ECMO) have been linked to advances in cardiopulmonary bypass (CPB) and repair of congenital cardiac malformations. Since C. Walton Lillihei[1] first employed the technique of controlled cross-circulation using the patient's parent, efforts to perfect cardiopulmonary support have transitioned from the operating room to the intensive care unit. In the intervening years, every facet of CPB has been studied and refined. Improvements in these techniques have afforded the surgeon the opportunity to tackle the most complex anatomic anomalies in even the smallest babies. Likewise, advances in extracorporeal support (ECLS) methods have led clinicians to expand their clinical indications and implementation in the ICU. However, despite the fact that the notion and use of extracorporeal circulation originated in the cardiac surgical suite, heart disease was, until the last decade or so, usually a contraindication for ECMO. Early experience in adults was discouraging,[2] with better success reported in the care of newborns with respiratory failure.[3] Extension to include older infants and children with respiratory failure followed.[4]

Pediatric cardiac ECMO, as it has come to be known, was first reported by Soeter and colleagues in 1973. He described the successful application of ECMO in a 4-year-old girl following repair of tetralogy of Fallot, who was weaned from support in 48 hours and discharged home 11 days later.[5] By the late 1980s and early 1990s, cardiac ECMO gained traction in the pediatric cardiac community, as many large centers reported favorable outcomes with postoperative support. With experience, refinement, and successes, cardiac ECMO has made the transition from "rescue" therapy, to "therapeutic" or even "preventive" management. Coincident with advances in pharmacologic and mechanical ventilatory support strategies for respiratory failure, the number of ECMO runs for the cardiac population has steadily increased as a proportion of the Extracorporeal Life Support Organization (ELSO) Registry (Fig. 87-1). In this chapter, we take a comprehensive look at cardiac ECMO, with attention to the different types (venoarterial or venovenous), their relative indications, and their respective advantages, disadvantages, and outcomes. In addition, we discuss the myriad equipment options and also review the physiology of ECMO and principles of clinical application. Last, we consider new opportunities and indications for mechanical circulatory support.

## VENOARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

In simplest terms, venoarterial ECMO (VA-ECMO) consists of taking deoxygenated blood from the venous circulation, oxygenating it, and then pumping it back into the arterial circulation. How this is accomplished depends on individual and institutional experience and preference. The obvious benefit is that the patient's entire cardiorespiratory system is bypassed, thereby ensuring adequate end-organ oxygenation despite respiratory and circulatory collapse. Ideally, the brain, kidneys, and other organs thereby maintain their essential functions in a circumstance that would otherwise almost surely lead to multi-organ failure and possibly death. Importantly, this support system likely creates an environment that is more conducive to functional improvement. There are ample data to support this assertion with regard to

the lungs, and advances in the understanding of the pathogenesis of cardiac failure suggest that the same is likely true for the heart.[7]

## Indications and Experience

Broad indications for VA-ECMO include preoperative stabilization, postcardiotomy support, bridge-to-transplant, cardiopulmonary arrest, myocarditis and cardiomyopathy, pulmonary hypertension, intractable arrhythmias, and occasionally, respiratory failure refractory to venovenous extracorporeal circulatiry support.

### PREOPERATIVE SUPPORT

Among neonates and pediatric patients, congenital heart disease is by far the most common indication for VA-ECMO,

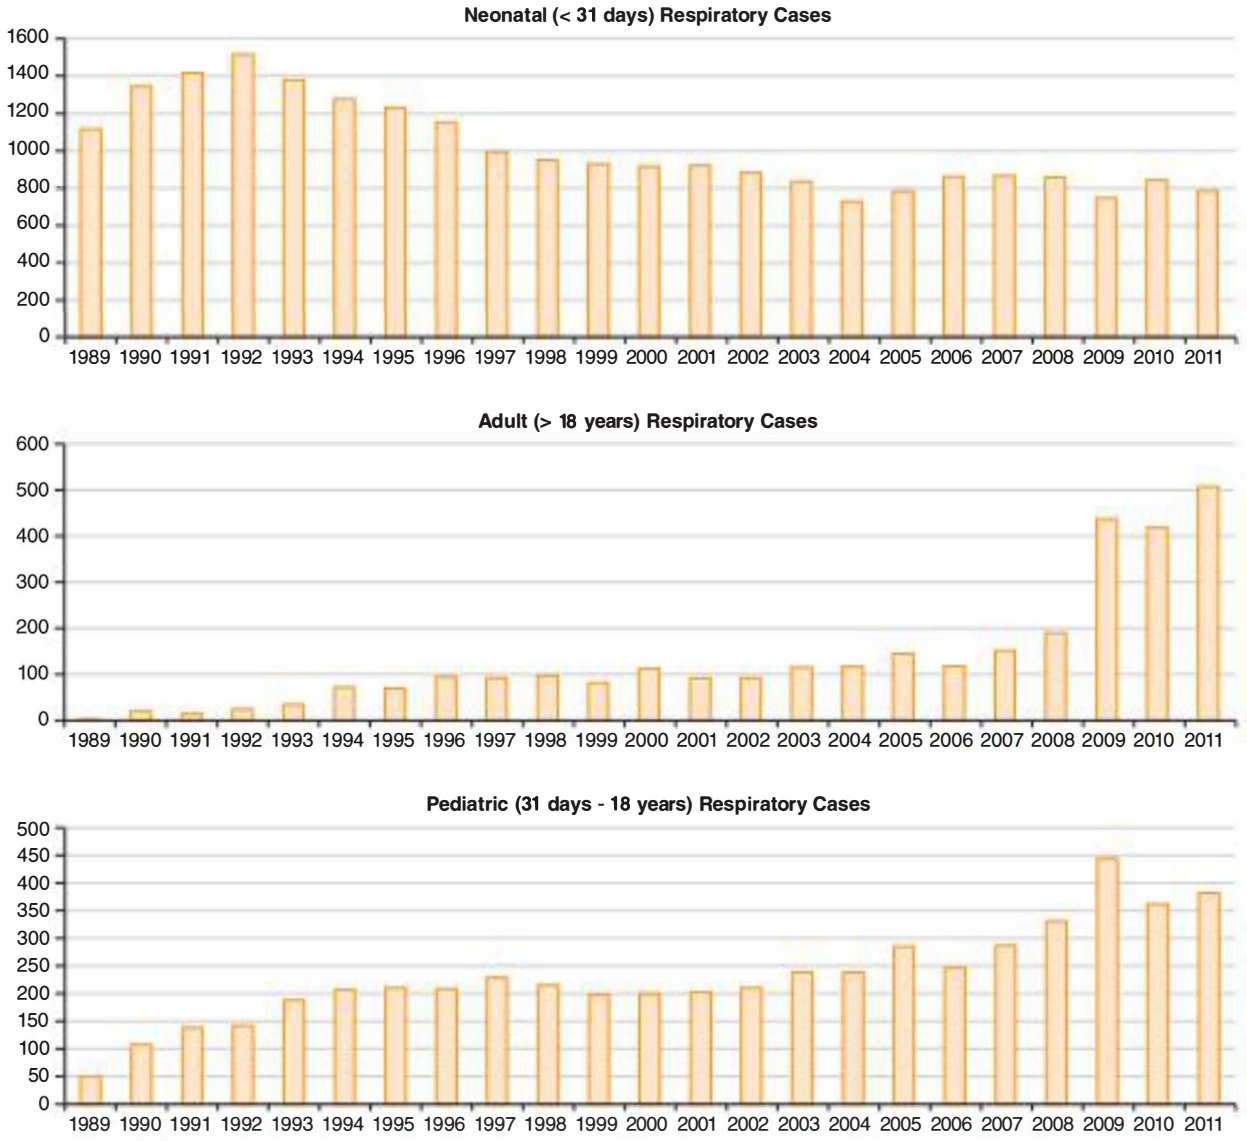

**FIGURE 87-1** Annual cardiac and respiratory ECMO volumes, segregated by patient age.

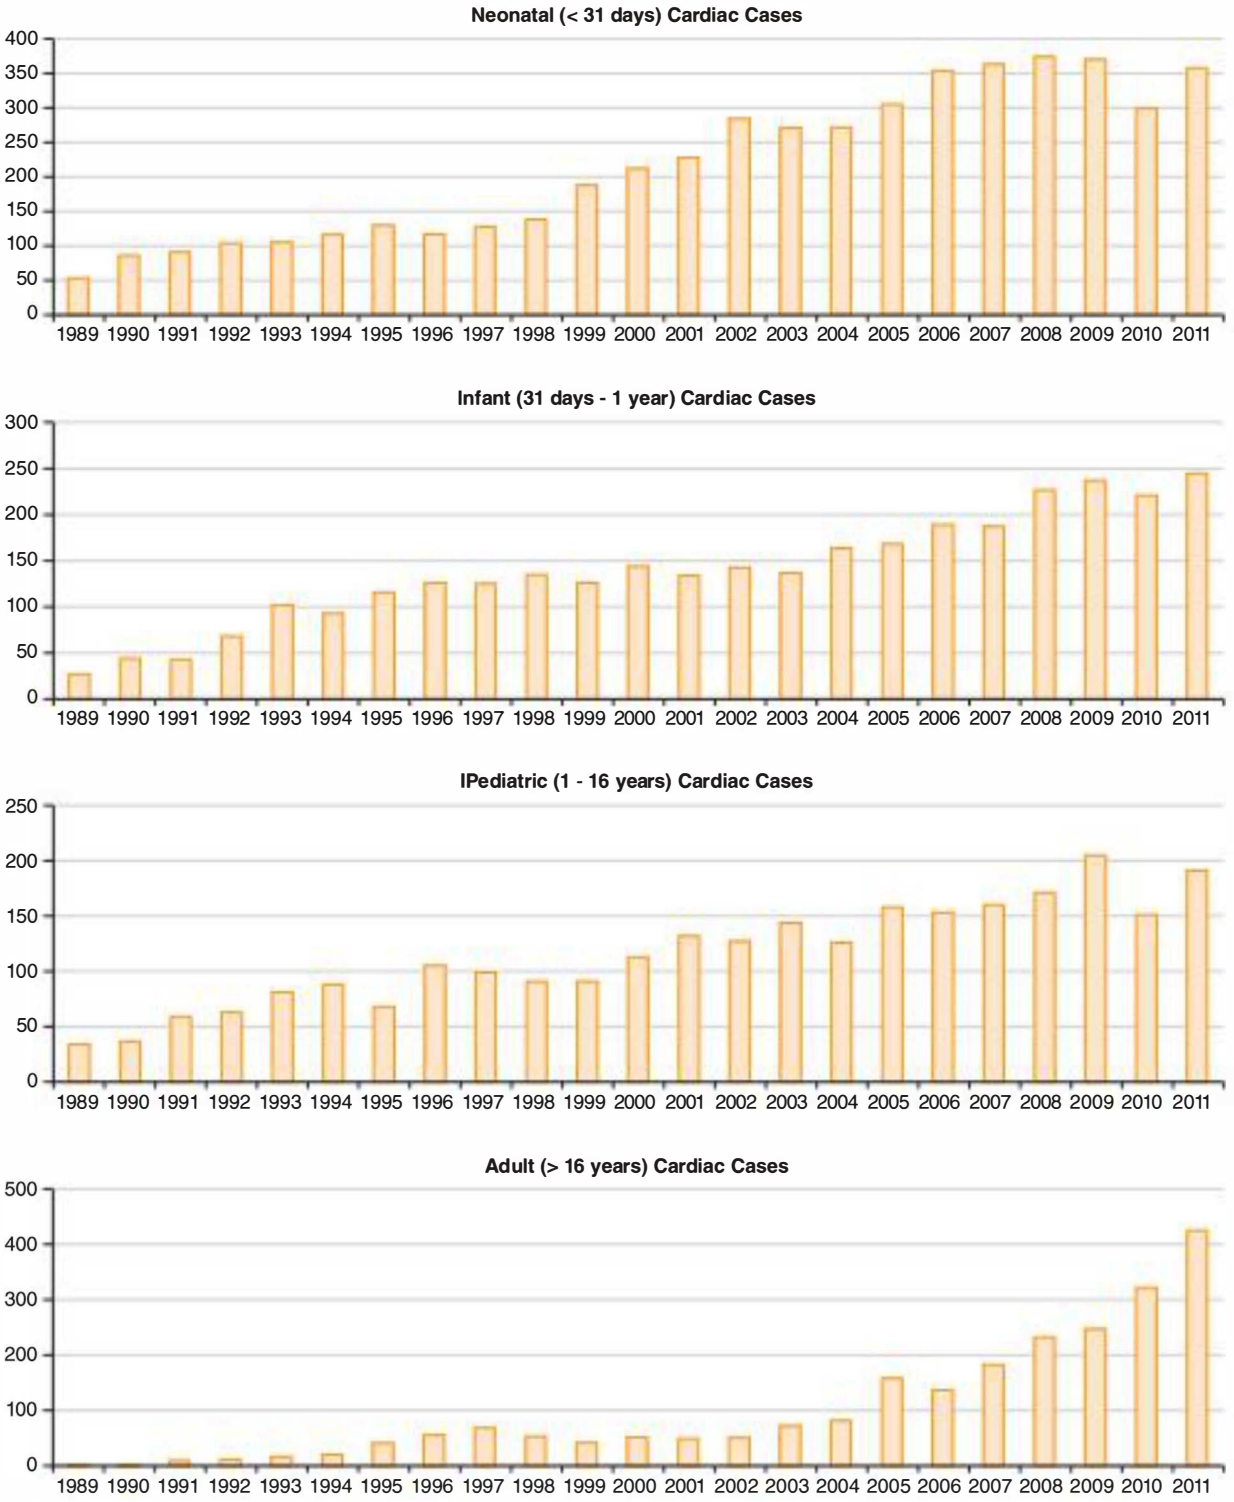

**FIGURE 87-1** (*continued*)

accounting for 72 percent of all cases, and 86 percent of neonatal (age <31 days) cases.[6] In neonates with congenital cardiac malformations, indications for VA-ECMO can arise soon after birth. The infant with obstructed total anomalous pulmonary venous drainage is the classic example of a newborn that can present in extremis and require emergent institution of VA-ECMO. Ideally, with VA-ECMO support, the baby's clinical condition can be optimized prior to surgical correction. Similarly, some neonates with congenital cardiomyopathy (i.e., dysrhythmias) will benefit from support while diagnostic studies and therapeutic interventions, such as radiofrequency ablation, are pursued. Without ECMO, these babies might die before a diagnosis is established and therapies implemented.

## POSTOPERATIVE SUPPORT

Postoperative instability is the most common indication for VA-ECMO in the cardiac setting. Whether due to prolonged CPB or circulatory arrest times, complex surgical repair and manipulation of the heart, exaggerated inflammatory response to CPB, or inadequate myocardial protection, the availability of VA-ECMO is often lifesaving as a bridge to recovery. Of course it is critical that residual structural lesions be ruled out as the cause for compromise; thus a thorough assessment (i.e., transesophageal echocardiogram) is imperative before initiating VA-ECMO. Standard postoperative ECMO must be distinguished from rapid or resuscitative ECMO (eCPR), a topic covered later in the chapter.

In 1987, Kanter and colleagues were the first to report some success with ECMO in patients who had undergone cardiotomy, with 6 of 13 surviving to discharge.[8] Since then, the literature is replete with institutional reports of ECMO use in patients with structural cardiac anomalies. Morris and coworkers at the Children's Hospital of Philadelphia (CHOP) reported their experience with 137 patients on cardiac ECMO[9] between 1995 and 2001. Diagnoses encompassed the spectrum of congenital cardiac malformations, including single ventricle with intracardiac mixing and single ventricle with separate circulations, as well as children with structurally normal hearts. Overall survival to discharge was 39 percent. Two-thirds of the patients had undergone cardiac surgery prior to ECMO, with 40 percent of those surviving to discharge. In that subset, risk factors for mortality included age less than 1 month, male gender, duration of mechanical ventilation before initiation of ECMO, and the development of renal or hepatic dysfunction on ECMO. Failure to separate from CPB was not found to be a predictor of death, which means that in those cases ECMO was literally life-saving. In addition, despite historical bias against placing patients with single ventricle physiology on ECMO, this factor did not prove to be significantly associated with death in this series. No factor analyzed was predictive of mortality in the subset of patients who had not undergone surgery and in whom survival to discharge was 35 percent. Overall, considering the fact that many of the survivors likely would have died without mechanical support, the authors concluded that, "it is imprudent to impose strict indications or contraindications to ECMO support."

Sivarajan and colleagues reported another large study of 116 patients supported with cardiac ECMO from Royal Children's Hospital in Melbourne. They included data from patients undergoing conventional ECMO as well as patients cannulated during eCPR. Survival to hospital discharge improved from 33 percent in the earlier era (1990–2001), to 48 percent in the recent era (2002–2006).[10] Another relatively large series from the Great Ormond Street Hospital in London reported on 81 cardiac patients managed with ECMO between 1992 and 2000.[11] More than half of these patients were placed on ECMO in the OR following multiple unsuccessful attempts at separation from CPB. Overall survival to discharge was 49 percent. Their report includes only patients with two-ventricle anatomy. Patients placed on ECMO in the surgical suite had a 64 percent survival to discharge, as compared to 29 percent in those patients cannulated in the ICU. They found, in agreement with many previous studies, that renal failure was a significant risk factor for mortality. Also, as with virtually all other reports of pediatric cardiac ECMO, their data support the contention that a residual cardiac lesion bodes poorly for outcome and is a contraindication for initiation of support. In our experience, however, there are situations where a patient can be supported for a period of hours or even days, subsequently return to the operating room or the interventional cardiology suite for correction of residual lesions, and then be weaned from ECMO; so even this contraindication is a relative one.

VA-ECMO can also be utilized for postoperative support following heart transplantation, either for the treatment of pulmonary hypertension or early graft dysfunction. Galantowicz and Stolar[12] reported 40 percent salvage rate among children requiring mechanical support following transplantation. Rarely, acute rejection episodes occurring remotely that are marked by severe myocardial dysfunction can be managed with VA-ECMO until the initiation of antirejection therapy.[13]

## BRIDGE-TO-TRANSPLANTATION OR BRIDGE-TO-BRIDGE

VA-ECMO can also be indicated in neonates and pediatric patients with cardiac failure waiting for transplantation, or more rarely, as an intermediate step prior to implantation of a ventricular assist device[14]. A recent series by Imamura et al.[15] at Arkansas Children's Hospital reported 43 percent mortality among 21 patients supported with ECMO as a bridge-to-transplant. The ELSO registry reported similar data, with 51 percent mortality for pediatric patients supported with ECMO prior to transplantation.[16]

Data from a large single-institution study from CHOP had comparatively better outcomes. These authors described 31 patients supported with ECMO as a bridge to cardiac transplantation.[17] No difference in long-term survival was found between heart transplant recipients who were supported with ECMO prior to transplant versus those who

were not. Of the 31 patients, 6 had sufficient recovery of function to be weaned from ECMO and discharged home ("bridged to recovery"), while 12 of the original 31 ultimately underwent cardiac transplantation. Overall survival to discharge was 48 percent (15 of 31).

The CHOP experience does not support the enforcement of an arbitrary cutoff for duration of support, as they have had several patients survive after more than 250 h on ECMO, including four who were successfully transplanted after 500 h of support and one who survived 1126 h before transplant. Furthermore, as others have reported, pre-ECMO cardiac arrest was not associated with poorer outcome.[18–20]

For patients requiring ECMO after cardiac transplantation, Kirshbom and coworkers[17] reported 22 percent survival to discharge in those patients requiring support soon after transplantation as compared to the three patients who required support in the late period; two of the latter survived to discharge. They concluded that ECMO can be an effective tool for management of the peritransplant patient.

Morales and colleagues reported the initial multicenter experience with the Berlin Heart EXCOR ventricular assist device in 73 patients from 17 institutions.[14] VA-ECMO was used as a bridge to EXCOR in 22 patients (33 percent). Though the overall mortality for the cohort was high at 24 percent, patients supported with ECMO prior to device implantation were not an increased risk for death. ECMO was therefore used successfully as a bridge-to-bridge in these patients. ECMO could also be applied as a "bridge-to-decision" in neonates in whom the decision to proceed with EXCOR implantation or heart transplantation is unclear for social, neurologic, infectious, or other reason. This is similar to the paradigm for application of short-term mechanical circulatory assist devices in older patients and adults.

## Rapid or Resuscitative Extracorporeal Membrane Oxygenation (eCPR)

*eCPR* refers to the application of ECMO as an immediate life-sustaining therapy in the setting of cardiopulmonary arrest. Most centers consider activation of an eCPR protocol after 10 min of resuscitation, or after two rounds of "code" drugs have been administered without success.[21] John Gibbon, the pioneer of CPB, speculated in 1939 on the ability of a heart–lung machine to temporarily take over the function of the heart and lungs during a period of deterioration and provide a time interval for the recovery of organ function, leading to potential survival.[22] eCPR has evolved from early reports of use following myocardial infarction, pulmonary embolism, and other emergency conditions.[23–26]

The acceptance of eCPR as a viable therapeutic intervention has been largely based on the study by Duncan and colleagues,[27] demonstrating that patients cannulated for eCPR had equivalent survival to patients cannulated for conventional cardiac ECMO. Its current form is the result of a slow iterative approach in the design and development of both the equipment and management principles over the past 20 years.

Though specific components may differ among institutions, successful application of eCPR generally requires the coordinated 24-hour involvement of surgical, nursing, perfusion, and ICU staff, as well as a modified ECMO circuit that can be primed and deployed rapidly (ideally within 15 min). A state-of-the-art rapid deployment circuit ideally would include a preassembled completely heparin-coated (Carmeda® Bio-Active Surface) surface, a centrifugal blood pump, a new-generation hollow-fiber oxygenator such as the Quadrox® or Minimax® oxygenator (approximately 250 mL priming volume), a Bio-Probe flow probe, and a BioTrend Oxygen Saturation and Hematocrit monitor. The entire circuit can be assembled and primed in under 5 minutes.[28] eCPR usually necessitates institution of VA-ECMO, with cannulation sites individualized to anatomy and postoperative status, and often patients are actively cooled for 48 hours to 34°C to lower metabolic demands and provide central nervous system (CNS) protection. Based on current literature, it is unclear whether the duration of conventional CPR should limit the application of ECMO. A recent study from Kane et al. showed no difference in survival based on conventional CPR duration.[21] Further, there are data demonstrating survival even after prolonged (>95 minutes) CPR.[29,30] On the other hand, however, a study by Sivajaran et al.[10] showed a clear survival disadvantage in patients undergoing ≥30 minutes of conventional CPR. It is also likely that other risk factors such as high lactate levels or low arterial pH, which have more consistently been uncovered, could be surrogates for prolonged conventional CPR duration. Neurologic status is intuitively influenced by prolonged CPR, and further studies will be required to elucidate optimam timing and prognostic factors implicit in these outcomes.

Despite the controversies regarding the specific criteria and development of eCPR protocols, there is clear evidence that eCPR is a useful and important strategy to salvage patients who would otherwise die. The study by Kane et al.[21] from Boston Children's Hospital reported their outcomes in 172 patients with cardiac disease undergoing eCPR between 1995 and 2008. They reported a laudable 51 percent survival to discharge, which was independent of anatomy, CPR duration, and location of cardiac arrest. Importantly, 75 percent of the survivors had either no or mild neurologic impairment as measured by pediatric overall performance category (POPC) and pediatric cerebral performance category (PCPC) scores ≤2. Data from another large series at the Hospital for Sick Children in Toronto,[30] which included prolonged conventional CPR duration of up to 95 minutes, also demonstrated the efficacy of eCPR, with 30 percent survival. These authors concluded that the lack of consistent poor prognostic factors in eCPR should prompt aggressive application of resuscitative ECMO in all patients without obvious contraindications. Institution of an eCPR protocol, as mentioned previously, requires a tremendous amount of resources, personnel, as well as a dedicated iterative approach to refining deployment. An additional caveat is that centers offering eCPR should possess both transplant and longer-term mechanical

circulatory assistance capabilities as an important (up to 11 percent) of eCPR patients will eventually require one of these exit strategies.[21,30]

## PATIENT SELECTION AND TIMING OF VENOARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

Defining which patients are appropriate candidates for cardiac ECMO support is complicated, and is evolving as the utilization of cardiac ECMO increases. Specific conditions including incurable malignancy, advanced multisystem organ failure, extreme prematurity, and severe neurologic or CNS damage constitute absolute contraindications for the application of mechanical support.[31]

Based on univariate and multiple logistic regression analysis of retrospectively collected data in 218 patients, Trittenwein and colleagues proposed inclusion criteria related to lactate and central venous oxygen saturations.[32] We believe that such criteria are too narrow and not universally applicable. As mentioned above, establishment of rigid inclusion and/or exclusion criteria is problematic; each case requires thoughtful consideration on an individual and institutional basis.

Timing of initiation of ECMO is critically important. Low-cardiac-output syndrome (LCOS)[33,34] is common to most scenarios in which cardiac ECMO is considered. Clinically, LCOS manifests as poor peripheral perfusion, oliguria, and lactic acidosis despite adequate intravascular volume and often elevated filling pressures. Mixed venous oxygen saturations are low, secondary to decreased oxygen delivery. After correcting for anemia, hypoxia, or obstructive cardiac disease, traditional therapy for this type of cardiogenic shock focuses on maximizing pharmacologic support. Usual agents act through a variety of mechanisms, but most cause an increase in biventricular afterload and heart rate. The net effect is to increase myocardial work and oxygen demand in a setting where myocardial oxygen supply is already compromised. This can exacerbate injury and delay or even prevent myocardial recovery. With ECMO, unloading the heart and decreasing its work creates an environment that is more favorable for repair and recovery.[35] In effect, earlier institution of mechanical support helps to ensure adequate perfusion of the heart, brain, kidneys, and other vital organs while minimizing ongoing myocardial insult and enhancing recovery. Most recent reports have documented better outcomes in those patients placed on ECMO in the OR as compared to those cannulated in the ICU.[11,18,36] Along these lines, Shen et al. reported 87 percent hospital survival in 23 patients who were routinely converted directly from CPB to VAD support in the OR after undergoing the Norwood procedure.[37] Although many of these patients would likely have survived without circulatory support, the authors assert that some patients might have otherwise developed acute heart failure and therefore benefited from early implementation of mechanical cardiac assistance, especially in the setting of hypoxemia that is associated with all Norwood patients. Research has demonstrated that in the setting of hypoxemia, the brain is extremely vulnerable to diminished cerebral oxygen delivery that can accompany a fall in systemic cardiac output.[38]

Experience with mechanical support of nonsurgical heart failure also merits consideration. In their series, Morris and associates report 35 percent survival in the nonsurgical population, which included patients with cardiomyopathy and myocarditis.[9] Marx and coworkers have reported 67 percent survival in patients supported with ECMO for acute myocarditis and 62 percent survival in patients with cardiomyopathy. Duncan and colleagues report 83 percent survival in 12 pediatric patients with myocarditis who were placed on ECMO.[34] Of their overall population (12 ECMO, 3 VAD), 47 percent recovered with return of native ventricular function, and 33 percent survived following successful ECMO bridge to cardiac transplantation.

## COMPLICATIONS ASSOCIATED WITH VENOARTERIAL EXTRACORPOREAL MEMBRANE OXYGENATION

Survival is not the only marker of a successful ECMO run. Long-term sequelae can be considerable and devastating and should bear considerable weight in any discussion of indications and outcomes. Assessment of neurologic insult directly related to cardiac ECMO is difficult due to the many confounding variables. Cyanotic heart disease alone is, as an example, associated with neurodevelopmental abnormalities.[39–42] Similarly, behavioral and cognitive impairment are well-documented in both adults and children following CPB, as are gross and fine motor deficits.[43–45] In addition, follow-up in neonatal respiratory ECMO survivors has revealed neurobehavioral and functional deficiencies.[46–54]

Acute abnormalities have been described in cardiac ECMO patients at the University of Michigan, as 14 percent had seizures and 7 percent had radiographic evidence of injury to the CNS.[18] Hamrick and colleagues report significant long-term impairment in their 11-year experience with infants supported by ECMO following cardiac surgery.[55] Of their 53 patients, 7 of the 14 survivors available for long-term follow-up (13 percent overall) were neurologically completely intact.

Golej and Trittenwein have looked critically at the issue of neurologic impairment associated with cardiac ECMO.[56] They advocate for early recognition and rehabilitation in this at-risk population. As with most advances in CPB and operating room management, monitoring devices and strategies are crossing over into the ICU (bi-spectral index monitoring and near-infrared spectroscopy). However, pre-ECMO intracranial imaging is not as universally possible in cardiac patients as it is in neonates with respiratory failure. In that population, evidence of preexisting intracranial hemorrhage is a contraindication for ECMO. In cardiac ECMO patients, serial cranial ultrasounds are routinely obtained after return to the ICU, but even these studies lack adequate capability to detect anything less than gross hemorrhage or infarct.[55] Refinements in the ECMO circuit and devices have allowed

for relative minimization of anticoagulation needs (discussed later), but the risks of hemorrhage and embolic events remain real and may be even more significant on a microvascular level than is currently appreciated.

## Implementation

Placing a patient on ECMO for cardiac support requires a cohesive team of surgeons, perfusionists, ECMO specialists, nurses, and cardiac intensivists. Though conceptually simple, ECMO cannulation is fraught with potential technical complications that are magnified by critical patient condition and need for expeditious completion. Experience and vigilance therefore are critical to ensuring optimal outcomes.

## Cannulation

The cannulation strategy for ECMO must be based on the type of support to be provided (VA-ECMO vs VV-ECMO), the age and weight of the patients, and underlying structural or functional cardiac abnormalities. When providing complete cardiopulmonary support (VA-ECMO), the arterial cannula is generally introduced into the ascending aorta, right common carotid artery, or either femoral artery. Other cannulation sites occasionally may be used depending on unique anatomic considerations. The importance of proper cannula selection and quality of the cannulation to successful ECMO support cannot be overemphasized. The right common carotid artery is generally the ideal site for peripheral arterial cannulation in neonates and infants because of the vessel's diameter and the fact that relatively direct access to the right atrium makes the right internal jugular vein the optimal site of venous cannulation. The optimal cannula size must take into consideration the size of the carotid artery and the projected amount of blood flow through the cannula. Cannulation with an oversized cannula should be avoided to prevent injury to the carotid endothelium or complete and catastrophic vascular disruption. The cervical arterial cannula is inserted into the common carotid under direct vision using a limited neck incision. The cannula is advanced so that the tip lies at the base of the innominate artery. It is important to avoid advancing the cannula too far into the aorta to prevent partial occlusion of the aortic arch, injury to the facing aortic wall, or retrograde orientation of the cannula into the ascending aorta. The latter puts unnecessary mechanical stress of the aortic valve that may lead to injury to the delicate valve leaflets or valvular insufficiency. When cannulating the carotid artery, the surgeons should consider the potential for carotid reconstruction once ECMO support is discontinued. Although prior neck cannulation does not preclude subsequent use of the carotid artery, occlusion of either carotid artery is an obvious contraindication to cervical arterial cannulation. Carotid artery reconstruction at the time of decannulation can be performed if cannulation techniques are employed that are conducive for this. Several reports have demonstrated very good short- and long-term patency following post-ECMO arterial reconstruction.[57,58] Carotid reconstruction is not performed by all centers and may not always be possible. There are no data demonstrating an advantage with respect to long-term neurologic function in patients with as opposed to without carotid reconstruction. Long-term neurologic outcome may be more related to the condition of the patient at the time of initiation of ECMO, as well as to other factors related to their underlying condition (such as hypoxemia and adequacy of cerebral blood flow). Despite the lack of conclusive data, carotid reconstruction has advocates and is generally recommended if feasible. Direct cannulation of the ascending aorta is generally performed in patients who require emergent circulatory support in the immediate postoperative period. This approach enables the clinician to evaluate the mediastinum for evidence of tamponade and perform direct cardiac massage when needed. The principles of aortic cannulation used during cardiac surgery are applicable to ECMO patients. The site of cannulation should be above the sinotubular junction to avoid injury or distortion of the aortic valve, which may lead to valvular insufficiency. The cannula is secured with a purse-string suture and flexible tourniquet. It is important to direct the tip of the cannula away from the aortic valve while avoiding injury to the back wall of the aorta. Oversizing the cannula or advancing the cannula too far into the aorta may cause a mechanical obstruction to antegrade flow through the aortic arch and can contribute to difficulties in weaning ECMO support before decannulation. Femoral artery cannulation is useful in larger patients and in patients with compromised carotid blood flow. Either femoral artery may be cannulated under direct vision or using percutaneous Seldinger technique. The cannula is advanced so that the tip lies in the descending aorta. We advocate direct suture repair of the femoral artery at time of decannulation to limit subsequent limb morbidity related to vascular insufficiency. In some patients, it may be safer to sew a side graft onto the femoral artery and place the cannula into this side graft. This may be especially useful in patients with small femoral arteries in whom placement of an adequate size cannula would otherwise be hazardous. For example, a 5-mm side graft is large enough to allow insertion of a 14-mm cannula and an 8-mm side graft would easily accommodate a 22-mm cannula. This technique can be extremely valuable in selected cases and greatly reduces the risk of dissection of the femoral or iliac vessels during cannula insertion.

Venous cannulation is generally performed through the right internal jugular vein, either femoral vein, or the right atrial appendage. However, as with arterial cannulation, certain anatomic considerations may require the clinician to adopt unique venous cannulation strategies, such as is seen in patients who require support following superior cavopulmonary (Glenn) anastomosis.

The technique for VA-ECMO jugular venous cannulation involves placing a standard venous cannula into the internal jugular vein, and advancing the tip to the cavoatrial junction. Although this may be performed using the percutaneous Seldinger technique, we prefer to perform venous

cannulation under direct visualization to prevent unnecessary injury to the vascular structures in the neck and chest. We routinely perform jugular vein reconstruction at time of decannulation, though, admittedly, short- and long-term patency rates are poor. Alternatively, femoral venous cannulation may be performed through either femoral vein. We prefer the percutaneous Seldinger technique of cannulation when possible. The femoral venous cannula is advanced until the tip lies within the right atrium. Placement must be confirmed by chest radiography. Cannulation involving both femoral vessels in one leg or either femoral vessel in each leg is possible. Femoral vein reconstruction is generally not necessary after removing a venous cannula. The technique for right atrial cannulation is similar to that used in the operating room for CPB, utilizing a broad-based purse-string situated mostly on the right atrial appendage. A variety of cannulae may be used. Care must be taken to avoid injury to the sinoatrial node or the tricuspid valve during cannulation.

Aortic valve insufficiency and increased systemic arterial pressure may contribute to left ventricular distention, particularly in the setting of poor ventricular function. The subsequent increase in wall tension and myocardial oxygen demand will ultimately impede myocardial recovery. Improper carotid and aortic cannulation can exacerbate this process, by generating a flow jet that is directed toward the aortic valve. When necessary, decompression of the left ventricle may be accomplished in several ways. In the setting of a closed chest, left ventricular decompression may be accomplished by creating, or augmenting, an interatrial communication (Fig. 87-2). When present, a patent foramen ovale can be enlarged at the bedside by balloon septostomy under echocardiographic guidance. Alternatively, blade or balloon septostomy may be performed in the catheterization laboratory, even in the absence of a preexisting interatrial communication. Recently, Cheung et al.[59] have described an alternative method of left heart decompression, utilizing a percutaneous technique for inserting a vent into the left ventricle that is connected to the venous arm of the ECMO circuit. More options are available for decompressing the left heart in cases of an open chest. Since many of these patients are placed on ECMO in the operating room, a cannula can be placed directly into the left atrium and connected to the venous return of the ECMO circuit. This cannula can be placed through the left atrial appendage or in the space between the two right-sided pulmonary veins. Either site is easily accessible and readily visualized in an ICU setting if reexploration for any reason becomes necessary. Alternatively, a surgical atrial level communication by atrial septectomy can be performed, precluding the need for additional cannulae. Irrespective of the technique used, we believe it is important that left ventricular decompression is achieved soon after initiating ECMO support in patients with severely depressed left ventricular function. In addition to decreasing the likelihood of recovery of ventricular function, left ventricular distension may lead to increased left atrial pressure, causing fulminant pulmonary edema to rapidly ensue. In addition, the relative amount of coronary blood flow derived from the ECMO circuit (aortic or carotid cannula) or the lungs (through antegrade flow through the aortic valve) is dependent upon the amount of cardiac support provided by the ECMO circuit. At lower levels of support, the blood delivered to the coronary arteries is predominately derived from the left ventricle, whereas all coronary blood flow is derived from the ECMO circuit during periods of total cardiopulmonary support and the absence of left ventricular ejection.[60] Even at high ECMO flow rates, the coronaries preferentially receive blood supplied by the left ventricle blood. Effective left-sided decompression ensures that adequately oxygenated blood derived from the ECMO circuit will preferentially perfuse the coronaries in the setting of severely depressed lung function. This is an important consideration when weaning ECMO support. Moderate levels of mechanical ventilation must be continued during partial ECMO support and lung function must be adequate to wean ECMO support. Left ventricle decompression can be a source of air being introduced into the ECMO circuit and ECMO technicians need to be aware of this possibility. The decision to utilize left ventricular decompression is one that is dependent on the circumstances of the underlying pathology as well as the experience of the center. Excellent results can be achieved in centers where left ventricular decompression is used sparingly, if at all. In fact, left ventricle decompression in the setting of severe aortic insufficiency may simply set up a "recirculation" circuit and in these cases, ECMO may be contraindicated in lieu of aortic valve replacement or repair.

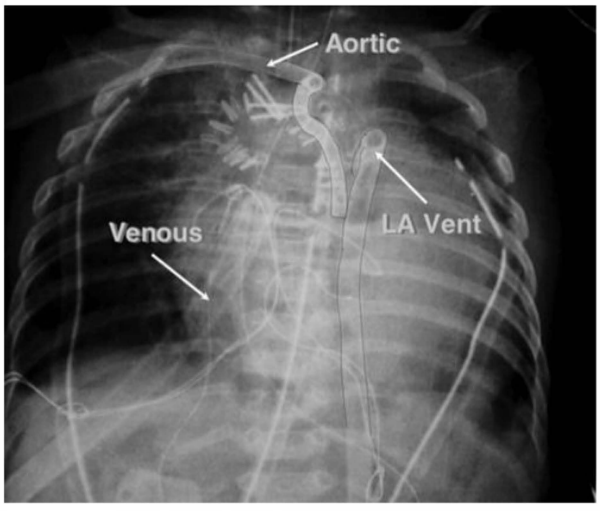

**FIGURE 87-2** Technique for left ventricular decompression.

## Management

Unlike the neonate with isolated respiratory failure, in whom ECMO flows and sweep gases are adjusted to maintain adequate oxygenation and ventilation, the infant or child on cardiac ECMO has cardiac insufficiency, often coupled with

respiratory insufficiency. The degree to which gas exchange is dependent on ECMO will obviously affect the management strategy. For the patient with isolated cardiac failure, ECMO flows are adjusted to ensure adequate end-organ blood flow. Clinical parameters, such as urine output and toe temperature, should be regularly scrutinized and ECMO flows adjusted to maintain adequate perfusion. Laboratory values, including arterial lactate and mixed venous oxygen saturations, are also important and should be followed serially. In general, flows of 100 to 150 mL/kg/min should be adequate to maintain homeostasis. Some circumstances, as in the case of an infant in whom the pulmonary and systemic circulations are in parallel (single ventricle with aortopulmonary shunt), may require considerably higher flows. It has been and continues to be our practice to keep aortopulmonary shunts open and utilize higher flows. Because of the non-pulsatile nature of generally available circuits, arterial waveform tracings may provide an indication of the degree of native cardiac contribution to systemic output. Lack of discernible pulse pressure indicates that the ECMO circuit is responsible for all the effective systemic blood flow. This circumstance can occur when the heart is completely bypassed, when there is "cardiac stun," or in the setting of cardiac failure. It is important to remember that coronary perfusion results from antegrade ejection of blood out the aortic valve, and it is only in the setting of nearly complete lack of cardiac output that coronary blood flow becomes dependent on the oxygen-rich blood returning via the arterial ECMO cannula. Bearing that in mind, it is important to ensure that whatever blood is being ejected out the left ventricle is well saturated, so that the heart does not suffer ongoing ischemia. Ventilator $F_{IO_2}$ should thus be maintained around 40 percent.

Serial echocardiograms can be helpful in gauging improvement in cardiac function, particularly in the setting of right ventricular failure where ventricular geometry and pressures can be assessed. Levels of brain natriuretic peptide (BNP) and cardiac troponin I can be followed serially as well. It is often necessary to reduce ECMO flows to allow cardiac filling in order to make a determination. During periods of flow reduction, systemic blood pressure and perfusion are monitored using the clinical parameters described above. Increases in arterial pulse pressure and perfusion indicate improving cardiac function and should encourage further weaning of ECMO flows. When flows have been sufficiently reduced, echocardiography is favorable, and perfusion is maintained on reasonable levels of inotropes, a trial off ECMO is warranted.

For the patient with combined cardiorespiratory failure, estimation of support needs and weaning preparedness are more complicated. In addition to ECMO flow rate, the sweep gas $F_{IO_2}$ and flow rate are important determinants of respiratory gas exchange. In many instances, restoration of adequate circulation with initiation of ECMO leads to rapid improvement in respiratory mechanics and gas exchange as interstitial and alveolar lung water is cleared. Likewise, restoration of normal arterial oxygen tensions and pH can precipitate significant improvement in cardiac function. In addition to the clinical and laboratory parameters previously discussed, regular monitoring of arterial blood gases is vital. Weaning involves gradual decreases in $F_{IO_2}$, sweep flow rate, and ECMO flow rate coupled with corresponding increases in mechanical ventilatory support. Once the patient can maintain physiologic values on reasonable ventilator settings and inotropes, a trial off ECMO is justified.

### Management of Systemic-to-Pulmonary Artery Shunts

One consideration for cardiac ECMO is how to handle systemic-to-pulmonary artery shunts, either in single-ventricle patients or in those with inadequate pulmonary blood flow. Our practice is to leave all shunts open, especially considering that the vast majority of our patients are peripherally cannulated through a cervical approach. Currently, we would support a patient with a modified Blalock-Taussig shunt on ECMO would be hypoxemia or evidence of a hyperactive pulmonary vascular bed. In both cases, we would employ venovenous ECMO (VV-ECMO) support with a single cannula placed in the internal jugular vein. In this case, the shunt is not affected by the presence of the ECMO cannula. In the case of a palliated HLHS patient, we again would favor VV-ECMO for low saturations. If a patient were in a state of low cardiac output after Norwood repair and required mechanical cardiac assist, we would use VA-ECMO via neck cannulation. However, we prefer the "Sano shunt" (a valveless conduit from the right ventricle to the pulmonary artery), which would not be affected by an arterial neck cannulation.

## VENOVENOUS EXTRACORPOREAL MEMBRANE OXYGENATION

Indications for VV-ECMO in the cardiac population may seem limited. In fact, as experience grows, more clinical applications become apparent. VV-ECMO has several potential advantages over VA-ECMO. First, in many instances only a single venous cannula is required and, obviously, no large-caliber arterial vessels are disrupted and potentially sacrificed. Second, physiologic pulsatile flow is maintained. Third, the pulmonary vascular bed is perfused with oxygen-rich blood. And last, the myocardium is perfused with oxygen-rich blood. The last two features deserve particular consideration as they apply to the cardiac population.

Pulmonary hypertension is a common comorbidity in the pediatric cardiac population.[61] Elevated pulmonary vascular resistance (PVR) and right ventricular dysfunction often lead to significant morbidity and even mortality in the perioperative period. In addition, infants with unrepaired cyanotic heart disease are at particular risk when they acquire common viral respiratory illnesses.[61–64] We have found VV-ECMO to be the ideal mechanical support mode in these settings to improve oxygenation, correct of respiratory acidosis, and reduce PVR. Clinically, the result is increased

pulmonary blood flow, decreased right ventricular strain, better left-sided filling, enhanced myocardial oxygenation, and improved cardiac output. We consistently note rapid decreases in inotropic requirements following the institution of VV-ECMO.

Imamura and associates at Arkansas Children's Hospital report a similar experience in 10 patients placed on VV-ECMO for support in the setting of acute viral pneumonia and another 8 patients with inadequate pulmonary blood flow.[61] In each of these two groups, VV-ECMO served as a bridge to recovery or surgical intervention. Survival to discharge was 95 percent.

## Implementation and Cannulation

Placing a patient on VV-ECMO is less complicated than placing one on VA-ECMO. Options for cannulation strategy with VV-ECMO, as opposed to VA-ECMO, are also greater, in that specialized bicaval cannulae are available that allow simultaneous venous drainage from both the superior and inferior vena cava and reinfusion of blood into the atrium through a third aperture. These cannula are currently available for larger patients (though shortly a wire-reinforced model suitable for neonates under 5 kg will be available), and mitigate recirculation and improve venous drainage. The cannula is inserted through the right internal jugular vein and advanced using echocardiographic guidance, so that the tip lies in or near the inferior vena cava and the side-port is within the atrium.

## Management

The management of VV-ECMO differs from that of VA-ECMO in many ways. Cardiac output is not supported in any way other than the improvement in native ventricular function discussed above. As such, adjustments in ECMO flow rates do not directly affect blood pressure and perfusion. Mechanical ventilation is usually maintained using a lung-protective strategy to minimize airway trauma and optimize lung repair. In addition, adequate lung inflation is necessary to avoid elevations in PVR related to interalveolar capillary collapse (Fig. 87-3). In those patients supported due to inadequate pulmonary blood flow, surgical creation of a palliative shunt or full repair can be accomplished when the patient's physiologic parameters have normalized, making the child a better candidate for anesthesia and/or CPB.

Functionally, pump flow rate, sweep gas flow, and $F_{IO_2}$ are adjusted to achieve the desired oxygen saturations and arterial blood gas parameters. Weaning is attempted when chest x-ray findings and pulmonary mechanics indicate improvement in respiratory function or when PVR and right ventricular function have improved. Sweep flow and $F_{IO}$ are weaned and mechanical ventilator settings increased accordingly. When sweep gas settings are minimized and ventilator settings are reasonable, removal of the patient from VV-ECMO can be tried by capping the gas source. Initiation of a pulmonary vasodilator (iNO, phosphodiesterase inhibitor V) in patients with pulmonary hypertension may facilitate the transition from mechanical support.

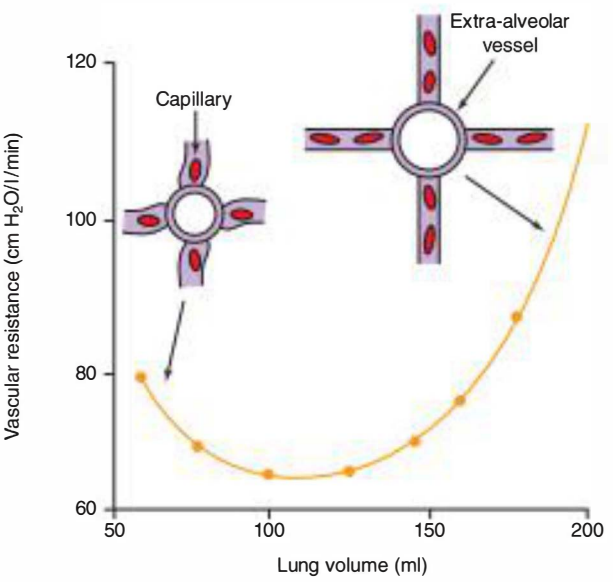

**FIGURE 87-3** Pulmonary vascular resistance in relation to lung volume. Pulmonary vascular resistance is at its nadir when the lung is at functional residual capacity (FRC). In settings of either atelectasis or overdistention, pulmonary vascular resistance increases.

## Anticoagulation

During open cardiac surgical procedures, the patient's entire blood volume is exposed to both the bypass circuit and the surgical wound, both of which stimulate activation of all blood elements involved in the inflammatory cascade.[65] Patients placed on ECMO following cardiac surgery continue to be exposed to a large biomaterial surface with its attendant complications. Over time, equilibrium can eventually be established between the activation and neutralization of inflammatory blood elements and this equilibrium is essential for continuation of ELCS. Most of our understanding of the activation of blood components comes from experience with intraoperative CPB, although there is a growing body of literature specific to ECMO.

Once blood contacts the ECMO circuit, plasma proteins are instantly adsorbed onto all nonendothelial surfaces.[66–68] These proteins are tightly packed, irreversibly bound, and stationary.[68] Fibrinogen is adsorbed by the hydrophobic surface of these biomaterials.[66] This surface will eventually stimulate clot formation and activate blood elements, including five plasma protein systems (contact system, intrinsic coagulation pathway, extrinsic coagulation pathway, fibrinolysis, and complement) and five blood cell types

(platelets, endothelial cells, neutrophils, monocytes, and lymphocytes).

Platelets adhere to the ECMO circuit and become activated, causing them to degranulate and release substances that in turn activate even more platelets.[69] Thrombin is generated by the coordination of the plasma protein systems and further activates platelets. Platelets change shape by extending pseudopods and begin to express GPIIb/IIIA receptors, which bind platelets, using fibrinogen as a bridge.[70] Adherent platelets will detach and fragment, leading to a decrease in the number of normal platelets in the circulating pool.[71] The activation of the coagulation system is not limited to activity within the ECMO circuit, as patients may develop systemic disseminated intravascular coagulation (DIC).

In addition to the impact of the circuit, the exposure of circulating monocytes to the surgical wound will potentiate the activation of the coagulation system. Monocytes will elaborate tissue factor and continue the activation of the intrinsic and extrinsic coagulation pathways.[70] Although this is usually of a self-limited nature in open cardiac procedures, it can have a protracted effect in patients who require transthoracic cannulation for ECMO.

The activation of the coagulation system from exposure to the ECMO circuit and the surgical wound makes anticoagulation a necessity. However, it can be exceedingly difficult to achieve the delicate balance between appropriate anticoagulation and hemorrhage control in postoperative cardiac surgical patients. The ideal anticoagulant would inhibit platelet activation and aggregation as well as activation of the coagulation cascade but would maintain enough procoagulant properties to allow for coagulation at the surgical site. Traditionally, heparin has been the most commonly used anticoagulant for all forms of ECLS, although it is far from an ideal agent.

Heparin inhibits thrombin and factor Xa generation, requiring normal levels of circulating thrombin and accelerating its action approximately 1000 times. Heparin's effects can be blocked with protamine, enhancing its attractiveness. However, heparin does not have any effect on platelet activation and does not inhibit the generation of thrombin merely its activity. Large doses of heparin are routinely required during ECMO, mainly due to inactivation of the heparin molecule by mechanisms in both blood and the circuit, which eliminate more than half of the administered heparin.[72] Of additional growing concern is the recent increase in awareness of allergic reactions to heparin, manifesting as heparin-induced thrombocytopenia (HIT).

The majority of ECMO centers continue to follow *activated clotting times* (ACT) to titrate heparin therapy. ACT is a crude measure of the effect of heparin on whole blood, but its ease of use in point-of-care testing makes it the preferred method. Prior to cannulation, patients not already anticoagulated require an initial heparin bolus (usually 75 to 100 U/kg), which is followed by a continuous infusion to maintain the ACT between 180 and 220s. Postoperative patients will usually require the lower end of the range and may not receive much heparin at all in the first 24 to 48 h in order to promote hemostasis at the surgical site. Other agents and techniques may be on the horizon, including a reduction in circuit thrombogenicity and the development of alternative selective anticoagulants.

Argatroban is a potent, reversible, direct thrombin inhibitor that has been suggested as an alternative therapy in patients who develop heparin sensitivity. In laboratory experiments, Argatroban is associated with absence of clot initiation and a decrease in thrombin generation, raising its potential as a heparin alternative.[73] Its use has been reported to facilitate CPB in a heparin-sensitized infant undergoing tricuspid valve removal secondary to bacterial endocarditis.[74] Recent reports from the Oregon Health Sciences University have noted the successful use of argatroban in ECMO patients with probable HIT.[75]

Nafamostat mesylate is a broad-spectrum protease inhibitor that suppresses activation of contact proteins during ECMO.[76] It has been shown to reduce heparin requirements and resulted in a shorter ACT in the patient than the ECMO circuit.[77] Use of this agent during CPB has been shown to reduce postoperative blood loss.[78] A 1997 study by Nagaya and colleagues used nafamostat in 12 newborns that had hemorrhagic complications before or during ECMO.[77] The ACT of the blood delivered to the patient was reduced by 27s compared to the circuit ACT and was associated with control of bleeding in 66 percent of the patients.

As previously discussed, heparin-bonded circuits have been developed using covalent (Cardmeda systems, described above) and ionic bonding (Duraflo II, Baxter) techniques. Heparin bound to the surface exerts an antithrombin-mediated inhibition of thrombin and factor Xa. The thrombin–antithrombin complexes bind to the surface without functionally blocking the activity of the immobilized heparin and serve to decrease exogenous heparin requirements.[69] A laboratory investigation of heparin-coated and uncoated systems was performed by Urlesberger and coworkers.[79] They found that coagulation system activation and D-dimer formation were significantly delayed in the heparin-coated group. After 6 h, no differences between the groups were detected, and after 24 h, markers had returned to near baseline values. The authors concluded that these circuits may provide only limited advantages in long-term ECMO use. However, they do offer benefits to those patients with a high bleeding risk, as they allow for less systemic heparinization.

Protease inhibitors, such as aminocaproic acid (Amicar), function primarily through inhibition of the fibrinolytic system and to a smaller extent by inhibition of the coagulation system. They have been shown to significantly reduce the requirements for blood products during CPB. A 1993 study reported a decrease in the incidence of intracranial hemorrhage and other hemorrhagic complications in patients on ECMO treated with Amicar.[80] In addition, Amicar's use is widely reported in the cardiac ECMO literature as an adjunct for postoperative patients with significant postoperative bleeding.[81] The caveat, however, is that Amicar will likely shorten the life expectancy of the ECMO circuit.

## FEEDING

Critically ill patients on ECMO typically have significant nutritional requirements. In fact, neonates on ECMO have demonstrated some of the highest rates of protein catabolism reported.[82] Postoperative cardiac surgical patients have the added burden of wound healing, which further increases their nutritional needs. Therefore, provision of adequate nutritional support in this population must be predicated on a clear understanding of these patients' perturbed metabolic state. Current guidelines published by the American Society for Parenteral and Enteral Nutrition recommended that nutritional support, consisting of 100 to 120 kcal/kg/day and protein of 3 g/kg/d), be initiated as soon as possible for neonates on ECMO.[83] Parenteral nutrition has traditionally been the primary source of calories for patients on cardiac ECMO because of the risk of impaired splanchnic perfusion and bacterial translocation in the setting of cardiopulmonary failure. However, enteral feedings have been shown to be beneficial by maintaining gut mucosal integrity, improving gastrointestinal immunologic function, and reducing septic morbidity.[84–88] The current guidelines support initiating enteral feeding once the patient has stabilized and gastrointestinal function is thought to be normal. Parenteral nutrition should be continued until the enteral feeds have been uptitrated to goal. Although there are no studies focusing exclusively on cardiac ECMO patients, a recent large retrospective study in neonates on ECMO demonstrated tolerance of enteral feeding without serious adverse events.[84] In that study, 67 of 77 VA-ECMO patients received enteral feedings. Dopamine infusion was administered to 80 percent of these patients, with a median dose of 7 μg/kg/min and a maximum dose of 20 μg/kg/min. Three patients were on both dopamine and dobutamine, and four patients received both dopamine and epinephrine. The patients on inotropic support did not have an increase in the rate of retained feedings or adverse outcomes. Another series retrospectively compared 13 patients on ECMO receiving total enteral nutrition to 14 matched patients receiving parenteral nutrition. These authors found that enteral nutrition was well tolerated without complications.[89] Administration of intravenous lipids in association with parenteral hyperalimentation for patients on ECMO raises particular concerns related to their effect on the extracorporeal circuit. In an in vitro analysis, a fat emulsion was infused into ECMO circuits at a rate of 3 mL/h.[88] All circuits showed layering (separation of fat emulsion from blood) and agglutination at 24 h. Adhesion of the emulsion to the circuit was evident in all samples. This study, along with anecdotal experience at many other ECMO centers, suggests that fat emulsions should be infused through separate intravenous sites whenever possible.

### Immune Prophylaxis

Some centers routinely utilize immunosuppressive agents prior to initiation of ECMO and during subsequent circuit changes. This practice has intuitive appeal due to the inflammatory cascade that is triggered upon exposure of the patient's blood components to the foreign surfaces of the ECMO circuit. Griffin and colleagues recently published a randomized, double-blind, controlled trial of dexamethasone versus placebo in infants placed on ECMO for respiratory failure.[90] They randomized 59 infants to either group and noted significant improvement in lung injury scores in the dexamethasone arm versus the placebo arm on day 3 of ECMO. However, they did not find a significant difference in outcome between the two groups, as the mean ECMO duration was 143.5 hours in the dexamethasone group and 160 hours in the placebo group. Therefore, although steroids may ameliorate some of the inflammatory response, their effect on long-term outcome is less certain.

Hypothermia is routinely utilized in CPB and appears to play a role in modulation of the immune response to the CPB circuit. Recent laboratory investigations have noted the role of hypothermia in altering the activities of neutrophils, which have been shown to be associated with decreased endothelial adherence and decreased release of L-selectin from the bone marrow in the setting of hypothermia.[91–93] These data are intriguing and suggest a new area of focus as investigators pursue ways to minimize the immunologic response to ECMO.

## EQUIPMENT

The typical ECMO circuit comprises three main parts: a pump, an oxygenator, and a heat exchanger. Additional components include the tubing to transport the blood and other pieces of equipment that serve as monitoring devices and ensure safe operation of the ECMO circuit. Regardless of the type of ECMO utilized, the basic principles of the circuit remain the same (Fig. 87-4). Deoxygenated blood is removed from the patient, accelerated in a pump, oxygenated, heated, and then returned to the patient. Tubing size, oxygenator volume, and requisite flow rates will differ based on patient size; these variables have hematologic and immunologic implications for the patient. Platelet consumption will increase in proportion to the surface area of the membrane lung (within the oxygenator), activating the immune response.[94] Neonatal circuits may require the equivalent of twice the patient's circulating blood volume to prime, while in an adult the circuit priming volume may represent only half the circulating blood volume.[95,96]

The following sections discuss details related to pumps, oxygenators, heat exchangers, tubing, and safety and monitoring devices.

### Pumps

First developed by Gibbon, the standard roller pump (Fig. 87-5) has been the device most widely used for ECMO over the past 30 years. Its popularity is based on the fact that

**FIGURE 87-4** ECMO circuit.

it is a relatively inexpensive, predictable device with a simple design that responds well to servo-control. Blood flow is generated by the compression of the tubing that forces blood forward ahead of the moving roller. As one end of the roller completes its compressive phase, the other end is just beginning. Compression is carefully adjusted to be just nonocclusive in order to generate forward flow and minimize hemolysis and tubing wear.[97] However, this device does have the following significant limitations. It is dependent upon gravity drainage from the venous system to maintain adequate inflow pressure. It requires continuous servoregulation and pressure monitoring to prevent the development of excessively negative or positive pressure within the circuit. Excessive negative circuit pressure may result in cavitation, causing air to be drawn out of solution. Furthermore, excessive negative pressure may result in hemolysis or damage to venous and/or atrial structures near the site of cannulation.[94] An in-line bladder is generally utilized to assist in monitoring and servoregulation of the ECMO circuit to prevent excessive negative pressure. Excessively elevated circuit pressure may result in circuit rupture. When the system is compromised, the roller pump has the potential to pump a large volume of air, leading to massive air embolism. Long-term use of the roller pump may cause spallation of the tubing within the pump housing, potentially resulting in embolization of particulate matter or even complete circuit rupture due to repetitive occlusions.

Owing to the concerns with roller pumps, attention has been refocused on centrifugal pumps. These pumps (Fig. 87-6) use rotating cones activated by a forced vortex pumping action. These pumps cause less trauma to blood elements, although fibrin deposits in the pumping chamber can limit their useful life to 5 to 7 days.[98] Unlike the

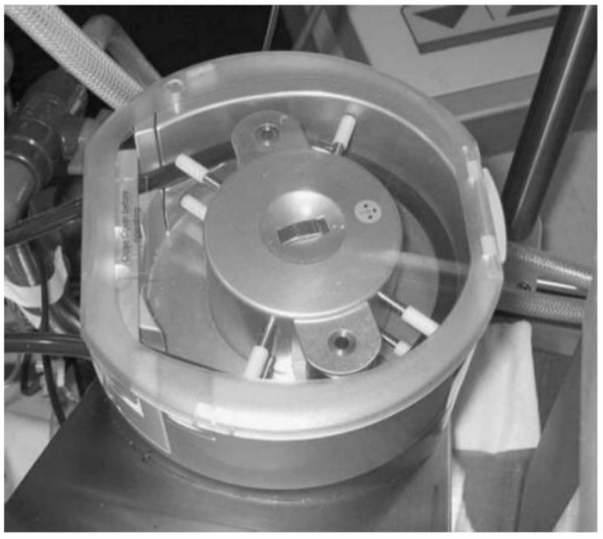

**FIGURE 87-5** Roller pump.

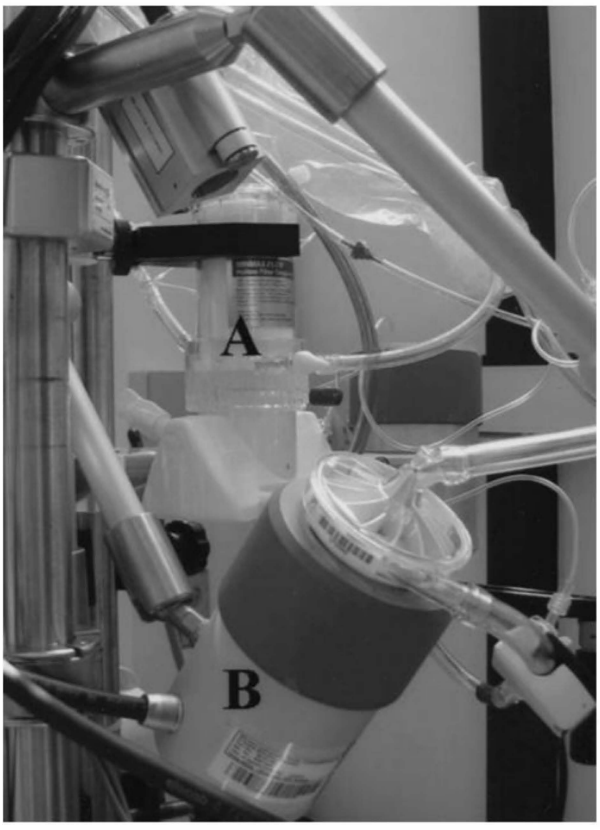

**FIGURE 87-6** **A.** Hollow-fiber oxygenator. **B.** Centrifugal pump.

case with roller pumps, inflow here is gravity-independent, allowing the pumps to be placed at any height. The pump is sensitive to preload and afterload, either of which will affect pump flow. Unlike roller pumps, centrifugal pumps will come to a stop when they have entrained a large amount of air. Centrifugal pumps, however, can generate large negative pressures, which may lead to cavitation and hemolysis. The development of newer hollow-fiber oxygenators such as the Quadrox, which have less resistance, interface much better with centrifugal pumps. An ECMO circuit consisting of a centrifugal pump coupled with a hollow-fiber oxygenator is rapidly becoming the preference of larger ECMO centers.[28]

## Oxygenators

The artificial oxygenator functions like a lung, adding oxygen to the circulating blood and removing carbon dioxide. An ideal extracorporeal lung should be noncompliant, so that blood volume remains constant, thus minimizing the risk of thrombosis and hemolysis.[94] In modern oxygenators, blood flows into a manifold region, from which it disperses to the microporous fibers of a *hollow-fiber oxygenator*. Oxygenated gas flows through the device in countercurrent to the flow of blood. Oxygen diffuses across the membrane into the blood and carbon dioxide is eliminated. Because of the high carbon dioxide diffusing capacity of these devices, in some instances carbon dioxide may actually need to be added to the gas mixture in order to normalize the patient's arterial blood gas. Oxygen does not diffuse as readily and is limited by the time period that the hemoglobin molecule is in transit through the oxygenator. As a result, oxygenators are limited in their oxygenating capacity based on the pump flow rate and are differentiated by the threshold rate above which the oxygenator is no longer able to increase the saturation of venous blood from 70 to 95 percent.[99]

Oxygenators are susceptible to clot formation, collapse, edema, hemorrhage, and thrombosis.[99,100] Ventilation/perfusion mismatching can ensue. Water, plasma, and blood may collect in the gas phase of the oxygenator and decrease the rate of carbon dioxide exchange. Accordingly, $P_{CO_2}$ can be a sensitive indicator of edema accumulation, which results in a decrease in the functional gas-exchange surface.[94]

Hollow-fiber oxygenators have low internal resistance, which allows them to be coupled with centrifugal pumps. These devices utilize microporous capillaries, around which blood flows and contacts the ventilatory gas. Advantages include low resistance and low priming volumes (as low as 250 mL). Disadvantages include a propensity for plasma leakage (exacerbated by intralipid use) and undesired ultrafiltration.[94] New-generation hollow-fiber oxygenators, such as the Quadrox®, appear to be less susceptible to these shortcomings.[102–108] Motomura and colleagues have achieved stable gas performance with minimal plasma leakage over a 2-week period of use.[108] With continued improvements in technology, hollow-fiber oxygenators are increasingly be used with ECMO and are encouraging a shift toward centrifugal pumps.

## Heat Exchangers

The *heat exchanger* is the last part of the circuit through which the blood passes en route back to the patient. Structurally heat exchangers are composed of silicone-coated stainless steel tubes that allow warm water to flow outside the ECMO circuit in a countercurrent fashion. Blood is heated as it flows vertically from the upper to lower portion, permitting air bubbles to be trapped in the upper section.[100] Heat exchangers are particularly important in the management of neonatal patients due to their propensity for temperature instability. Device failure occurs in some 1 to 2 percent of ECMO cases.[109] Most commonly, failure is due to the leakage of water from the connectors at the top and bottom of the device. Leakage of blood is uncommon and, because of the higher pressure in the ECMO circuit, leakage of water into the blood phase is even less common.[100]

## Tubing

Circuit tubing has improved significantly since the advent of ECMO 30 years ago. Most of the circuit consists of polyvinyl chloride tubing, a readily available and relatively inexpensive product. One potential disadvantage with polyvinyl chloride tubing has been the release of the plasticizer di(2-ethylhexyl) phthalate (DEHP), which animal studies show may result in decreased fertility, reduced sperm production in males, and ovarian dys-function.[110–112] However, a 2004 study by Khodayar and associates found that adolescents exposed to DEHP as neonates on ECMO showed no adverse effects on their physical growth, maturation, or liver, thyroid, renal, and gonadal function.[113]

Polyvinyl chloride tubing, however, is not durable enough for the "raceway" the portion of the circuit passing through the roller pump. Instead, most ECMO centers currently utilize Super Tygon tubing, S-65 HL, in the raceway, as it is more resistant to rupture and has been shown to minimize spallation (fragmentation and release of microparticles from plastic). Heparin-bonded circuits have been developed in an effort to reduce thrombotic complications (see the discussion of anticoagulation, below). The Carmeda Bioactive Surface (CBAS; Carmeda, Stockholm, Sweden) is a covalent endpoint bonding coating that attaches the heparin molecule to the plastic while the antithrombin-binding site remains exposed.[114] Systemic heparin requirements are significantly reduced in heparin-bonded circuits versus nonheparin-bonded circuits.[115,116] In addition, the Carmeda coating has been shown to reduce DEHP leakage from polyvinyl chloride tubing.[117]

## Cannulae

Appropriate choice of cannulae is critically important to maximize ECMO efficiency and limit hemolysis. The size of cannulae used is based on patient body weight and the size of the vessels to be cannulated. Several types of cannulae are

currently used for ECMO. Each type of cannula is associated with distinct advantages and disadvantages; there is no perfect cannula. Arterial cannulae (VA-ECMO) are available in sizes ranging from 8F to greater than 23F to accommodate vessels ranging from even the smallest carotid artery to an adult ascending aorta. Because they are essentially incompressible and resist kinking, wire-reinforced cannulae are especially well suited for ECMO. Smaller arterial cannulae are often packaged with a specialized stylet to facilitate cannulation of small vessels. Venous cannulae used for VA-ECMO contain multiple fenestrations to improve venous return to the circuit. Some cannulae feature a malleable distal tip that enables the cannula to be tailored to the unique geometry of the heart during chest cannulation. Larger diameter, dual-lumen cannulae are designed to allow VV-ECMO support through a single cannulation site.

## Safety and Monitoring Devices

### BLADDER RESERVOIR

A recent survey by Lawson and coworkers found that 92 percent of American ECMO centers utilize a bladder reservoir (Fig. 87-7) in the ECMO circuit.[101] The bladder is situated just proximal to the pump and serves a variety of functions. Aspiration ports associated with the bladder allow for the removal of any air that may have inadvertently been introduced into the circuit. Likewise, the bladder provides access to the circuit whereby medications, infusions, blood products, and volume may be administered. Last, prebladder pressures are routinely measured via a transducer and provide a quantifiable estimate of the venous return pressure (volume). Servoregulated pumps will decrease and even shut off flow as the bladder pressure approaches or falls below a critical value.

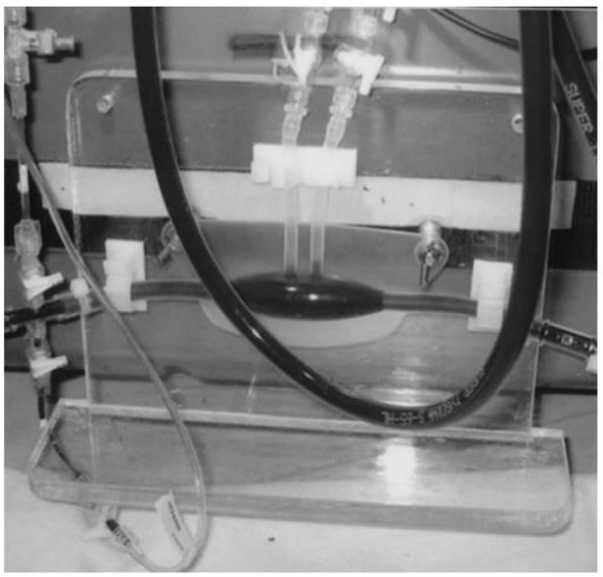

FIGURE 87-7 Bladder reservoir.

A small volume bladder is frequently incapable of handling large flow rates and pressure (volume) fluctuations associated with older patients. In this situation, the ECMO circuit may incorporate a parallel segment of tubing to allow blood to bypass the bladder and be diverted directly into the pump.

### PRESSURE TRANSDUCERS

Circuit pressures are usually monitored prebladder ("inflow") and between pump and patient ("line").[118] Pre- and postoxygenator pressures are usually monitored in an effort to detect distal circuit (especially within the oxygenator) thrombosis and/or tubing kinking, both of which could lead to catastrophic circuit rupture if uncorrected.[94] Isolated increases in preoxygenator pressure in the setting of a normal postoxygenator pressure indicates thrombosis within the oxygenator, and is an early harbinger of oxygenator failure. Generally speaking, a rising pressure gradient across an oxygenator predicts oxygenator failure. There is a greater risk of circuit disruption when preoxygenator pressures are above 400 mm Hg, probable when they are above 500 mm Hg, and imminent when the pressure exceeds 600 mm Hg.[94]

### BUBBLE DETECTORS

Bubble detectors are an added safety precaution, and are usually incorporated into the circuit near the site of patient inflow.[101] Although the bladder, oxygenator, and heat exchanger all scavenge large bubbles, making air-embolism unlikely, bubble detectors typically have automatic shutoff switches and serve as a last check before blood returns to the patient.[119] Once the circuit shuts down, the air bubbles rise to the top of the heat exchanger, where they can be removed through distal circuit aspiration ports.

### THE BRIDGE

A segment of tubing, referred to as "the bridge," usually connects the arterial and venous limbs of the ECMO circuit. Its main function is to allow the patient to be temporarily removed from the ECMO circuit during a trial off support or during an emergency. In such an instance, the bridge is unclamped and the proximal arterial and venous lines are clamped. The patient is thereby excluded from the circuit and blood can continue to circulate within the ECMO circuit. During normal ECMO operation, the bridge remains clamped but must be "flashed" every 20 to 30 minutes to prevent stagnation and possible thrombosis within that segment. Flashing of the bridge has been associated with an initial decrease and then a secondary increase in mean arterial pressure and mean left carotid artery blood flow.[120] Cerebral oxygen delivery is decreased because of this arteriovenous shunt, which may lead to an increase in cerebral oxygen extraction and vasodilatation and eventually an increase in cerebral blood volume and excess cerebral oxygen delivery.[121]

Reperfusion injury, with free-radical formation, could occur in this setting and potentiate or cause cerebral injury.

Experimental work done by Totopally et al. suggests that leaving the bridge open throughout normal ECMO support reduces fluctuations in systemic arterial pressure caused by flashing the bridge. However, this is not routine practice.[122]

## CONCLUSIONS

Exciting advances in extracorporeal membrane support equipment, techniques, and experience have led to the expansion of its use in the pediatric cardiac population. Consideration of earlier initiation of support is warranted based on outcomes reported in the literature as well as the theoretical advantage of avoiding multiorgan dysfunction associated with LCOS. Furthermore, improved myocardial repair and recovery is possible when demands on the failing heart are decreased. Nevertheless, thoughtful, realistic consideration of the myriad clinical and programmatic issues associated with cardiac ECMO must be pursued on an individual case basis to ensure its judicious use and to avoid application of futile or heroic care.

## EXTRACORPOREAL MEMBRANE OXYGENATION IN PEDIATRIC CARDIAC CARE BOARD REVIEW QUESTIONS (CHAPTER 87)

1. Which is not a risk factor for mortality on VA-ECMO?
   A. Age less than 1 month
   B. Male gender
   C. Duration of mechanical ventilation prior to initiation of support
   D. Single ventricle physiology
   E. Hepatic dysfunction

2. Which is true for VA-ECMO as bridge to transplantation?
   A. Mortality approaches 50 percent.
   B. There is lower survival compared to recipients not requiring VA-ECMO.
   C. Overall survival to discharge is 70 percent combining transplant recipients and patients bridged to recovery.
   D. Pre-ECMO cardiac arrest is not associated with poorer outcome.
   E. Mortality with the Berlin Heart EXCOR is about 10 percent.

3. Which is correct regarding surgical technique for ECMO?
   A. The right common carotid artery is the preferred site for arterial cannulation in neonates and infants.
   B. The tip of the arterial cannula should lie in the ascending aorta.
   C. Carotid reconstruction has been shown to improve long-term neurologic function.
   D. If the femoral artery is used, the tip of the cannula should lie in the iliac artery.
   E. The tip of the venous cannula should lie well into the right atrium.

4. Which is true for VV-ECMO?
   A. Two cannulae are preferred.
   B. Physiologic pulsatile flow is eliminated.
   C. The pulmonary vascular bed is perfused with oxygen-rich blood.
   D. The myocardium can be at risk for poor oxygenation.
   E. The lungs are collapsed.

5. Which is true regarding anticoagulation for ECMO?
   A. Heparin inhibits the generation of thrombin.
   B. The ACT is maintained between 250 and 300 s.
   C. Heparin-bonded circuits delay activation of the coagulation system for up to 48 h.
   D. Amicar decreases the incidence of intracranial hemorrhage.
   E. Nafamostat does not reduce heparin requirements.

## ANSWERS

1. **Answer: D.** Single ventricle physiology is not a risk factor for mortality on VA-ECMO. Age less than 1 month, male gender, duration of mechanical ventilation prior to initiation of support, renal dysfunction, and hepatic dysfunction are all risk factors.
2. **Answer: A.** Mortality is 40 to 50 percent for VA-ECMO as a bridge to transplantation. Survival is equivalent to patients not requiring VA-ECMO prior to transplantation. Overall survival to discharge is 50 percent combining transplant recipients and patients bridged to recovery. Pre-ECMO cardiac arrest is associated with poorer outcome. Mortality with the Berlin Heart EXCOR is about 25 percent.
3. **Answer: A.** The right common carotid artery is the preferred site for arterial cannulation in neonates and infants. The tip of the arterial cannula should lie at the base of the innominate artery. Carotid reconstruction has not been shown to improve long-term neurologic function. If the femoral artery is used, the tip of the cannula should lie in the descending aorta. The tip of the venous cannula should lie at the cavoatrial junction.
4. **Answer: C.** The pulmonary vascular bed is perfused with oxygen-rich blood. A single venous cannula is often all that is required. Physiologic pulsatile flow is maintained, and the myocardium is also perfused with oxygen-rich blood. The lungs are ventilated to avoid elevations in pulmonary vascular resistance.
5. **Answer: D.** Amicar decreases the incidence of intracranial hemorrhage and other hemorrhage complications. Heparin does not inhibit the generation of thrombin. The ACT is maintained between 180 and 220 s. Heparin-bonded circuits do not delay activation of the coagulation system past 24 h. Nafamostat has been shown to reduce heparin requirements.

# Ventricular Assist Devices in Children

*Kristen Nelson*
*Luca A. Vricella*

**KEY CONCEPTS**

- The parallel growth of pediatric cardiac surgery and ventricular assist device (VAD) technology has led to the development of mechanical support specifically tailored to the management of pediatric heart failure. Pediatric VADs are used for heart failure refractory to conventional medical therapy and act as bridges most often to transplantation, but may also act as a bridge to recovery. Each one of the numerous devices currently available has specific advantages, but device selection must be individualized to the patient's particular anatomy and clinical circumstances. A large NIH trial is currently ongoing to further develop continuous flow VADs for the smaller pediatric population, due to the promising results seen in adult continuous flow device studies. Anticoagulation and infection prophylaxis remain major concerns in the management of pediatric patients undergoing VAD placement, but protocolized management will allow us to further study the complex interactions between inflammation, immunity and use of VADs in the pediatric population.

## INTRODUCTION

Ventricular assist devices (VADs) can be invaluable tools for the management of end-stage heart failure in children. While development of such devices in adults has grown significantly since the 1960s and has led to several generations of VAD enhancements, the development of such devices in children has not grown at the same rate. This slower evolution has been due to a number of factors, such as the inherent differences in anatomic and physiologic parameters in children, especially in patients with congenital heart disease involving a variety of defects, as well as developmental changes in the coagulation system. The last 10 years, however, have witnessed an increased attention for VAD development and use in the pediatric population. This increase is due to the fact that while heart transplantation remains the ultimate therapy for children with advanced heart failure, the number of pediatric heart transplants has not increased over the past 10 years to meet the increase in demand. In fact, of all patients on the waiting list for solid-organ transplantation in the United Sates, children listed for heart transplantation face the highest waiting list mortality regardless of age.[1,2] Therapeutic options, therefore, become limited at the point of end-stage heart failure, particularly with pediatric heart transplant wait times often exceeding 4 to 6 months, especially for patients 5 years of age and younger. Due to these factors, it is anticipated that more children with both congenital heart disease and cardiomyopathy-associated heart failure will require long-term VAD support in the coming decade as a bridge to transplantation or recovery.

Historically, extracorporeal membrane oxygenation (ECMO) was the only readily accessible form of mechanical assist for both long and short-term (i.e., postcardiotomy) support. Long-term use of ECMO was limited by complications and often lack of rehabilitation of patients in preparation for transplantation. There were limited options for other long-term assist devices until 2000, when the Berlin Heart EXCOR pulsatile VAD was first utilized in a US pediatric patient under compassionate use approval by the FDA. Over the ensuing 10 years, the Investigational Device Exemption (IDE) study was conducted by Berlin Heart, Inc., eventually leading to FDA approval in late 2011.[3,4] Over this time, there have been advancements in the design of such devices, which permit their placement in neonates and older children in univentricular or biventricular support configuration. There is also a wealth of research currently underway for the development and evaluation of new VADs to further

enhance outcomes for pediatric patients requiring these devices as part of the PumpKIN (Pumps for Kids, Infants and Neonates) trial sponsored by the NIH NHLBI.

While pediatric indications for mechanical circulatory support are often very different from those of the adult population, the same goal of bridging the failing heart to recovery or transplant may be accomplished. Successful myocardial recovery may occur with temporary mechanical assist for myocarditis, failure to wean from bypass (i.e., postcardiotomy) and heart transplant graft failure, through the use of ECMO, Tandem Heart or Rotaflow, to name a few examples, with ECMO remaining the most commonly used short-term device at present. More long-term mechanical support for heart failure due to cardiomyopathy, some cases of myocarditis or various congenital heart lesions often requires a VAD such as Berlin Heart EXCOR for infants and children and Thoratec HeartMate II or HeartWare for older children and adolescents. Most commonly, long-term pediatric VADs are placed with the intent of successful bridging to transplantation, although recovery has been reported.[5–8] The results of several studies indicate a definite benefit in this patient population, with a recent study revealing significantly higher survival rates with the Berlin Heart EXCOR device than with ECMO for pediatric patients with heart failure. However, VADs can be associated with significant morbidity and mortality, most commonly due to infection, hemorrhage and/or thromboembolism resulting in stroke.[2]

Mechanical support for failing pediatric hearts must be customized to the individual's need, size, anatomy and physiology. Certainly, in children from neonatal age to adolescence, one size does not fit all. In the United States, the initial reports of mechanical pediatric cardiac support entailed utilization of devices initially intended for the adult patient population. Therefore, many of these devices were too large to accommodate the specific requirements of the small child and ECMO was the mainstay of circulatory assist in this particular group. Fortunately, with the development of the EXCOR Berlin Heart VAD and FDA approval for study in the United States, it has become the most commonly used VAD for pediatric patients less than or equal to body surface area (BSA) 1.5 $m^2$. (Of note, Berlin Heart EXCOR has pumps available for adult size patients, but is not FDA approved for use above 1.5 $m^2$ at this time.) For older patients requiring VAD support, Heartmate II and Heartware have become viable options and allow patients to resume normal daily activities, such as participation in school.

Pediatric patients in acute need of ventricular assistance often differ from those who present with more chronic heart failure that has progressed despite maximal medical therapy. Indeed, the decision as to which device to use should be based on the indication and prognosis (Fig. 88-1). A patient who cannot be weaned from cardiopulmonary bypass might only need ventricular support for a few days while the myocardium recovers, while another patient with end-stage heart failure might require a VAD designed for longer use that is both portable and durable in anticipation of a lengthy wait on a heart transplant list.

New devices are constantly being developed, and adult VADs will continue to be adapted to the pediatric patient population. As the technology evolves and becomes more readily available, VADs will likely become a mainstay of the management of pediatric heart failure in both the acute and chronic settings.

## PATHOPHYSIOLOGY

Pediatric heart failure severe enough to necessitate a VAD often differs from adult heart failure (Table 88-1). For children, the most common etiologies of myocardial failure include postoperative failure to wean from cardiopulmonary bypass, congenital heart disease, cardiomyopathies, and acute myocarditis.[8,9] Children do not usually suffer from the typical adult problems of hypertension and ischemic heart disease. Congenital heart disease, for example, may entail elements of right and left ventricular (LV) and pulmonary dysfunction and cardiomyopathy with LV failure may result in elevated pulmonary vascular resistance (PVR). While biventricular support is available for such patients, the outcomes for patients with BiVAD (right and left) support are worse than those with univentricular support.[2] Furthermore, with the advent of pulmonary vasodilators, such as milrinone and sildenafil, patients with elevated PVR due to left heart failure may have near normalization of their pulmonary pressures following unloading of the diseased LV through the use of an isolated LVAD.

By assuming much of the responsibility for cardiac output, VADs may allow for the failing myocardium to recover or at least for the patient to have increased mobility and rehabilitation and improved nutrition if transplantation is required. Decompression of the cardiac chambers through mechanical assistance can lower wall stress, reduce myocardial oxygen consumption, and allow for recovery of the myocardium. Other advantages of VAD support include potentially lower requirements for inotropic and vasoactive agents that have, as some of their side effects, arrhythmias, peripheral vasoconstriction, and hyper- or hypotension. For those patients with reasonable pulmonary function, VADs offer isolated ventricular support without the need for oxygenation. In these patients (as opposed to patients on ECMO, for example), the benefits of not requiring an oxygenator in the circuit include potentially lower anticoagulation requirements, less platelet destruction, fewer bleeding complications, and the possibility of mobilization.

## CLINICAL FEATURES

Congestive heart failure in children is primarily attributable to congenital heart defects, cardiomyopathies, and myocardial dysfunction following cardiac surgical repair. The yearly incidence of heart failure from structural defects is 0.1 to 0.2 percent of live births, while the yearly incidence of cardiomyopathy in infants and children has been estimated to

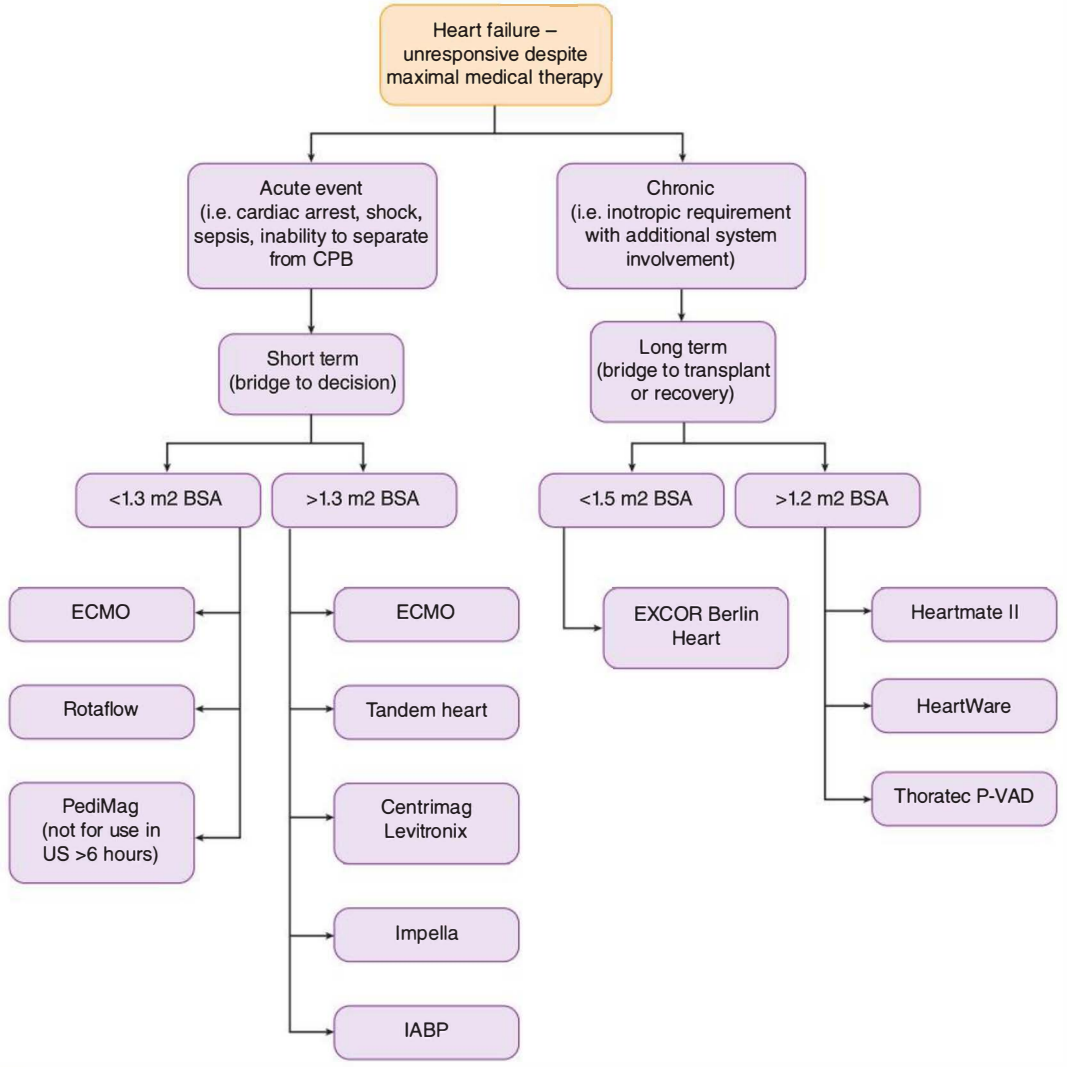

**FIGURE 88-1** Decision-making flowchart (in PowerPoint).

| Cardiac arrest (postarrest ventricular dysfunction) |

be 0.6 in 100,000. The number of children being hospitalized with heart failure is increasing. In an analysis of 15 million pediatric hospitalizations in the US, it was reported that the number of children requiring hospitalization for heart failure increased by 25 percent between 2003 and 2006. During that time period, there was a 32 percent increase in patients hospitalized for heart failure whose underlying diagnosis was congenital heart disease, and a 14 percent increase in patients with cardiomyopathy. Furthermore, about 10 to 20 percent of those who have undergone complex repairs of congenital cardiac defects will develop heart failure by young adulthood.[2]

Aside from failure to wean from cardiopulmonary bypass, typical symptoms of heart failure in infants include tachypnea, tachycardia, failure to thrive, and poor feeding. Patients

may develop signs of congestion, including an enlarged cardiac silhouette on chest radiographs, pulmonary edema, and hepatic enlargement. In toddlers and older children, jugular venous distention and edema might be findings observed in association with growth failure and fatigue. As children become adolescents, the severity of heart failure can be classified as it is in adults, typically with the New York Heart Association (NYHA) functional classification.

If untreated, heart failure ultimately compromises end-organ perfusion, thus leading to the downward spiral of multi-organ system failure. Altered mentation, decreased urine output, rising creatinine, increasing liver function indices, and elevated lactic acid levels all point to inadequate perfusion. If cardiac output or perfusion pressures do not meet the metabolic demands of the body, persistent decline and circulatory collapse will ensue.

## INDICATIONS FOR VENTRICULAR ASSIST DEVICE IMPLANTATION

Initial therapy for pediatric heart failure will usually include diuretics (including aldosterone), and β-blockers as well as angiotensin-converting enzyme inhibitors and/or digitalis. As heart failure progresses, patients will require admission to the intensive care unit, along with inotropic and vasodilator support to maintain adequate cardiac output. Milrinone is most commonly used in these circumstances with the addition of low dose dopamine and/or low dose epinephrine if further inotropic support is necessary, realizing that all of these medications have the potential to result in development or worsening of arrhythmias. With worsening failure, patients may require intubation and ventilatory support, hemodynamic monitoring with a central venous or Swan-Ganz catheterization, close monitoring of renal function and placement of an indwelling urinary catheter. Adequate enteral nutrition must also be provided, usually by means of a feeding tube whenever possible.

The indications for VAD placement are much the same in larger children as in adults, even though the disease process is often different (Table 88-2). For smaller children, such as infants and toddlers, indications for VAD support are much more vague and often rely on clinical judgment. Signs such as recurrent ventricular arrhythmias, inability to feed and recurrent pulmonary edema are particularly ominous in this patient population. Some centers utilize involvement of more than one system as a potential trigger for VAD placement (Table 88-2). The inability to tolerate enteral feeds, for example, suggests worsening heart failure with decreased splanchnic perfusion. In pediatric patients, catastrophic collapse can occur with great rapidity and without the usual clinical warning signs often seen in adults. Near-death and resuscitation events, even when patients are stabilized, should not be given another chance to occur. In a medically optimized patient, elevated cardiac filling pressures along with persistent acidosis and hypotension indicate poor perfusion, often secondary to poor ventricular function. These

**TABLE 88-2: Indications for a Ventricular Assist Device**

1. Inability to wean from cardiopulmonary bypass - usually a short-term device
2. Persistent heart failure after maximal treatment with inotropic support with evidence of end-organ dysfunction in at least one other system:
   a. Neurolocical: altered mental status
   b. Cardiovascular: additional need for second inotrope or persistently low-mixed venous saturations (widening AV O2 gradient)
   c. Respiratory: need for intubation with mechanical ventilation or persistent need for noninvasive ventilation
   d. Renal: rising creatinine, fluid overload despite diuretic use
   e. Gastrointestinal: inability to tolerate enteral feeds, rising LFTs (liver function tests)
   f. Musculoskeletal: inability to ambulate or fatigue limiting activities

are the types of "gray-zone signs" that should lead one to contemplate institution of VAD support. In essence, if clinical deterioration secondary to heart failure continues despite maximal inotropic support, strong consideration should be given to insertion of a VAD.

Pediatric VADs are by definition "bridging" devices to either recovery or transplantation.[2,10] The concept of "destination therapy," which is gaining acceptance for the adult population, is not accepted for pediatric patients at this time. Ethical considerations (including futility and hopelessness) must also be addressed before placing a VAD, particularly in cases of cardiac arrest.

The indications for VAD placement can be divided into acute and chronic heart failure. This distinction may affect the choice of which device to place once the decision for VAD implantation has been made. For example, postcardiotomy patients can initially be maintained on VADs designed for short-term use. Options like ECMO may be equivalent if not better in this setting. Patients with chronic heart failure might benefit more from a continuous flow device (such as HeartMate II or HeartWare) or a pulsatile VAD (such as Berlin Heart EXCOR) that allow for earlier mobility and less lifestyle restrictions. There is a rising population of patients who will fail to wean successfully from "acute" devices and will need conversion to more "chronic" support.[11] This will increasingly become the case, as more pediatric VADs become available.

As pediatric VADs become more commonplace in clinical practice, new indications may arise for their utilization. Rather than merely representing a salvage procedure, VADs may become a standard adjunct for some complex congenital heart operations. One group of investigators has suggested routine ventricular assist after complex congenital reconstructions like the Norwood procedure, citing greater ease of postoperative management as an advantage.[12] With greater use and long-term follow-up, the indications for VAD placement will change and might be further broadened.

## SURGICAL THERAPY

At present, only a limited number of pediatric VADs are available in the United States. This should change in the near future, as promising results from European studies are being reported along with ongoing US studies as well. The range of mechanical assist devices for the pediatric heart includes ECMO circuits as well as pulsatile and nonpulsatile VADs. Intra-aortic balloon pumps (IABPs) are used much less frequently in the pediatric population. Although ECMO for cardiac support has been directly compared to nonpulsatile and pulsatile VADs in some series,[13] there are few data directly comparing one VAD to another.

### Intra-Aortic Balloon Counterpulsation

Although use of the IABP has greatly facilitated the management of adult patients with heart failure, adaptation to the pediatric population has not been as fruitful. The IABP is a biocompatible balloon that is introduced into the descending thoracic aorta and intermittently inflated/deflated (triggered by the electrocardiogram or blood pressure tracing) to augment diastolic blood pressure. By deflating prior to the initiation of systole, the device decreases afterload and thus ventricular work, by creating a "vacuum." During diastole, inflation of the balloon improves coronary as well as splanchnic perfusion. Pediatric anatomy and physiology have posed many obstacles for the use of this technology. Difficulty with insertion remains a challenge even with smaller designs, while higher pediatric heart rates make timing a significant challenge, particularly in a 1:1 setting. Moreover, some feel that the pediatric aorta is considerably more elastic and compliant than that of the adult, which limits the counterpulsation effect; this assertion has nevertheless been challenged.[14] Furthermore, most pediatric patients have unobstructed coronaries, rendering the increased coronary perfusion afforded by the IABP less relevant than it is in adults. Patients with IABP suffer from problems with thrombosis and emboli, as well as the destruction and consumption of cellular blood components, therefore requiring transfusion. For these reasons, the IABP has a limited role in the pediatric population.[15] Although they may be reasonable for short-term support in larger children, IABPs have a very limited role in their long-term mechanical support or bridging to transplantation.

### Extracorporeal Membrane Oxygenation

ECMO consists of a centrifugal or roller pump combined with an oxygenator, which is used for venoarterial or venovenous bypass (Fig. 88-2). Introduced in 1957, this modality has proven to be most useful for neonates with respiratory failure.

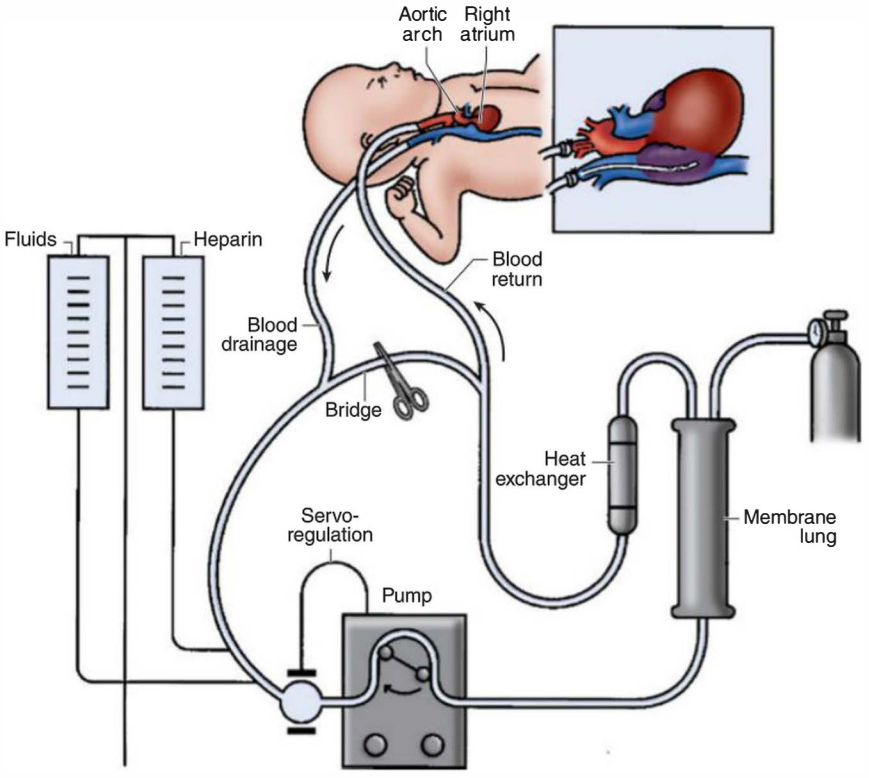

**FIGURE 88-2** Typical extracorporeal membrane oxygenation (ECMO) circuit with right common carotid/internal jugular cannulation.

However, it has also been utilized with success in pediatric cardiac failure. At this time, it is the most widely used method of pediatric ventricular support in the United States, mostly secondary to its availability and ease of placement. Unlike some other VADs, ECMO can be used for children of all sizes, from premature neonates to near-adults. It can be placed centrally (through the chest) or peripherally with either carotid artery and jugular vein or femoral artery and vein cannulation. Physiologically, venoaterial ECMO does result in a decrease in LV preload as well as an increase in LV afterload as ECMO flow is increased. Furthermore, without venting the left heart, it can result in increased ventricular wall stress because of the inability to decompress the left-sided cardiac chambers. Left atrial and ventricular distention occurs to a degree proportional to the number of aortopulmonary collaterals; it may be managed by venting the left atrium either directly or trans-septally via the right atrium.[16,17] ECMO by design improves arterial oxygenation and, if cannulated in a venoarterial fashion, acts to decompress and support both ventricles. For those patients with mainly pulmonary dysfunction (meconium aspiration, for example), ECMO can be instituted in a venovenous configuration, thereby improving venous blood oxygenation and myocardial oxygen delivery. Pulmonary hypertension resulting from low venous blood saturations may also be improved, allowing for some offloading of the right heart. Since the ECMO circuit involves both a pump and an oxygenator, it is reasonable that the pump alone may suffice for those patients without pulmonary insufficiency. By eliminating the oxygenator, it is possible to decrease the amount of foreign surface contact in the circuit, thus decreasing the inflammatory response. Moreover, if the venous cannula is placed in the left atrium or ventricle, the same pump may be used as a left VAD. For this reason, the most commonly used true VAD in the United States has been the centrifugal pump. ECMO is discussed in further detail in Chapter 87. For the purpose of this chapter, we categorize VADs into nonpulsatile and pulsatile types.

## Nonpulsatile Ventricular Assist Devices

### CENTRIFUGAL PUMP

The centrifugal pump has been the most widely used VAD in pediatric cardiac surgery. These VADs consist of inflow and outflow cannulas connected by a centrifugal pump for blood propulsion. Often, the same cannulas utilized during cardiopulmonary bypass may be used for the institution of postoperative ventricular support. Additional cannulation of a pulmonary vein, left atrial appendage, or the pulmonary artery will allow for univentricular or biventricular support. Centrifugal pumps do not generate pulsatile flow and are considered to cause less hemolysis than roller heads. Roller pumps are less portable and also pose a risk of raceway rupture with resultant gas embolism.[16,17]

Successful results using centrifugal VADs have been reported in children of all sizes, including one series of 35 neonates weighing less than 6 kg with postcardiotomy failure.[17] Sixty-three percent of these patients were successfully weaned from centrifugal pumps in this series. Patients may be weaned from these VADs by progressively decreasing the flow rate while observing the ventricular and hemodynamic response under echocardiographic guidance. Cardiac chamber dilation indicates inability of the native heart to maintain adequate cardiac output, thus necessitating continued support. If the patient fails to wean from the centrifugal pump within a few days, a decision to convert to a longer term bridging device or withdrawal of care should be considered. In a series from Boston studying pediatric patients who required VAD or ECMO placement, patients who were unable to wean from the VAD or ECMO within 72 hours either died or required cardiac transplantation. Lack of ejection (identified by pulsatility of the arterial line waveform) is also regarded as an adverse prognostic indicator for ventricular recovery.[18]

Centrifugal pump VADs are not designed for mobile patients; most remain intubated, sedated, and sometimes pharmacologically paralyzed while recovering. In summary, the centrifugal pump is essentially an ECMO circuit deprived of an oxygenator. The advantage to this type of VAD is avoidance of blood trauma known to be caused by the oxygenator; as well as the ability to minimize anticoagulation in the persistently bleeding patient; however, if a patient has pulmonary compromise or intracardiac shunts, ECMO is probably the better choice for short-term supportive care. Also, most neonates requiring postcardiotomy ECMO will have combined respiratory and cardiac failure.

### AXIAL FLOW PUMPS

Axial flow pumps (Hemopump, MicroMed DeBakey VAD-Child, Jarvik 2000, HeartMate II, Heartware, Streamliner, Impella system, Valvo pump, the IVAP VAD, and Berlin

**TABLE 88-3: FDA-Approved Pediatric VADs**

| Device | Size or Age Limits | Ventricular Support | Use Classification | Anticoagulation Regimen |

| HeartWare (HVAD) | >1.2 $m^2$ BSA | Left | Continuous centrifugal flow; intracorporeal | Warfarin (INR 2–2.5)<br>Aspirin 325 mg |
| Thoratec PVAD | >0.73 $m^2$ BSA (smallest to date) | Left, right or biventricular | Pulsatile, paracorporeal | Heparin initially<br>Then warfarin or enoxaparin ± aspirin or other antiplatelet therapy |
| Thoratec IVAD | >0.89 $m^2$ BSA (smallest to date) | Left, right or biventricular | Pulsatile, intracorporeal | Heparin initially<br>Then warfarin or enoxaparin ± aspirin or other antiplatelet therapy |
| Jarvik 2000 | >1.5 to <2.3 $m^2$ BSA | Left | Continuous axial flow; intracorporeal | Heparin initially<br>Then warfarin<br>With aspirin ± other antiplatelet therapy |
| Abiocor TAH | >1.7 $m^2$ BSA | Biventricular | Intracorporeal | Heparin initially<br>Then warfarin<br>With aspirin ± other antiplatelet therapy |
| SyncardiaCardioWest TAH | >1.7 $m^2$ BSA | Biventricular | Pulsatile, intracorporeal | Heparin initially<br>Then warfarin<br>With aspirin ± other antiplatelet therapy |
| Novacar | >1.5 $m^2$ BSA | Left | Continuous axial flow; intracorporeal | Heparin initially<br>Then warfarin<br>With aspirin + other antiplatelet therapy |

INCOR) are some of the devices in an emerging technology that aims at incorporating nonpulsatile flow into miniaturized devices that support pediatric heart failure patients; this is the focus of the PumpKIN trial previously mentioned. Tables 88-3, 88-4, 88-5, and 88-6 list some of the more common devices currently available with a description of the devices under the NIH trial.[19] They are typically small, tubular, implantable rotary pumps connected either directly to the ventricle or to inflow and outflow cannulas. They operate at higher rotational speeds than centrifugal pumps and generate higher flow with lower increases in pressure. They operate at slightly less power, which might, in turn, facilitate the development of lighter and more portable power supplies in the future. There is a growing experience with axial flow pumps in larger pediatric patients, which has been reported. Considering their smaller size and the possibility of implantation via a left thoracotomy, these pumps may become a viable option for VAD support in children awaiting transplant.

## Pulsatile Ventricular Assist Devices

The Berlin Heart EXCOR is a device specifically designed for children. There have also been reports of adult pulsatile

**TABLE 88-5: Temporary Mechanical Assist Devices**

| Device | Max Cardiac Output/Flow Rate; Type of Pump | Approximate Maximum Duration | Anticoagulation |

VADs (Thoratec, Novacor, Abiomed) adapted in larger children with some success. Although there are various different designs, most of these devices involve inflow and outflow cannulas, a pneumatically driven pump with air and blood chambers separated by a biocompatible membrane, and valves that assure unidirectional flow. They are mostly paracorporeal units and require central cannulation of the heart and great vessels.[20,21]

Patients with pulsatile VADs have been shown to have fewer bleeding complications,[22,23] fewer severe infectious complications and, of course, increased mobility when compared to children treated with ECMO; importantly, they can often be weaned from mechanical ventilation, become more mobile and have improved nutrition. To date, pulsatile VADs have been more effective in treating myocarditis and cardiomyopathy patients than postcardiotomy patients.

The Thoratec pVAD is a pneumatically driven paracorporeal pump with mechanical valves and a maximum stroke volume of 65 mL (Fig. 88-3). In a recent review, a total of 101 children (under 18 years of age) received a Thoratec VAD. Anticoagulation was achieved initially in the postoperative period with heparin, with a goal aPTT of 60 to 80 seconds. The anticoagulation regimen was changed to warfarin once the patient was tolerating an enteral diet, with a target international normalized ratio (INR) of 2.5 to 3.5, which is similar to protocols designed for adults. Overall, 66 patients survived to transplant while 10 were bridged to recovery and VAD explantation. Preoperative weight was greater than 20 kg in all but one patient, with the majority of children weighing more than 50 kg. Pediatric patients supported by Thoratec fared better if treated for myocarditis or cardiomyopathy than for postcardiotomy rescue or congenital heart disease. Patients who had LV cannulation had fewer neurologic events than those who were cannulated via the left atrium.[24]

The Abiomed BVS 5000 is a pneumatically driven pump with an electromagnetic console, a gravity-filled chamber, and an air-actuated ventricular chamber to induce pulsatile contractions (Fig. 88-4). It is intended for use as a short-term device. It has been used successfully though only sporadically in a few pediatric patients, all of whom were adolescents.[10] No series have been reported with this device in smaller children.

The Berlin Heart EXCOR assist device is the European counterpart of the Thoratec VAD; however, it has been successfully modified to fit smaller patients (Fig. 88-5). The Berlin Heart is also a pneumatically driven paracorporeal pump with either tilting-disk or trileaflet polyurethane valves. The pump is available in numerous stroke-volume sizes down to 10 mL, and there are different size cannulas. By 2011, over 900 patients have been supported by a Berlin Heart EXCOR device. Anticoagulation is initially maintained with heparin infusion to maintain aPTT between 60 and 80 seconds with an anti-Xa level of 0.3 to 0.7 IU/mL. In the recently published review (2012), thromboelastography has also been incorporated into coagulation evaluation and management. Ultimately, patients require aspirin, dipyridamole and either warfarin or enoxaparin for long-term anticoagulation. Overall, 88 percent of the participants with body surface area <0.7 $m^2$ (cohort 1) and 92 percent of those with BSA between 0.7 to 1.5 $m^2$ (cohort 2) survived to undergo either heart transplantation or weaning from the device. The most common serious adverse events in this study were major bleeding (in 42 percent of participants in cohort 1 and in 50 percent of those in cohort 2),

**FIGURE 88-3** Thoratec VAD.

FIGURE 88-5 Two month-old, 4.5 Kg infant with Berlin Heart LVAD Excor implanted at the Johns Hopkins University Hospital.

infection (in 63 and 50 percent, respectively), stroke (in 29 and 29 percent), and hypertension (in 50 and 33 percent).[2,10,25]

The Medos assist device is another European pneumatically driven paracorporeal pump designed to accommodate pediatric patients, with pump stroke volumes as low as 10 mL, as well as several different size cannulas (Fig. 88-6). The device is, however, not approved by the FDA if not for compassionate use. Anticoagulation is achieved with intravenous heparin and oral antiplatelet therapy with aspirin. Of 56 patients with known outcome supported by the Medos device, 11 survived to transplantation and 10 were weaned to recovery, for an overall survival rate of 37.5 percent.[20] Again, there was a trend toward a greater survival advantage in patients treated for cardiomyopathy than for postcardiotomy patients.

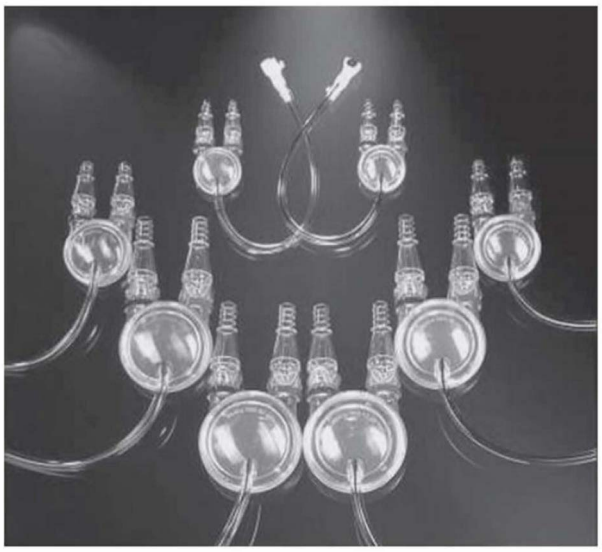

FIGURE 88-6 Medos VAD.

The Toyobo VAD is a Japanese model with 20-mL stroke volumes and a maximal output of 2.4 L/min; it was reportedly implanted in eight patients.[26] Three of the patients were weaned and none ultimately survived in this small series. Nevertheless, with further refinement and development, this VAD might have pediatric applications in the future.

## SURGICAL CONSIDERATIONS

### Peripheral Cannulation

The most common technique involves a cutdown of the right carotid artery and jugular vein. Alternatively, the femoral artery and vein may be used; the former approach is most commonly applied, while maintenance of perfusion to the lower extremity should be a concern when performing the latter. An appropriately sized cannula is placed in each vessel and securely fixed. Meticulous de-airing is performed during all connections. The carotid artery must be either ligated or reconstructed after successful weaning from peripheral support such as ECMO.

### Central Cannulation

Numerous techniques and sites have been used for both inflow and outflow cannulas (Table 88-7).

Initiation of LVAD support in a patient already on cardiopulmonary bypass is usually accomplished with standard bypass cannulas inserted through the superior pulmonary vein into either the left atrium or across the mitral valve into the LV. Alternatively, the LV apex can be cannulated directly. This may minimize neurologic complications and improve pump inflow, leading to superior flow rates. This is also the

**TABLE 88-7: Inflow and Outflow Cannulation Options**

| Device | Inflow | Outflow |
|---|---|---|
| LVAD | LV apex (most common)<br>Left atrium | Ascending aorta |
| RVAD | Right atrium | Pulmonary artery |
| BIVAD | LVAD inflow<br>RVAD inflow | LVAD outflow<br>RVAD outflow |
| VA ECMO | • Internal jugular vein (neck cannulation)<br>• Right atria (chest cannulation)<br>• Femoral vein (groin cannulation) | • Internal carotid (positioned just above aortic arch)<br>• Ascending aorta (chest cannulation)<br>• Femoral artery (groin cannulation) |

access utilized for most long-term LVADs. If only an RVAD is to be utilized, inflow is via the right atrium and return into the pulmonary artery.

If postcardiotomy ECMO is required, venous cannulation is via the right atrium and return directly into the aorta, utilizing the cannulas that have been utilized during the procedure.

## CLINICAL ISSUES

### Anticoagulation

Anticoagulation is used for all pediatric VADs, although the regimen varies by device. One of the major technical difficulties with developing pediatric VADs involves the thrombogenicity of smaller devices.[27,28] Although there may be slight variations in company recommendations, full anticoagulation is recommended for all pulsatile devices to keep the aPTT between 60 and 90 seconds with an anti-Xa level of 0.3 to 0.7 IU/ml. The use of thromboelastrography is also incorporated into the Berlin Heart EXCOR anticoagulation protocols. If the patient is converted to an oral anticoagulation strategy (warfarin), an INR of 2.5 to 3.5 is usually recommended. Some centers may use enoxaparin instead of warfarin. This regimen does contribute significantly; however, to the bleeding episodes associated with VADs. The risk of thrombosis with resultant embolic phenomena must therefore be weighed against the severity of bleeding as measured by transfusion requirements and hemodynamic instability. Antiplatelet therapy is also utilized in many VAD protocols, with the use of aspirin and potentially other antiplatelet agents. Light aggregometry may be used to evaluate the desired block in particular platelet pathways.

For continuous flow devices, such as the HeartMate II, postoperative heparin is not routinely used due to the incidence of bleeding in the initial clinical trial patients. Instead, patients are started on warfarin and aspirin therapy within a few days postimplant. Of note, most patients will develop acquired von Willebrand deficiency and will need to be monitored for bleeding. In the postapproval study, the rate of ischemic stroke was 4.7 percent, with hemorrhagic stroke rate of 1.2 percent.

Regardless of device used, the highest risk for thrombus formation during VAD therapy occurs with infection or inflammation, resulting in increased WBC counts and prothrombotic tendencies. It is imperative to reevaluate the anticoagulation levels for these patients during these periods of higher risk, as increases in anticoagulation therapy may be needed.[29]

As mentioned above, antithrombotic medications are often utilized as well in an effort to reduce anticoagulation requirements and improve safety margin. For example, Berlin Heart EXCOR technology utilizes heparin coating within the VAD chambers to protect against thrombogenesis. Further development of circuit coating might reduce anticoagulation requirements and therefore bleeding complications that often accompany the use of VADs.

### Antibiotic Prophylaxis

Routine antibiotic prophylaxis is mandatory in the perioperative phase. Prophylaxis against gram-positive microorganisms is usually all that is indicated in an otherwise uninfected patient. First-generation cephalosporins are our first choice; these should be given 30 min prior to skin incision for VAD placement and are routinely administered for 24 hours postoperatively. Any signs of infection must be addressed aggressively.

### Infection

Despite the use of strict aseptic techniques during both the insertion and maintenance of VADs, infections continue to be a major cause of morbidity and mortality.[30] Any suspicion of infection should be aggressively managed with immediate cultures and the administration of broad-spectrum antibiotics, followed by change to a more targeted regimen as soon as culture results and sensitivities are available. Very little has been published regarding pediatric VAD infections; some have advocated antifungal prophylaxis in adults at least for the early perioperative period.[24] Adult studies have shown device-related infections to be very serious and often fatal. Treatment must include timely antimicrobial therapy, surgical drainage or debridement, and, sometimes, device removal. As noted above, reevaluation of anticoagulation levels is necessary as well to ensure appropriate anticoagulation.

### Bleeding

Owing to the need for anticoagulation, bleeding is an inherent risk that can lead to devastating complications. Intracerebral hemorrhage occurs in 5 to 15 percent of patients supported with pulsatile VADs,[21] with the majority of these proving to be fatal. In the NEJM study previously mentioned, 42 to 50 percent of study patients developed major bleeding. However, other studies that specifically compared the blood transfusion requirements of patients on ECMO versus those supported with a Berlin Heart have found that patients with the Berlin Heart required significantly less blood, platelet, and plasma replacement than those on ECMO.[23]

### Neurologic Complications

Poor neurologic outcomes following institution of cardiac support are often multifactorial in etiology, including underlying disease, duration and severity of low-cardiac-output state as well as complications of bleeding and thromboembolism due to the assist device. In reviewing long-term follow up of children with cardiac disease who required mechanical support, poor neurologic outcomes were more common in ECMO survivors (60 percent) than nonpulsatile VAD survivors (20 percent). Finally, LV cannulation might lower the

risk of neurologic events in patients with pulsatile VADs.[16] In the Berlin Heart EXCOR study by Fraser et al. published in 2012, 29 percent of children were found to have neurologic complications.[2]

## Multidisciplinary Ventricular Assist Device Management

Due to the complexities of management, choice of device, timing of implant, potential for infectious disease evaluation and the complex interplay between inflammation and thrombosis, it is important to develop a multidisciplinary group to systematically evaluate patients with end-stage heart failure that requires VAD support particularly in light of the often infrequent use in many pediatric hospitals.

# CONCLUSIONS

In comparison to the adult population, development of pediatric VADs is still in its relative infancy. However, as technology continues to improve, VADs are likely to become invaluable tools in the treatment and management of both acute and chronic heart failure in children. The decision of which device to use must be tailored to the individual patient. While for many years it has been thought that it was necessary to maintain physiologic pulsatility for long-term support, reports describing the use of HeartMate II and HeartWare devices in adolescents and young adults have shown that the use of continuous-flow devices does not result in end-organ damage, and that the rates of thrombosis and hemorrhage are significantly lower. Ongoing pediatric trials may in fact reveal that miniaturized continuous-flow devices are effective, with lower complication rates. Clinicians must also continue to investigate different anticoagulation regimens in order to maximize prevention of thrombosis and bleeding.

As pediatric patients survive the initial insult of acute cardiac failure with the assistance of short-term VAD support, they must be weaned, changed to more suitable long-term VAD support, or transplanted. Decisions must often be made quickly, before refractory infections or end-organ failure occur. As transplantation is limited by organ availability, there is currently a real need for reliable, long-term VADs in small children. As further research and development advances in the field of cardiac support, pediatric patients will hopefully have in the future more treatment options to improve long-term survival.

## VENTRICULAR ASSIST DEVICES IN CHILDREN BOARD REVIEW QUESTIONS (CHAPTER 88)

1. A 3-year-old patient develops desaturations to 82 percent in the PICU after placement of a Berlin Heart LVAD. CXR shows good position of the ETT and no mediastinal widening. On 50 percent $FIO_2$, the ABG is 7.29/57/74/23. The SBP 78/40 on a moderate dose milrinone infusion. Which of the following is *not* appropriate therapy?
   A. Temporarliy increase $FIO_2$ to 100 percent
   B. Initiate nitric oxide therapy
   C. Increase ventilatory rate
   D. Increase LVAD rate
   E. Obtain an echocardiogram

2. A 14-year-old patient is post-op day #2 after Heartmate II LVAD, now post-op day #2. She remains intubated with some end-organ dysfunction, including renal and liver dysfunction. The patient is on a heparin infusion for left common femoral vein thrombus, and the platelet count has declined from 125,000 to 42,000. Which alternative anticoagulation therapy is most appropriate?
   A. Bivalirudin
   B. Lepirudin
   C. Argatroban
   D. Warfarin
   E. Enoxaparin

3. A 9-month-old patient with dilated cardiomyopathy is admitted for worsening heart failure. ECHO reveals EF 10 percent with no effusion and severe biventricular failure. Of the following, which support device is most suitable for this patient as a bridge to transplant?
   A. Heartmate II
   B. Heartware
   C. IABP
   D. Berlin Heart
   E. Total artificial heart

4. You have just inserted a Berlin Heart LVAD in a 4-year-old patient with dilated cardiomyopathy. Upon weaning from bypass, the patient's saturations decrease to 79 percent, systemic BP decreases to 60/30, and CVP increases to 22. Which of the following could explain these events?
   A. Inadequate LV decompression
   B. Outflow graft obstruction
   C. Tamponade
   D. Right heart dysfunction
   E. All of the above

5. Of the following, the clinical condition *least* likely to be managed successfully with an LVAD is:
   A. Dilated cardiomyopathy
   B. Postcardiotomy failure
   C. Cardiogenic shock from myocarditis
   D. Failing Fontan
   E. Cardiac arrest after Norwood reconstruction

## ANSWERS

1. **Answer: D.** This patient is experiencing a pulmonary hypertensive crisis, such that the LVAD is not filling due to lack of forward flow from the right heart. Simply increasing the LVAD rate will have little effect on the clinical situation. Pharmacologic relaxation of the reactive pulmonary vasculature includes increasing oxygen concentration until other therapies take effect, as well as NO, milrinone and correcting the $PCO_2$ with improved ventilation. Volume resuscitation and BP stabilization may also be necessary in the initial phase. Tamponade is another important consideration that can result in poor LVAD filling which can be rapidly diagnosed with echocardiography.
2. **Answer: A.** The concern is for heparin-induced thrombocytopenia (HIT), and anticoagulation using a non-heparin agent is appropriate. Bivalirudin is metabolized by a combination of renal mechanisms and proteolytic cleavage, but is less toxic to the kidneys than lepirudin (which is primarily metabolized through the kidney). Argatroban is cleared primarily through hepatic metabolism. Warfarin is not appropriate this soon after surgery and has delayed onset. Enoxaparin is low-molecular weight heparin that can also result in HIT.
3. **Answer: D.** Mechanical support may be necessary if end-organ function is beginning to be compromised, particularly in this age patient. Given the patient's age and size, the Berlin Heart would be most appropriate. Patients under 1 year of age may wait 6 months or longer on the heart transplant waiting list, depending on a variety of factors, such as blood type. There are no continuous flow VAD devices currently FDA approved for infants in the US, but there is a large ongoing NIH trial investigating such devices in the smaller pediatric population.
4. **Answer: E.** Pulmonary edema from LV distension and high left atrial pressure can occur if LV decompression is not achieved, or with outflow graft obstruction. Right heart dysfunction and tamponade will independently decrease filling of LVAD. All of these conditions can lead to elevated CVP with hypotension.
5. **Answer: D.** Fontan physiology is the least likely to be successfully managed with an isolated LVAD, as it is very difficult to maintain adequate pulmonary blood flow. All of the other conditions are indications for ventricular assistance.

# Pediatric Cardiac Transplantation

*Amy L. Rahm*
*Nahidh W. Hasaniya*
*Leonard L. Bailey*
*Anees J. Razzouk*
*Richard E. Chinnock*

**KEY CONCEPTS**

- Epidemiology
  - Since 1982, over 8000 pediatric heart transplants have been recorded in the Registry of the International Society of Heart and Lung Transplantation. The current number of reported pediatric heart transplants is about 450 per year, which originate in 80 global centers.
- Indications
  - Heart transplantation is the most effective and often the only treatment for end-stage pediatric heart disease. Complex congenital heart disease is the main indication for heart transplantation in infants, whereas end-stage cardiomyopathy is the main indication after the first year of life.
- Contraindications
  - The main contraindication is elevated pulmonary vascular resistance that is unresponsive to oxygen and vasodilators.
- Techniques
  - Heart transplantation is performed using either biatrial or bicaval techniques, depending on the size of the recipient child. Graft procurement and implantation are modified to accommodate the specific anatomic variations present in recipients with congenital heart disease.
- Outcomes
  - Mortality while waiting for a donor is 12 to 40 percent. The overall actuarial survival at 10 years is 66 percent. It is 74 percent for newborn recipients. Causes of mortality include graft rejection and failure, infection, cardiac allograft vasculopathy (CAV) (16 percent), and malignancy (8 percent).

## BACKGROUND

The quest for clinical cardiac transplantation (CT) originated in research laboratories of the 1960s. Principal North American investigators included Norman Shumway and Richard Lower at Stanford University in California and Adrian Kantrowitz at Albert Einstein College of Medicine in New York, among others. While Shumway and Lower were focused on the potential for CT among adults, Kantrowitz' studies were aimed at young infant recipients. At Stanford, investigators were learning the difficult balance between control of the host immune response and lethal opportunistic infections. Utilizing immunosuppressants of that era, adult laboratory animals were beginning to achieve survival of more than a year following orthotopic CT. In New York City, Kantrowitz observed that transplanted puppies experienced prolonged survival, even without immunosuppression. Then, unexpectedly, came news from Capetown, South Africa, that Christiaan Barnard and his team had accomplished the first clinical human CT.[1] On December 3, 1967, 55-year-old Louis Washkansky underwent orthotopic CT. He died of pneumonia 18 days later, but the celebrated transplant stimulated global interest, and a bevy of similar transplants. The vast majority of these early recipients experienced abbreviated survival, dying of rejection, infection, or both.

Just 3 days after the South African transplant, the first infant (neonatal) CT was attempted by Kantrowitz. The heart of an anencephalic infant was transplanted "off-pump" (i.e., with surface-induced hypothermia alone), into a neonate with severe Ebstein anomaly. The baby appeared to have a satisfactory operative procedure, but died suddenly and without clear explanation 6.5 h later. Kantrowitz did not pursue pediatric CT, and it would be 16 years before neonatal CT was to be attempted again. With the advent of cyclosporine for selective control of the cellular immune response,[2] clinical pediatric CT was successfully performed in the summer of 1984. Eric Rose, of Columbia University, transplanted a 4.5-year-old boy. Then, Douglas Behrendt performed CT in a 2-year-old girl at the University of Michigan. Neonatal CT was once again attempted on July 30, 1984 by Magdi Yacoub in London. The infant, who had hypoplastic left heart syndrome (HLHS), lived 18 days with an allograft from a Dutch infant donor.

On October 26, 1984, one of the authors (Leonard L. Bailey) performed CT on a premature human newborn with HLHS using the heart of a 9-month-old female baboon. The infant recipient became known as Baby Fae. She lived 3 weeks, dying of incompletely understood mechanisms. Her experience raised social and professional consciousness about the potential for infant CT. This new awareness led to the first successful neonatal CT, which occurred at Loma Linda University (LLU) on November 15, 1985.[3] The recipient was near death from HLHS at 4 days of age, when a distant neonatal donor was identified and transferred to LLU. The newborn recipient, now fully grown and gainfully employed, turned 27 years old in the fall of 2012. Additional infant allograft CTs were accomplished as procurement agencies began to take note of this donor organ resource. Throughout the decade of the 1990s, pediatric recipients produced major growth in the number of CTs performed worldwide.

Since 1982, CT has been recorded by the Registry of the International Society for Heart and Lung Transplantation (ISHLT) in over 8000 pediatric recipients. The incidence of pediatric CT has plateaued, with about 450 infant and childhood recipients reported annually to the ISHLT Registry. Today, infants and children (0–18 years old) constitute 12.5 percent of all reported recipients of CT.[4]

This chapter reviews indications for and contraindications to pediatric CT, timing for surgery, surgical techniques, immunosuppression regimens, rejection surveillance, complications, outcomes (highlighting the LLU experience), and future trends.

## INDICATIONS

CT provides the most effective treatment for end-stage heart disease, whether myopathic or congenital. Complex congenital heart disease remains the primary indication for CT among patients in the first year of life. Over the past decade, however, increasing numbers of CTs have been performed in infants for both primary and secondary cardiomyopathy, or for failure of single ventricle physiology. End-stage primary cardiomyopathy (including "burned-out" congenital heart disease) is the predominant indication for transplantation among recipients who are beyond the first year of life. Retransplantation accounts for 5 percent of all pediatric CT (Table 89-1).[4] The various cardiac diagnoses (myopathic and congenital) that may be considered for orthotopic pediatric CT are shown in Tables 89-2 and 89-3.

**TABLE 89-1: Indications for Pediatric Cardiac Transplantation Based on Age**

| Indication (%) | <1 year | 1–10 years | 11–17 years |
|---|---|---|---|
| Congenital | 63 | 36 | 24 |
| Myopathy | 31 | 55 | 64 |
| Other | 5 | 3 | 7 |
| Retransplant | 1 | 6 | 7 |

Adapted with permission from Hertz MI, Aurora P, Christie JD, et al. Scientific Registry of the International Society for Heart and Lung Transplantation: introduction to the 2009 Annual Reports. *J Heart Lung Transplant*. 2009;28(10):989–992.

## CONTRAINDICATIONS

The main contraindication to CT is elevated pulmonary vascular resistance (more than 5 Woods units) that is unresponsive to oxygen, intravenous vasodilators, and inhaled nitric oxide. Children with a transpulmonary gradient greater than 15 mm Hg are largely unsuitable for isolated CT.[5] Pulmonary vascular resistance is seldom an issue during early infancy, but it can become an important contraindication in older children and adolescents. Other contraindications are listed in Table 89-4. They include multisystem organ failure, active neoplasia, profound neurologic dysfunction, untreated clinical infection, and severe chromosomal abnormalities that limit survival, among others.

**TABLE 89-2: Cardiomyopathies that may be an Indication for Orthotopic Cardiac Transplantation**

Dilated—75%

Restrictive—12%

- Less amenable to medical or surgical therapy than other forms of cardiomyopathy
- High incidence of pulmonary hypertension and thromboembolic events

Hypertrophic—5%

- One-fourth of all hypertrophic cardiomyopathies include syndromes such as Noonan and Beckwith–Wiedemann

Myocarditis—8%

Distribution of cardiomyopathy subtypes within Pediatric Heart Transplant Study Group recipients transplanted.[29]

**TABLE 89-3: Congenital Cardiac Malformations that may be an Indication for Orthotopic Cardiac Transplantation**

Hypoplastic left heart syndrome (hypoplastic aortic tract complex)
Hypoplastic left heart equivalent:

- D-TGA with hypoplastic right ventricle and aortic tract
- Single ventricle with hypoplastic aortic tract
- L-TGA with single ventricle, heart block, and aortic tract hypoplasia
- Shone complex, including severe mitral valve stenosis, left ventricular outflow obstruction, coarctation of the aorta

Symptomatic severe Ebstein's anomaly with normal pulmonary arteries
Multiple obstructive rhabdomyomas or fibromas
Pulmonary atresia/intact ventricular septum (large coronary-dependent sinusoids)[a]
AV septal defect with hypoplastic left ventricle and mitral component (frequently associated with coarctation)
Single ventricle with subaortic obstruction (bulboventricular foramen)
Severe intrauterine AV valve insufficiency and ventricular dysfunction
Straddling AV valve and tensor apparatus
Complex truncus arteriosus
Severe congenital cardiomyopathy at end-stage with maximal medical management

AV, atrioventricular; D-TGA, D-loop transposition of the great arteries; L-TGA, L-loop transposition of the great arteries.

[a]Diminutive right heart malformations must have adequate-size right and left pulmonary arteries. Neonates unresponsive to $PGE_1$ may require placement of a systemic-pulmonary shunt while waiting for a donor.

## TIMING

Proceeding with CT is a team decision and is multifactorial. Pretransplant evaluation of potential recipients should be expeditious, leading to early registration with the national organ procurement and distribution center. Delay leads to unnecessary morbidity and mortality. Even when registered, a potential recipient's waiting time is entirely unpredictable. A waiting recipient may encounter major morbidities, such as overwhelming sepsis, cerebral hemorrhage, necrotizing enterocolitis, cardiac arrest, and hepatorenal failure, among others. Such morbidities may become contraindications to CT.

**TABLE 89-4: Clinical Conditions that may Contraindicate Orthotopic Cardiac Transplantation**

Marked prematurity (<34–36 weeks)[a]
Excessively low birth weight[a]
Active malignancy
Multisystem organ failure
Recalcitrant acidosis with pH <7.0
Abnormal neurologic status, suggesting a poor long-term prognosis[a]
Active, untreated infection
Genetic anomalies or syndromes that significantly limit survival
Socioeconomic factors leading to noncompliance[a]
Hypoplastic obstructive pulmonary veins
Hypoplastic left heart syndrome with intact atrial septum
Fixed pulmonary vascular resistance (>5 Woods units)

[a]Relative contraindications.

Recipients with complex congenital heart disease who are not candidates for surgical repair or palliation are listed early for primary CT. An occasional infant with unmanageable primary cardiac tumor or those with severe familial cardiomyopathy are also registered early for CT. Older pediatric recipients are typically listed for CT when they become resistant to medical management for congestive heart failure (CHF) and/or malignant arrhythmias, or when they fail to respond favorably to palliated single-ventricle physiology. Progressive deterioration, failure to thrive, and poor quality of life, even with optimal medical care indicate the need to list for CT. Also, patients with progressive pulmonary hypertension that might preclude transplantation at a later date are being listed more expeditiously.[6] As indications for CT have expanded, and as organ supply has remained constant, recipient waiting time and morbidity have increased. Mortality while waiting for a donor heart graft ranges between 12 and 40 percent.

Mechanical circulatory support as a bridge to pediatric CT has become increasingly important. Extracorporeal membrane oxygenation (ECMO, Chapter 87) is useful only for relatively short periods, but may bridge to a more durable device.[7] Utilization of infant-sized ventricular assist devices (VADs, Chapter 88) has proved to be a viable option for bridging to CT, similar to their use in older children and adolescents. VADs have been shown to improve waiting time survival without negatively affecting CT outcome.[8] Early listing for CT optimizes recipient survival and reduces the need for intermediate mechanical circulatory support.

## PROCUREMENT OF THE DONOR HEART GRAFT

Donor heart recovery is tailored to the individual anatomic demands of the recipient. En bloc excision of the heart, the central pulmonary arterial tree, the superior vena cava (SVC) in continuity with the brachiocephalic vein and the origin of the internal jugular veins, and some or all of the aortic arch may be required to simplify recipient reconstruction. Concomitant lung donation may not be suitable when replacement of the main and branch pulmonary arteries is anticipated in a recipient, or when a recipient has situs inversus or anomalous pulmonary venous connections. A general rule of thumb is to obtain more, rather than less, of what the recipient will require. Aggressive trimming of the donor heart is postponed until its implantation into the recipient.

Heart recovery is usually accomplished in concert with the recovery of other organs (by other teams) through a long midline incision. The donor is given 25 mg/kg of cephalosporin antibiotic and 10 to 25 mg/kg of methylprednisolone. Fifty percent dextrose (0.5–1.0 mL/kg) is administered

intravenously to the donor every 15 minutes until the organ is excised. The aorta is separated from the pulmonary artery, and the aortic arch vessels are doubly ligated and divided. The SVC and the innominate vein (as needed) are isolated. The azygous vein is ligated and divided. Its posterior location becomes a landmark for the future SVC anastomosis, or it can be used to enlarge the donor SVC if there is size discrepancy. Both pleural spaces are opened to accommodate drainage. When each team has completed their dissection, the donor receives intravenous heparin in a dose of 500 U/kg, and the heart is decompressed by transecting the inferior vena cava (IVC) and both of the left pulmonary veins. The aorta is cross-clamped, and 250 to 500 mL of antegrade cold crystalloid cardioplegia is administered by gravity infusion while the heart is being removed. The authors utilize cold Roe's solution for myocardial protection. An infusion volume of 50 to 75 mL/kg is used in neonates and smaller children. The idea is to gently chill the heart, but not freeze it. Cardiectomy is completed by lifting the heart upward; the posterior attachments, including the right pulmonary veins, are divided. The SVC, the aorta and the pulmonary arteries are divided to include the amount of tissue needed. If the lungs are being recovered, the left heart is vented through a broad incision in the left atrium (anterior to the left pulmonary veins). This is done before the infusion of lung preservation solution. The pulmonary veins are, in this particular instance, not divided at the pericardial reflection. Instead, the left atrium is opened and carefully transected to preserve a posterior atrial cuff around the pulmonary veins, much as in the case for cardiectomy in the recipient. The main pulmonary artery is divided before the bifurcation. The remainder of the heart recovery is as described above. The heart is removed from the operative field to a back table, where it is examined while being immersed in ice-cold saline solution. If present, a patent foramen ovale is closed. The graft is packaged in a self-sealing plastic bag containing 5 percent dextrose in normal saline solution. The packaged graft is placed in a sterile, sealed container and immersed in ice in a chest for transport. Portions of donor thymus, spleen, and hilar or mesenteric lymph nodes are obtained and stored for immunologic evaluation. Frequent communication between the recovery team and the recipient team will minimize graft cold ischemia time. It is generally recommended that graft cold ischemic time be kept less than 4 h. However, successful CT with longer cold ischemic times (up to 10.5 h) have been reported by investigators at LLU.[9]

## CARDIAC GRAFT IMPLANTATION

The biatrial technique (Fig. 89-1A) of graft implantation during CT was described by Lower and Shumway in 1967.[10] This technique may create oversized atria and may distort right atrial geometry leading to atrioventricular valve insufficiency and/or arrhythmias. Bicaval anastomosis, described by Dreyfus and colleagues,[11] is now the most commonly employed technique (Fig. 89-1B). Bicaval CT preserves right atrial morphology and is applicable at any age. It is particularly useful during reoperative CT or when space is an issue. The recipient procedure is accomplished through a median sternotomy. The thymus is excised. At LLU, the recipient is placed on cardiopulmonary bypass using aortic and right atrial cannulation. Systemic cooling to a core temperature of 18 to 20°C is utilized routinely. The aorta is cross-clamped, and when target hypothermia is achieved, bypass flow is markedly reduced, and the passive venous cannula is replaced by flexible pump suckers. The aorta and pulmonary trunk are divided. Both the SVC and the IVC are divided, preserving a small atrial cuff on each cava to facilitate anastomoses. A left atriectomy is performed, leaving a posterior atrial cuff that contains the pulmonary veins. The native heart is removed from the chest. The donor heart is evaluated, and the left atrium is trimmed to match the recipient left atrial cuff. The left atrioatrial anastomosis is performed first. A small area of the anastomosis is kept incomplete so that cold saline can be flushed intermittently through the left-sided structures. The IVC anastomosis is then completed, followed by an end-to-end anastomosis of the SVC. The passive venous cannula for cardiopulmonary bypass is inserted into the donor right atrium, via the appendage. The aortic anastomosis is completed, and intracavitary air is displaced by flushing of the left heart with cold saline. The aortic clamp is removed, ending graft cold ischemia. The pulmonary arterial anastomosis is completed during reperfusion of the allograft. All anastomoses are performed with continuous polypropylene sutures. The graft and the patient are rewarmed and reperfused for at least an hour to permit full recovery of the allograft heart. As the recipient rewarms, nitroglycerin is infused intravenously. Drugs, such as dopamine and milrinone, are infused in low dosage intravenously when the recipient reaches 34 to 36°C. The recipient is then separated from extracorporeal circulation.

A biatrial anastomosis is usually employed in neonates and very small babies. The interatrial septum is anastomosed first, followed by the right atrium and then the left atrium. The recovery and trimming of the donor heart and the techniques of CT are modified to cope with various anatomic situations, examples of which are discussed below.

### Infants Who Require Replacement/ Reconstruction of the Aortic Arch

The technique of orthotopic CT and aortic arch reconstruction is exemplified by that used for HLHS or its equivalent (Fig. 89-2) and was first described in detail in 1986 and later modified to reduce the duration of circulatory arrest.[12] The chest is opened through a midsternal incision and thymectomy is accomplished. Cardiopulmonary bypass is initiated using a single venous drainage cannula in the right atrium, and an arterial perfusion cannula that is placed in the pulmonary trunk and directed into the arterial duct. The ductus containing the arterial cannula is snared to prevent flow into the lungs. Systemic cooling to a core temperature of

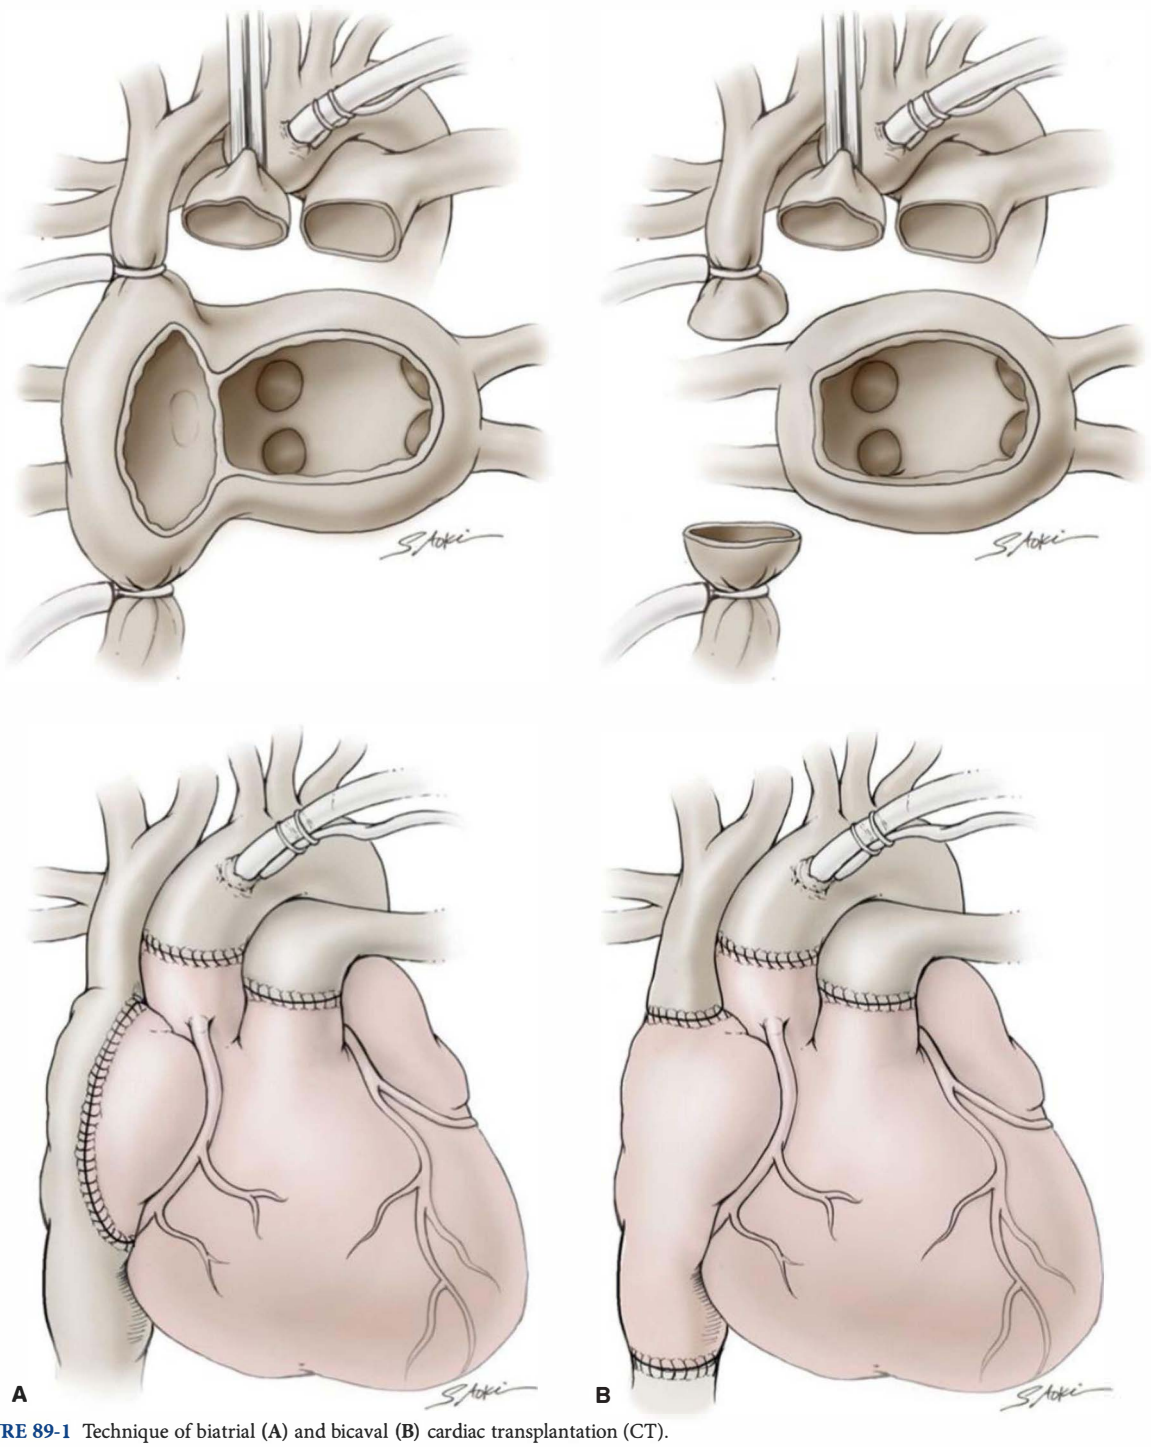

**FIGURE 89-1** Technique of biatrial **(A)** and bicaval **(B)** cardiac transplantation (CT).

18 to 20°C is achieved within 12 to 15 minutes. During this period, branches of the aortic arch are dissected and surrounded individually with loose tourniquets. The perfusion rate (or volume) is reduced to approximately 20 cc/kg/min, and thereafter varies between 10 and 30 cc/kg/min until rewarming is begun. The diminutive ascending aorta is ligated and divided just proximal to the brachiocephalic artery. Traction on this ligature facilitates exposure of the proximal descending aorta. The passive atrial drainage cannula is replaced with a flexible pump sucker. The main

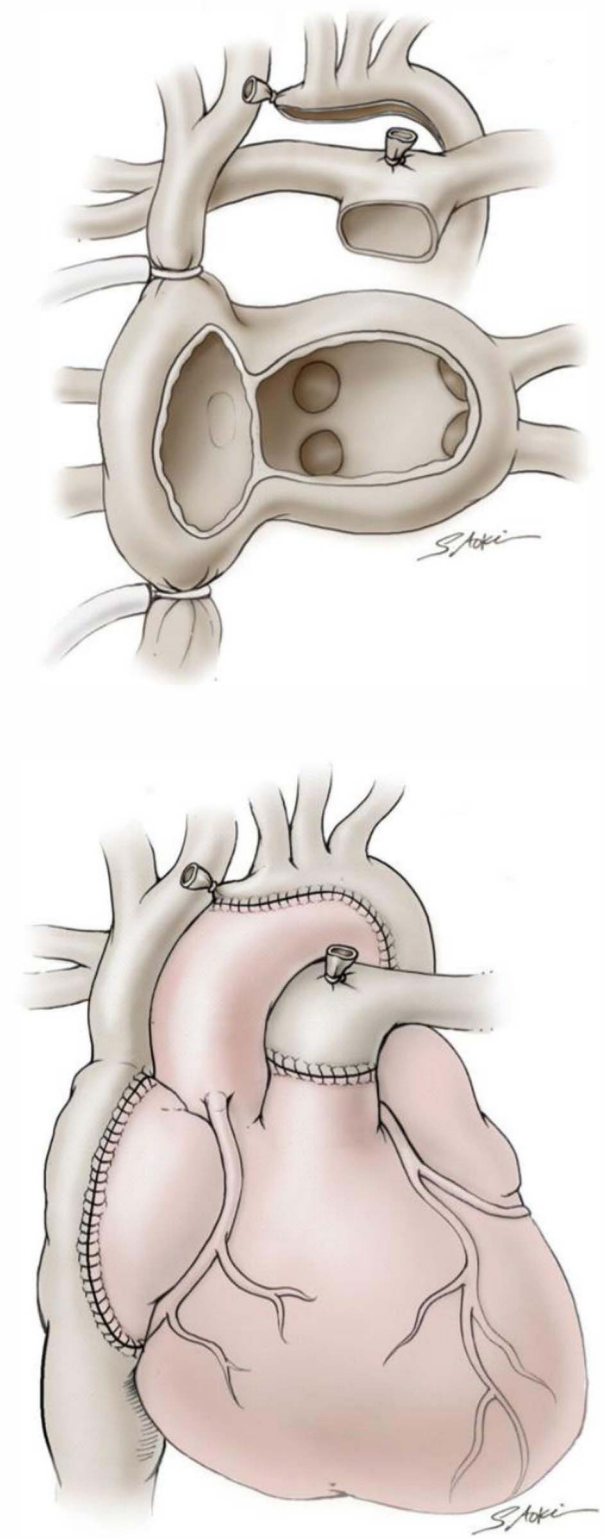

FIGURE 89-2 Cardiac transplantation of infants with hypoplastic left heart syndrome (note the technique for aortic arch reconstruction).

pulmonary artery is transected at the level of the valve. The hypoplastic heart is excised, leaving in place posterior atrial wall cuffs and a rim of atrial septum.

After inspection of the recipient's pulmonary veins, implantation of the donor heart begins with the atrial septum at its caudal aspect using a continuous monofilament suture, a portion of which is carried up the septum and around the top of the right atrium. The other portion of the same suture is used to anastomose the caudal portion of the right atrium, eventually meeting up with the segment of suture used to attach the upper portion of the atrium. A flexible suction catheter is repositioned into the right atrial appendage while the graft is retracted toward the operating surgeon and the left atrial anastomosis is initiated at its junction with the caudal septum. After half a dozen sutures, the heart graft is replaced into the remaining posterior pericardial well, and the dome of the left atrium is anastomosed toward the surgeon. Again, a small portion of the left atrial anastomosis is left incomplete so cold saline can be flushed through the left-sided structures. With the infant in Trendelenburg position, the aortic arch vessels are snared, the circulation is arrested, and the arterial perfusion cannula is withdrawn. The arterial duct is ligated and divided, and nearly all ductal tissue is excised. The undersurface of the aortic arch is incised from the level of the brachiocephalic trunk to about 1 cm down the descending aorta, beyond the ductus arteriosus. Special care is exercised to identify and avoid injury to the recurrent laryngeal and phrenic nerves. The neoaortic arch is reconstructed with the opened, long segment of donor aortic arch, starting at the descending aorta, beyond the amputated duct. Selective low-flow hypothermic cerebral perfusion may be employed here, but a period of 15 to 25 min of circulatory arrest provides an unencumbered, bloodless field for this part of the procedure, without additional neurological risk. The aorta is filled with cold saline by way of the donor brachiocephalic artery stump, which is also used for reinsertion of the arterial cannula. The passive venous cannula is placed through the appendage into the donor right atrium. Perfusion is resumed, the left atrial anastomosis is completed, and any residual air is evacuated through a vent site in the donor ascending aorta. The occluding tourniquets around the arch vessels are removed. The pulmonary arterial anastomosis is completed during the early warming phase of recirculation. The patient is gently rewarmed to 36°C, using a minimum of 60 minutes of extracorporeal reperfusion. In instances when cold graft ischemic time is markedly prolonged (as in very distant retrievals), reperfusion time may be extended to 80 or 90 minutes to achieve complete functional recovery of the heart.

## Infants Who Have Failed Norwood's Stages I or II Procedures

In this special situation, the donor heart procurement includes the central pulmonary arteries, the SVC, and the complete aortic arch. Recipient dissection exposes the aortic

arch, the aortopulmonary or cavopulmonary shunt, and both branch pulmonary arteries. The shunt is divided, the native pulmonary arterial bifurcation and central branches are replaced as necessary with donor pulmonary arteries, and the donor aorta is connected end-to-end to the previously reconstructed aortic arch. If the distal arch is obstructed, the aortic arch is completely reconstructed with donor aorta. Circulatory arrest is unnecessary in the first instance, but may be employed to enable arch reconstruction. The rest of the implantation is similar to the procedure for HLHS described previously.[13] Cavocaval anastomoses are utilized if CT follows stage II hemi-Fontan or bidirectional Glenn procedures.

## Recipients with Situs Inversus

Donor cardiectomy is performed with en bloc removal of the SVC and the innominate vein, which together are used to reconstitute cephalic venous drainage in the recipient. The donor left pulmonary vein orifices are oversewn, and the left atrium is opened vertically between the right pulmonary veins. This approach helps align the donor graft for anastomosis with the recipient right-sided pulmonary atrium. The recipient procedure is performed with low-flow hypothermic perfusion, as described above. The left pericardium, which is anterior to the phrenic nerve, is excised. The recipient heart is removed, leaving behind a small pulmonary atrial cuff and abundant systemic atrial tissue in continuity with the leftward-positioned IVC. The recipient systemic venous atrial remnant is fashioned into a short conduit in continuity with the IVC, thus directing IVC drainage toward the right side of the recipient. Graft implantation begins with the pulmonary atrial anastomosis. The IVC of the recipient, which is lengthened toward the right, is anastomosed to that of the donor heart. The recipient's pulmonary artery is opened longitudinally into the left pulmonary artery. The short stump of native main pulmonary artery is closed right-to-left with a running suture, leaving a left-sided recipient pulmonary arterial orifice, which is anastomosed to the donor main pulmonary artery. Both native recipient and donor aortas are intentionally shortened to reduce anterior bulging of the ascending aorta. The aortic anastomosis is then accomplished. Air is displaced from the left-sided structures, and low-flow hypothermic graft reperfusion is commenced. The donor SVC/innominate vein is anastomosed to a large recipient transverse brachiocephalic (innominate) vein or to the left-sided SVC, anterior to the great arteries. The passive venous cannula is inserted into the systemic atrium, and recipient and graft rewarming is begun as extracorporeal flow is gradually increased.[14] The procedure is illustrated in Figure 89-3.

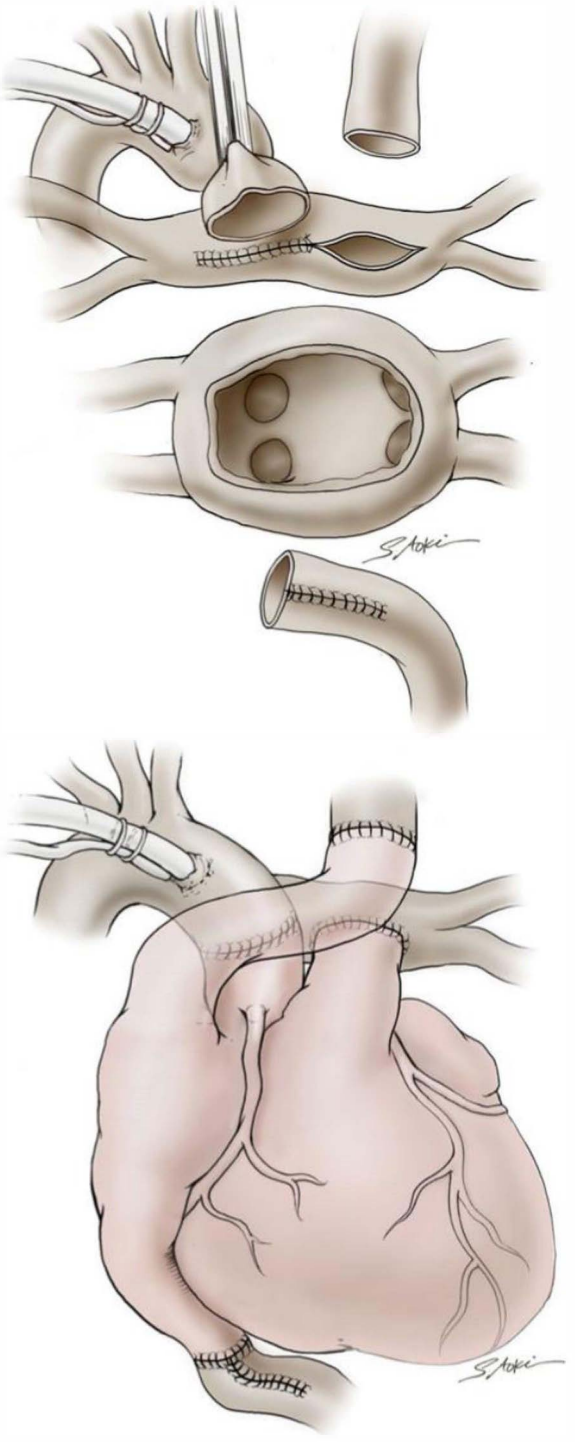

**FIGURE 89-3** Cardiac transplantation in children with situs inversus. Cardiectomy is performed, the pulmonary anastomotic site is relocated to the left, and the inferior vena cava is rerouted to the right of the midline (top). Graft implementation is performed in the usual fashion, with the donor's left brachiocephalic vein anastomosed to the left superior vena cava (bottom). The superior caval connection is positioned anterior to the shortened aorta.

## Cardiac Transplantation After a Failed Fontan Operation

Multipalliated children are always a challenge. Most have had three or more previous sternotomies, and may be nutritionally depleted following attempts to establish satisfactory

Fontan physiology. These children usually have atrial situs solitus, but may occasionally have situs ambiguous or inversus. The donor heart is recovered with adequate systemic veins and pulmonary arteries for reimplantation, using a cavo-caval strategy. Profound hypothermic cardiopulmonary bypass is established with the use of single aortic and venous cannulae, and a low-flow state is established. Using flexible "sucker" venous drainage, cardiectomy is performed. Graft implantation begins with attachment of the pulmonary atria. This is followed by anastomosis of the IVC, the main pulmonary artery (or separate right and left pulmonary arteries), one or both superior cavae or internal jugular veins and, finally, the aorta. These features are illustrated in Figure 89-4.

## SURVEILLANCE

At LLU, CT recipients are followed and evaluated by a specialized team that consists of pediatricians, coordinators, and pharmacists. Cardiologists and other pediatric subspecialists, including surgeons, act as consultants. Initially, office surveillance occurs twice weekly, then weekly, and then monthly for the first year. Follow-up visits are usually less frequent after that time. Transplant surveillance is a lifetime commitment that should prove mutually beneficial to both the recipient and the CT recipient's parents. The outpatient follow-up visits include history and physical examination, electrocardiography (ECG), echocardiography (ECHO), indicated chest roentgenograms (CXR), complete blood count, immunosuppression drug levels, measures of renal function, and viral titers. Cardiac biopsy, coronary angiography, and intravascular ultrasound (age 6 and older) are accomplished annually beyond the first posttransplant year. Testing throughout the patient's life is tailored to individual requirements and specific protocols.

## IMMUNOSUPPRESSION STRATEGIES

Immunosuppression strategies in pediatric CT are built around induction versus no induction, and double- versus triple-drug regimens. None of these strategies, however, have been evaluated in large-scale, randomized, controlled studies. Their use in pediatric CT has evolved from experience in laboratory animal models of infant CT, or has been adapted from adult thoracic and pediatric noncardiac solid organ trials. An algorithm for the management of immunosuppression is shown in Figure 89-5.

## INDUCTION

Induction therapy (the use of monoclonal or polyclonal antibody T-cell depleting agents) remains controversial. Induction was employed early in transplantation and then fell out of favor because of concerns about overimmunosuppression

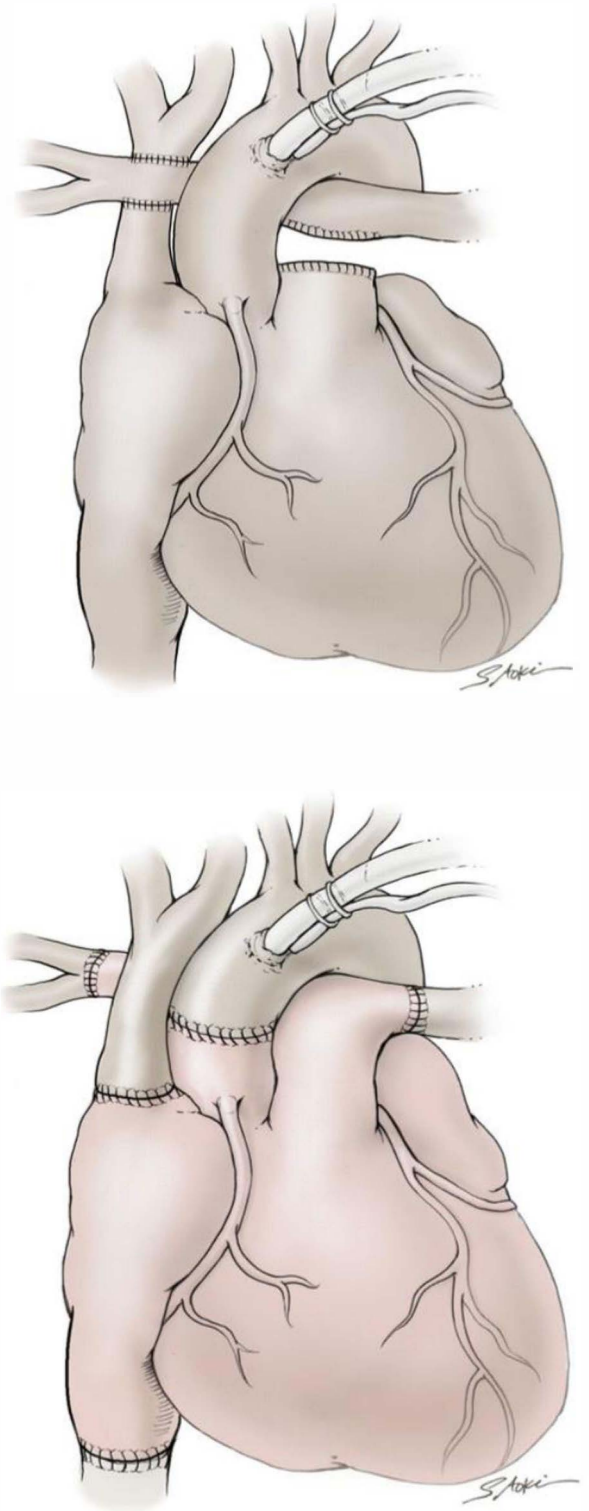

**FIGURE 89-4** Cardiac transplantation after a failed Fontan procedure (top). A cavocaval strategy is employed (bottom). On occasion, the central pulmonary arterial tree may require replacement with en bloc donor pulmonary arteries, as illustrated here.

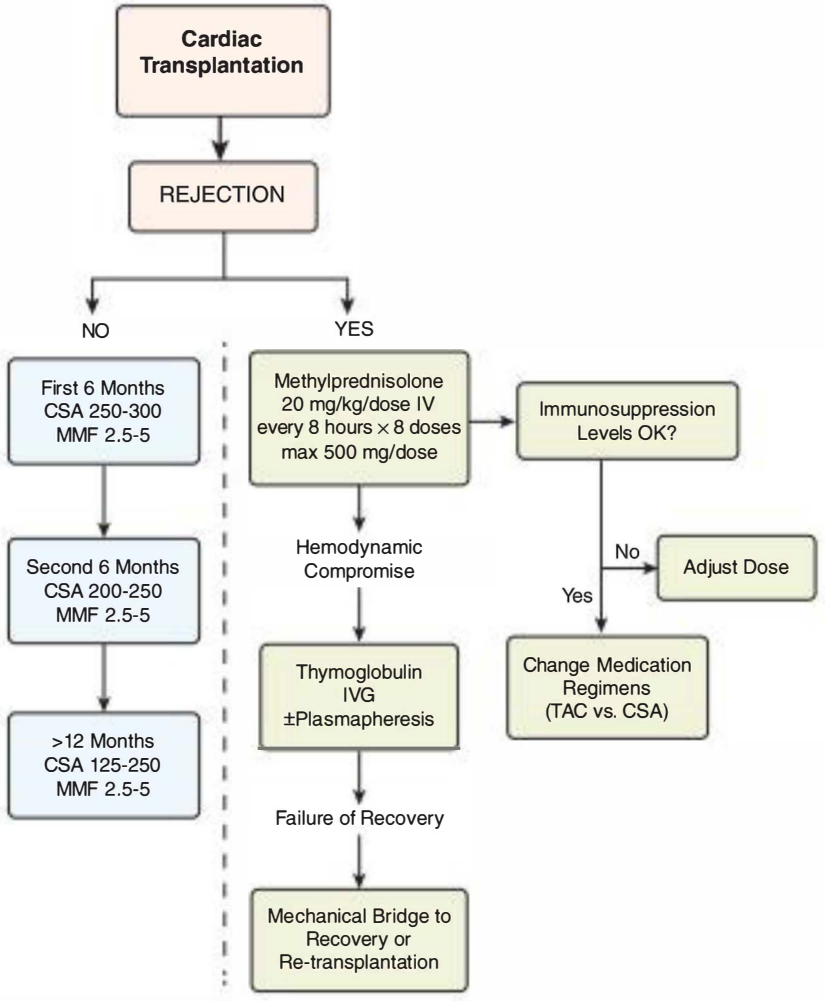

**FIGURE 89-5** Decision-making flowchart for immunosuppression management after pediatric cardiac transplantation (Loma Linda University protocol). CSA, cyclosporine trough level (ng/mL); IVG, intravenous gamma globulin; MMF, mycophenolate mofetil blood level (mycophenolic acid) (μg/mL); TAC, tacrolimus; TX, transplant.

with resultant CMV infections and the development of post-transplant lymphoproliferative disease (PTLD) associated with Epstein–Barr virus (EBV). Renewed interest in the use of induction antibody preparations occurred as a means to reduce or eliminate the need for corticosteroids. Studies have demonstrated the efficacy of this approach.[15] In the most recent report from the registry of the ISHLT,[4] 60 percent of pediatric CT patients were treated with induction agents in 2008 compared with 37 percent that were treated with induction agents in 2001. The registry data did not show a difference in rejection episodes from initial discharge to 1-year follow-up between patients with or those without induction therapy. Nor has there been an increase in the incidence of PTLD with induction. With the exception of neonates in whom induction is not used, rabbit-derived polyclonal antibody is employed in all LLU-managed pediatric recipients in a steroid-avoidance regimen.

## DOUBLE- VERSUS TRIPLE-DRUG MAINTENANCE REGIMENS

Maintenance immunosuppression is typically employed in two forms: a dual-drug regimen consisting of a calcineurin inhibitor (CNI) and a cell cycle inhibitor (CCI) versus a triple-drug regimen with a CNI, CCI, and prednisone. Although this is the typical therapy, there are many variations used in actual practice. A list of immunosuppressive agents used for induction and maintenance therapy is summarized in Table 89-5.

## CALCINEURIN INHIBITORS

Essentially, all immunoregulative regimens start with a CNI, either cyclosporine or tacrolimus. These immunosuppressive

**TABLE 89-5: Commonly Used Immunosuppressants for Cardiac Transplantation**

| Class | Mechanism | Toxicity |
|---|---|---|
| IL-2 Receptor inhibitors (Induction)<br>• Basiliximab (Simulect)<br>• Daclizumab (Senapax) | Antibodies to IL-2 receptor that block T-cell proliferation | • No toxicity |
| Polyclonal antibodies (Induction)<br>• Antithymocyte globulin (ATG) | Nonspecific lysis and clearance of coated B and T cells | • Viral infection<br>• Serum sickness |
| Calcineurin inhibitors<br>• Cyclosporine (Neoral)<br>• Tacrolimus (Prograf) | Blocks IL-2 production via activated T-cells; decreases cellular proliferation | • Neurotoxicity<br>• Nephrotoxicity<br>• Diabetes<br>• Hirsutism |

Data from Baker TB, Axelrod D. Transplantation. In: Makary MA (ed). *General Surgery Review*. Washington, DC: Ladner-Drysdale, 2004:302.[30]

agents target T-lymphocytes and inhibit their activation in response to alloantigen stimulation. Calcineurin-inhibitors block IL-2 gene expression and the production by activated T-cells. In the ISHLT registry report, the use of tacrolimus 1 year after transplantation surpasses the use of cyclosporine 58 to 38 percent. The main advantage of tacrolimus is its reduced cosmetic (e.g., hirsutism and gingival hyperplasia) side effects. It is 100 times more potent than cyclosporine, and is used successfully in patients with recurrent rejection who cannot be controlled with cyclosporine. There are real concerns, however, about an increased incidence of PTLD and posttransplant diabetes among recipients managed with tacrolimus. Newer strategies that use lower target blood levels of tacrolimus have helped ameliorate both of these concerns. Interestingly, long-term survival tends to favor the maintenance use of cyclosporine, but does not establish cause and effect.

Cyclosporine has been the preferred CNI at LLU. Target trough levels (whole blood monoclonal assay) are 250 to 300 ng/mL for the first 6 months, 200 to 250 ng/mL for the next 6 months, and 125 to 150 ng/mL thereafter if the rejection history is acceptable. Tacrolimus is used primarily in selected situations such as high-risk candidates (multiple prior cardiac surgeries), high recipient panel-reactive antibody, and/or African American recipients. Tacrolimus is also used in patients with recalcitrant rejection, after retransplantation, and among children for whom cosmetic side effects (with the use of cyclosporine) become seriously problematic.

## CELL CYCLE INHIBITORS

There are two main categories of CCIs (also known as antiproliferative agents). They are antimetabolites and regulatory kinase inhibitors. Antimetabolites, such as azathioprine (AZA) and the more recent mycophenolate mofetil (MMF), function by blocking purine synthesis. Production of DNA is blocked; hence, the normal cell cycle is arrested. Historically, AZA has been the drug of choice in this class of immunosuppressants. However, ISHLT registry data suggest MMF is now used in 60 percent of pediatric CT recipients (at the 1-year follow-up) instead of AZA. Studies in children have indicated that potential benefit can result from the use of MMF.[16,17] Decreased risk of rejection, decreased cardiac allograft vasculopathy (CAV), and improved survival have been observed with its use.[18] MMF may also decrease the progression of coronary intimal thickening.[19] Like AZA, MMF can produce bone marrow suppression. Significant gastrointestinal side effects may occur with the use of MMF, limiting patient tolerability. The primary immunoregulation protocol at LLU utilizes MMF in a dose of 600 mg/m$^2$/day divided twice daily, advancing the dose as tolerated to maintain a blood level of 2.5 to 5.0 µg/mL (measuring mycophenolic acid levels).

Regulatory kinase inhibitors cause cellular arrest at the G1-stage of the cell cycle by inhibiting the TOR protein. The regulatory kinase (or M-TOR) inhibitors currently used for immunosuppressive therapy in pediatric CT are sirolimus and everolimus. They each function

synergistically with CNI, and have been found useful in the management of rejection, and in the reduction of renal dysfunction and other side effects of CNIs.[20] Sirolimus is employed at LLU for recurrent rejection, in conjunction with MMF (to decrease or eliminate calcineurin use) in children with renal insufficiency, as solo therapy after treatment for PTLD, and in children who have evidence of moderate-to-severe CAV.

## CORTICOSTEROIDS

Oral prednisone has been a historic mainstay of rejection prophylaxis in pediatric CT. The ISHLT registry data show that 55 percent of patients are still being treated with prednisone at 1 year post CT. Nevertheless, experience indicates that effective rejection prophylaxis in pediatric CT recipients can be achieved without the use of maintenance prednisone therapy. Indeed, ISHLT registry data reveal that prednisone usage falls to 38 percent by the fifth posttransplant year. Some believe steroid avoidance requires antibody induction therapy. However, the use of newer immunosuppressive agents has paved the way for prednisone reduction or elimination regardless of the use of an induction antibody. Programs that use maintenance prednisone typically start at a dose of 2 mg/kg per day and wean over the first 3 months to a maintenance dose of 0.1 to 0.3 mg/kg once per day or every other day.

Steroid avoidance has been practiced at LLU from the inception of the program. Oral prednisone may be used temporarily in the treatment of rejection or chronically in the very few children in whom no other combination of agents is effective or tolerated.

## NONPHARMACOLOGIC ANTIREJECTION MEASURES

Three other therapies may play a role in pediatric CT. Total lymphoid irradiation has been used in the treatment of recalcitrant rejection.[21] It has become less important; however, with the availability of newer immunosuppressive agents. Plasmapheresis has been used[22] either before CT (in highly sensitized patients) or in posttransplant recipients who experience acute antibody-mediated rejection (AMR) or in whom AMR is anticipated. Another measure, photopheresis, involves the extraction of lymphocytes from recipients. The lymphocytes are pretreated with psoralen, exposed to ultraviolet A light, and reinfused into the recipient. Photopheresis has been helpful in the prevention[23] and treatment of recurrent rejection in adults, but there are no published reports of its efficacy in children.

## DIAGNOSIS OF ALLOGRAFT REJECTION

A noninvasive strategy is utilized to diagnose graft rejection among infants less than 2 years of age. This approach consists of frequent and thorough examinations. Office evaluation is coupled with diagnostic testing that includes CXR, ECG, and ECHO. Changes in shape and size of the cardiac silhouette and the presence or absence of pulmonary infiltrates on CXR provide clues to the possibility of graft rejection or pulmonary infection. Serial CXR comparisons will identify subtle, and perhaps earlier, changes. Obvious CXR changes imply a late diagnosis of rejection.

The ECG is of questionable value in the early diagnosis of graft rejection, although a >20 percent decrease in combined voltage is suspicious of allograft edema caused by the rejection process. Such a dramatic fall in ECG combined voltage simply adds one bit of data to the noninvasive rejection diagnosis algorithm.

Serial ECHO is a powerful tool for the diagnosis of graft rejection. In general, overall subjective impression is of immense value, but objective findings are just as important. Findings include an increase in ventricular wall thickness, a loss of diastolic compliance, a fall in systolic markers (percent shortening fraction and ejection fraction), new atrioventricular valve regurgitation, and a new pericardial effusion. The more of these findings that are present, the more certain the diagnosis of rejection, particularly if they occur between 3 weeks and 3 months after CT when graft rejection is more commonly encountered.

Older, larger infants, children, and adolescents are subjected to regularly scheduled weekly endomyocardial biopsies until two consecutive biopsies are free of microscopic rejection. Additional biopsies are largely confirmatory in nature, and are tailored to individual recipient requirements.

The risk of graft rejection is being explored through molecular expression testing among adult recipients of cardiac allografts. This methodology has not yet proven to be of value in the anticipation of graft rejection in infants and children.

## TREATMENT OF ACUTE REJECTION

Treatment of a first-time acute graft rejection episode involves high-dose intravenous or oral administration of corticosteroids. Intravenous treatment is often followed by the use of oral prednisone, which is tapered gradually to discontinuation over several weeks. Acute rejection in LLU infants and children is treated with intravenous methylprednisolone in a dose of 20 mg/kg per dose to a maximum of 500 mg per dose twice per day for eight doses. Uncomplicated rejection that is diagnosed by biopsy alone may be treated with oral prednisone 2 mg/kg per day for 3 days, with a taper to 0 over 3 weeks. Patients with recurrent rejection or with acute rejection manifested by hemodynamic compromise are managed in the pediatric intensive care unit with the use of anti-T-cell antibodies (monoclonal or polyclonal) in addition to corticosteroids. At LLU, antithymocyte globulin (ATG) in a dose of 1.5 mg/kg per day is administered intravenously over 6 hours. The dose is repeated daily for 7 to 10 days. A lymphocyte profile is obtained on day 3, targeting an absolute CD3 count of less than 200 cells per mL. Intravenous

immunoglobulin, administered in relatively high doses, may also be useful in the management of acute rejection.

The etiology of acute graft rejection requires investigation, especially if occurring late after CT (>3 months). If immunosuppressive doses have been administered faithfully, and if the desired therapeutic levels have been maintained, the desired level should be increased or the agent should be changed. Noncompliance must be suspected in any late rejection episode, especially among recipients with low drug levels and among adolescents.

## COMPLICATIONS

The most important untoward early consequences of CT are rejection and infection. Other early complications are largely drug side effects or toxicities, and they include hypertension, seizure, renal dysfunction, hematologic abnormality, and hepatic dysfunction. Late complications include chronic rejection, neurodevelopmental delay, CAV, chronic renal failure, and PTLD. Leading causes of late mortality include CAV, chronic graft dysfunction, and malignancies.

## CARDIAC ALLOGRAFT VASCULOPATHY

CAV is a major issue, resulting in increased morbidity and mortality. It probably represents subclinical chronic graft rejection and, as such, may be preventable or even reversible with current drug management. The reported prevalence in pediatric CT ranges between 25 and 45 percent, with the lowest prevalence among recipients who are <10 years old when they have CT. Thus far, the prevalence of this phenomenon appears to be lower among pediatric recipients than it is in the adult population. The most important risk factor associated with increased CAV is increased frequency and severity of graft rejection.[24] Prevention of CAV includes the use of increased immunosuppression, calcium channel blockers, and lipid-lowering agents. As previously mentioned, regulatory kinase inhibitors have been shown to reduce the development of CAV, but whether this translates into improved long-term outcomes has yet to be determined. Treatment of severe, established CAV is elective retransplantation.

## RETRANSPLANTATION

Retransplantation accounts for 5 percent of all pediatric CT, and will certainly increase in use over time. Indications for retransplantation include primary graft failure, irreversible acute rejection, chronic graft dysfunction and advanced CAV.

## OUTCOMES AND THE LOMA LINDA UNIVERSITY EXPERIENCE

Data from the Pediatric Heart Transplant Study (PHTS) Registry, gathered since 1982, show an overall actuarial survival at 10 years of 66 percent in all pediatric age groups (Fig. 89-6).[25] Allograft rejection has been the primary cause of death during the first 3 posttransplant years and CAV is the major cause of late mortality.

Since 1985, 474 infants and children under 18 years of age have been recipients of CT at LLU. The majority ($n$ = 315) of the recipients have been under 12 months of age. Overall actuarial survival, including operative mortality, at 10 years is 66 percent. Three-quarters of newborn recipients are expected to be alive at 10 years. There is a 79 percent incidence of freedom from CAV at 10 years in our patient population.

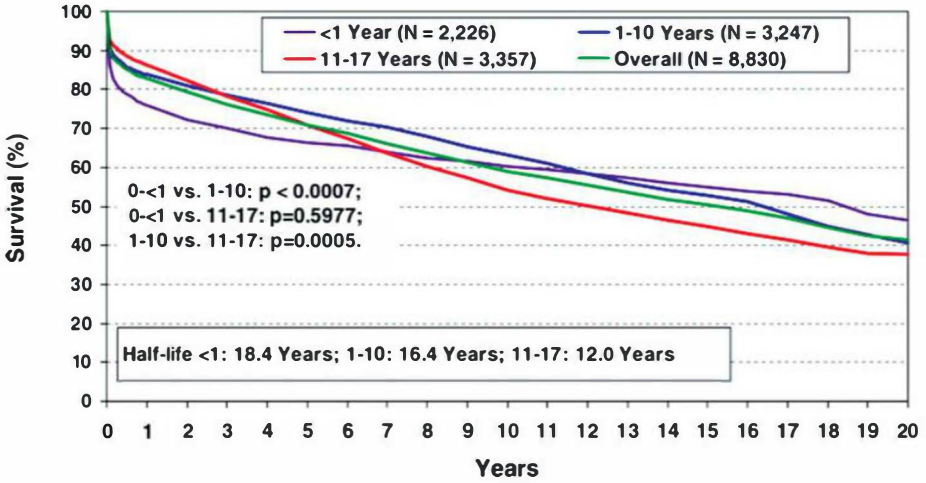

**FIGURE 89-6** Actuarial survival of 537 pediatric patients, stratified by age (January 1982–June 2009). (Reproduced with permission from Kirk R, Edwards LB, Kucheryavaya MS, et al. The registry of the international society for heart and lung transplantation: fourteenth pediatric heart transplantation report—2011. *J Heart Lung Transplant*. 2011;30(10):1095-1103.)

The incidence of freedom from posttransplant malignancy is 89.7 percent at 10 years with the most common malignancy being lymphoproliferative disease. As mentioned above, the first survivor of neonatal transplantation celebrated his 27th birthday with his original allograft in November 2012.

The availability of donor organs remains a challenge, particularly for recipients in very early life. Hence, biological replacement of the heart will continue to be reserved for infants and children who have no other option. Today, for example, just a few young infants with HLHS are ever considered for CT. They fall into two categories: (1) those for whom palliative intervention is judged unlikely to succeed and (2) those who fail to respond favorably to initial palliative reconstruction. Outcomes probably will reflect the nature of this strategy in managing infants with HLHS when compared with elective primary transplantation. A total of 157 HLHS patients have received CT at LLU since the program inception in 1985, but only 5 HLHS patients have been transplanted in the last 5 years. Among this cohort, operative mortality has been 11.5 percent (18/157) and 12-month actuarial survival has been 82.7 percent.

## FUTURE TRENDS

The relatively fixed number of donors for pediatric recipients requires that their distribution and utilization be maximized. Hence, distribution policies have been developed to ensure that adolescent organs reach pediatric recipients preferentially. In addition, a protocol has been devised for the use of ABO-mismatched hearts in young infant recipients.[26] The outcomes of this approach have been excellent, mortality among infants waiting for transplantation has been reduced, and fewer donor hearts have been wasted in this age group. Still, only two-thirds of potential North American pediatric donor hearts are utilized.[27] Strategies to use more of these donor organs should be evaluated. Heart grafts from non–heart-beating donors are a potential resource. The Denver Children's Hospital group reported three successful infant CTs using non–heart-beating donors.[28] Their particular protocol created some debate, but a variation of the protocol that includes a longer waiting period between cessation of cardiac function and donor heart recovery should succeed in increasing the donor organ supply.

As the requirement for CT among young infants with HLHS and its equivalent has diminished, there has been an increasing number of children and adolescents with end-stage congenital heart disease for whom transplantation is the only route to survival. In addition, the demand for retransplantation is on the rise. VADs and perhaps innovative ventricular remodeling procedures will play a more prominent role in bridging these children to transplantation.

Finally, the future ability to induce graft-specific tolerance will make organ transplantation an exceedingly attractive therapy. Indications for pediatric CT will expand, as will the demand for donor organs, including organs from other species. Some of today's most promising research in xenotransplantation is focused on a tolerance model. Together, tolerance induction and xenografting may become the future of pediatric CT.

## PEDIATRIC CARDIAC TRANSPLANTATION BOARD REVIEW QUESTIONS (CHAPTER 89)

1. CNI toxicity profile includes all of the following, except
   A. Diabetes
   B. Hirsutism
   C. Leukopenia
   D. Neurotoxicity
   E. Nephrotoxicity

2. True or False: Complex congenital heart disease has been the most common indication for heart transplantation in infants who are less than 12 months of age.

3. Prevention of CAV includes the use of all the following, except
   A. Immunosuppression
   B. ACE inhibitors
   C. Calcium channel blocker
   D. Lipid lowering agents
   E. Regulatory kinase inhibitors

4. The following pediatric indications for orthotopic CT are correct, except
   A. A child with protein-losing enteropathy following a Fontan operation.
   B. A 2-month-old infant with multiple large cardiac rhabdomyomas, incessant ventricular tachycardia, and pulmonary hypertension.
   C. A young adult who had CT during early infancy and now has grade 3–4 CAV.
   D. A 14-year-old girl whose history includes a Ross–Konno procedure and mitral valve replacement. She now has end-stage cardiomyopathy and pulmonary vascular resistance of 8 Woods units; unresponsive to pulmonary vasodilators.

5. CNI mechanism of action consists of
   A. Inhibits TOR protein causing arrest of cell cycle in G1 phase
   B. Inhibits DNA synthesis by interrupting purine synthesis
   C. Antibodies to IL-2 receptor that block T-cell proliferation
   D. Blocks IL-2 production via activated T cells
   E. Blocks cytokine production

## ANSWERS

1. **Answer: C.** (Found in Table 89-5.)
2. **Answer: True.** (Found in Indications section.)
3. **Answer: B.** (Found in CAV section.)
4. **Answer: D.** (Found in Contraindications section.)
5. **Answer: D.** (Found in Table 89-5.)

# Management of Adults with Congenital Heart Disease

*Kaushik Mandal*
*Nihal A. Weerasena*

The extraordinary advances and dramatic successes of pediatric cardiology and surgery over the past 50 years have witnessed an increase in children born with congenital heart disease (CHD) who survive into adulthood. This success in survival has created a new population of patients of adults with congenital heart disease (ACHD). The number of ACHD will very likely continue to increase in the near future.[1] The 32nd Bethesda Conference had estimated that there were approximately 800,000 adults with CHD in the United States in the year 2000[2]; in the United Kingdom alone there are currently approximately 250,000 ACHD patients.[3]

Since about 0.8 percent of live births are complicated by cardiovascular malformations (disregarding the two most common congenital cardiac anomalies: functionally normal congenital bicuspid aortic valve and mitral valve prolapse), approximately 2800 adults per million population will have some form of CHD, with half of them having moderate- or high-complexity defects.[2] These patients are at significant risk of early mortality from complications of future treatment including reoperation, especially if undertaken in facilities or by physicians not resourced or trained in their care. At present, there is shortage of facilities dedicated to the care of adults with CHD.[4] Care givers and ACHD should have been taught in adolescence about their condition, their future outlook, and the possibility of further surgery and complications, as appropriate. They should be advised about their responsibility in ensuring self-care and professional surveillance. Copies of operative reports should accompany patients being transferred for adult care, along with other key documents from pediatric medical records. Recommendations on transfer of care, organization of ACHD service network, infrastructural requirements, involvement of multidisciplinary teams and their training/certification have been dealt with in detail in the ESC[5] and ACC/AHA[6] taskforce guidelines. A well-working network of specialist centers with general adult care is of paramount importance since, although complex defects can be easily recognized and assigned to high-level care, even simple defects may still require specialist care under certain circumstances [i.e., atrial septal defects (ASD) in the setting of pulmonary hypertension (PAH)].

The subsequent sections of this chapter deal with clinical management of ACHD patients, with special emphasis on issues unique to each lesion, in line with the recently published ESC-2010[7] and ACC/AHA-2008[6] taskforce guidelines.

## CLINICAL EVALUATION

A detailed history from an ACHD patient aims at analyzing present and past symptoms including any significant intercurrent event. Changes in lifestyle should be recorded. Clinical examination during initial and follow-up visits should lay special emphasis on any changes in oxygen saturations, auscultatory findings, blood pressure measurements or signs of heart failure development. A 12-lead electrocardiography (ECG) and pulse oximetry should be part of the examination. Chest x-ray is performed if the clinical situation demands, and provides useful information on changes in heart size, configuration, and pulmonary vascularity.

Noninvasive investigative modalities like echocardiography, cardiac MRI (CMR) are being increasingly used for delineating the anatomy and pathophysiology in ACHD patients in preference to invasive angiographic techniques. Evaluation of arrhythmias with Holter monitoring, event recorders and detailed electrophysiological testing makes management more objective. Cardiopulmonary exercises testing (CPET) has also been gaining popularity in the assessment and follow-up of ACHD patients, especially in deciding about timing of interventions.

### Echocardiography

Echocardiography remains the first line investigation, and 2D transthoracic echo is an essential tool to objectively document the findings after a thorough clinical evaluation.

Recent developments in the field of echocardiography like 3D echo, Doppler tissue imaging, strain rate imaging, contrast echocardiography, and perfusion imaging have significantly improved its ability of functional and anatomical lesion assessment. Transesophageal echo (TEE), with its superior image quality is a useful adjunct; however, supplants 2D echo only in minority of situations like echo guided ASD closure, percutaneous valve implantations etc. It remains a versatile tool for guiding a surgeon during repair of complex pathologies; confirmation of repair quality by intraoperative TEE is a standard of care.

Echocardiography provides information on basic anatomy including cardiac position and orientation, venous return, atrioventricular and ventriculoarterial concordance. It allows evaluation of cardiac chamber morphology, ventricular function, morphology, and function of valves and detection and evaluation of shunt lesions. Echocardiographic distinction between ventricular volume overload (increased end-diastolic volume and stroke volume) and pressure overload (hypertrophy, increase in ventricular pressure) is of crucial importance in deciding the timing of intervention. Doppler echocardiography provides useful hemodynamic information such as gradients across obstructive lesions, right ventricular (RV) pressure, pulmonary artery (PA) pressure, and flow velocities.

Despite its versatility, echocardiography still remains a highly user-dependent investigation that requires special expertise for ACHD patients. Evaluation of ventricular volumes and function may be complicated by geometry and regional incoordination especially in systemic and nonsystemic RV and single ventricle pathologies. Doppler gradients may be misleading when two or more stenotic lesions lie in series. Venous return and great arteries may be difficult to image. Echocardiography is, however, the first line investigative modality, while further noninvasive imaging and invasive hemodynamic assessment are considered to supplement information missing after echocardiographic assessment.

## Cardiac Magnetic Resonance Imaging

CMR is an essential tool in the assessment of ACHD patients. It allows 3D anatomical reconstruction, not restricted by body habitus and acoustic windows and has an excellent spatial and temporal resolution. It is of immense value in volumetric assessment, anatomical delineation of great vessels and detection of myocardial fibrosis.

CMR is an alternative to echo and can provide all the information obtained by echo. Echo, however, is superior to CMR in estimating gradients, PA pressure and detecting small mobile vegetations. CMR can add value to the diagnostic work-up when echo measurements are ambiguous, e.g., ventricular volume, ejection fraction measurement and quantification of valve regurgitant fraction and help in deciding about timing of valve-related surgery.

CMR is superior and should be performed in preference to echocardiography[8] for: (1) quantification of RV volume/ejection fraction in tetralogy of Fallot (ToF); (2) evaluation of RV outflow tract obstruction (RVOTO) and RV–PA conduits; (3) quantification of pulmonary regurgitation; (4) evaluation of PA and aortic pathologies (Fig. 90-1); (5) evaluation of systemic and pulmonary venous anomalies/obstructions; (6) collaterals and arteriovenous malformations; (7) quantification of myocardial mass; (8) evaluation of myocardial fibrosis with gadolinium late enhancement and (9) tissue characterization (fibrosis/iron/adipose tissue). Patients with permanent pacemakers/defibrillators and those who are severely claustrophobic cannot be imaged with CMR; high-resolution spiral computed tomography (CT) provides in these cases a valid alternative, albeit in the setting of increased radiation exposure.

## Computed Tomography

CT plays an ever increasing role in the evaluation of ACHD patients in view of its excellent spatial resolution, ECG-gated image acquisition and rapid scanning with use of newer rotational techniques. It is particularly suited and is superior to CMR for imaging epicardial coronary arteries, collaterals

**FIGURE 90-1** Magnetic resonance imaging in an adult with severe aortic coarctation.

and for evaluating parenchymal lung disease. Its major drawback is its high dose of ionizing radiation, which makes it unattractive for serial evaluations.

## Cardiac Catheterization

Cardiac catheterization is now reserved for resolution of specific anatomical and physiological questions or for therapeutic intervention. Continuing indications include evaluation of pulmonary vascular resistance (PVR), left ventricular (LV) and RV diastolic function, pressure gradients, and shunt quantification, evaluation of aortopulmonary collaterals especially when noninvasive modalities are equivocal.

Accurate measurement of PVR in patients with shunt lesions is crucial for therapeutic decision making. Estimation of PVR requires accurate calculation of pulmonary flow, often difficult to ascertain with echo in patients with complex CHD. Measurement of oxygen uptake rather than estimation is required when the reversibility of PAH would determine the optimal treatment. Preoperative coronary angiography should be performed in men above the age of 40 years, postmenopausal women and patients with family history of or risk factors for coronary artery disease (CAD).

## Cardiopulmonary Exercise Testing

CPET including assessment of objective exercise capacity ($VO_2$ max), ventilation efficiency ($VE/VCO_2$ slope), chronotropic and blood pressure response, and exercise-induced arrhythmias give a broader evaluation of function and fitness and has end points which correlate well with mortality and morbidity in ACHD patients.[9] Serial exercise testing should be an integral part of long-term follow-up protocols and intervention trials in these patients, and has an important role in determining the timing of reinterventions.

# TREATMENT CONSIDERATIONS

Medical management in ACHD patients with heart failure, arrhythmias, pulmonary and systemic hypertension is largely supportive. Prevention of thromboembolic events and endocarditis require appropriate prophylactic measures to be instituted at appropriate times and when significant residual structural abnormalities need reintervention.

## Heart Failure

Congestive heart failure (CHF) is a common problem in ACHD patients. Specialists caring ACHD patients should follow current guidelines.[10] However, given the contrasting and different pathophysiological mechanisms at work in this group of patients, direct extrapolation of results from published studies to ACHD patients may be difficult; this is particularly true for patients with atrial switch repair for transposition of great arteries (TGA) or those with Fontan circulation. The relative lack of published data for these patients makes it difficult to specify the management of heart failure in this group of patients. Cardiac resynchronization therapy (CRT) has gained increasing interest recently in a specific subset of ACHD patients with CHF; however, objective indications for use and outcome measures are at present not clear.

## Arrhythmias and Sudden Cardiac Death

Arrhythmias are one of the most important causes for hospitalization and morbidity and mortality in ACHD patients. Risk stratification, investigation, and management algorithms are often different from those with acquired heart disease with structurally normal hearts.[11] Moreover, the onset of arrhythmia may herald hemodynamic decompensation, with amplified detrimental effects in the presence of an abnormal circulatory physiology. Results of catheter ablation are generally unpredictable in ACHD patients compared to those with ischemic heart disease. Technological improvements, however, allow consideration of catheter ablation for tachyarrhythmias for documented indications in a center with specific expertise. Antiarrhythmic drug therapy with its antecedent negative inotropic effect is poorly tolerated and there are limited data on its long-term safety and efficacy.

Sudden cardiac death (SCD) is of particular concern in ACHD patients. Five defects with greatest risk of late SCD are ToF, TGA, ccTGA, aortic stenosis (AS), and single ventricle lesions.[12,13] Unexplained syncope is alarming. Current guidelines[13] for prevention of SCD in ACHD patients recommend as follows:

- AICD implantation is indicated in survivors of cardiac arrest after exclusion of reversible causes (level of evidence IB).
- Patients with spontaneous sustained ventricular tachycardia (VT) should undergo invasive hemodynamic and electrophysiology (EP) evaluation. Recommended therapy includes catheter or surgical ablation as deemed appropriate and, if this is not successful, ICD implantation should be considered (level of evidence IC).
- Invasive hemodynamic and EP evaluation is reasonable in patients with unexplained syncope and impaired ventricular function. In absence of defined, reversible cause, ICD implantation is reasonable (level of evidence IIaB).
- EP testing may be considered for patients with recurring ventricular couplets or nonsustained VT to determine the risk of sustained VT (level of evidence IIbC).
- Prophylactic antiarrhythmic therapy is not indicated for asymptomatic patients with isolated premature ventricular contractions (level of evidence IIIC).

## Surgical Treatment

Many ACHD patients will have undergone surgery in childhood, but reintervention during adulthood may be required

for: (1) patients with prior repair with new and/or residual hemodynamic complications; (2) patients with conditions not diagnosed during childhood; (3) patients with palliative procedures; and (4) rarely, patients who have not been offered surgery due to the lack of expertise at the time the diagnosis was initially made.

ACHD patients requiring surgery have to be assessed and managed quite differently from those undergoing cardiac surgery for other acquired pathologies. Therefore, it is vital to concentrate all resources into a specialist unit for both treatment and training.[5] Even noncardiac surgery may carry a high risk in this particular group of patients, and appropriate consultation from specialists should be sought; careful preoperative planning and intraoperative monitoring are vital to ensuring a successful outcome.

One of the most challenging surgical issues in ACHD patients is heart and heart–lung transplantation. Risk-stratification scores are available for terminal CHF but may not correctly apply to ACHD patients, making decisions regarding timing of transplantation difficult. In addition to the standard pretransplant work-up, specific issues in ACHD patients are: (1) sensitization from previous transfusions that increases the risk of rejection. Treatment to reduce HLA antibody levels may be needed prior to transplant. (2) The assessment of PVR is difficult in patients with low cardiac output, residual lesions, and shunts/collaterals and has direct outcome on early graft function. (3) Detailed planning of surgical approach is crucial in many complex lesions and all anatomic details, including systemic and pulmonary venous returns that need to be defined. (4) Nonadherence to post-transplant medications is a major problem in young adults, and preexisting psychosocial issues require thorough evaluation before listing. (5) Issues that are specific to patients with Fontan circulation such as protein-losing enteropathy (PLE) and pulmonary arteriovenous malformations need to be accounted for and treated if possible before listing. (6) An increasing number of patients with end-stage cardiopulmonary lesions have underlying chromosomal anomalies which further complicate decision making. (7) Surgical issues in previously operated patients include difficulties during reentry, dissection, cannulation, bleeding, longer bypass, all of which have the potential to raise pulmonary arterial pressure (PAP) and jeopardize right heart function following engraftment. Additional point to consider during procurement for ACHD patients is to harvest extra length of vessels/pericardium for reconstruction.

As per the 2008 UNOS report 1-, 5- and 10-year survival after heart transplantation in non-ACHD patients is 88, 74 and 55 percent. For heart–lung transplantation survival is similar at 71, 50, and 30 percent. Survival after transplantation in ACHD patients is significantly lower, primarily due to higher early attrition.[14] Late attrition after transplantation has not improved significantly in the last 10 to 20 years despite introduction of newer immunosuppressants. The increasing donor shortage and inferior results in ACHD patients may influence organ allocation, strongly penalizing this particular population of recipients. Alternatives, such as long-term mechanical support and/or xenotransplantation will therefore remain important areas of research.

### Catheter Intervention

There has been a marked increase in the number and range of interventional catheterization procedures in ACHD patients, sometimes obviating the need for surgery and, in other cases, facilitating surgical intervention by the intraoperative deployment of stents (hybrid approach). Newer techniques include stenting of systemic or pulmonary vessels and percutaneous valve implantation. The decision to perform an intervention should involve a process of rigorous peer review and multidisciplinary discussion, as currently limited data exist to demonstrate noninferiority over surgery for many of these approaches.

## INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) risk in ACHD patients is substantially higher than in the general population, with marked variation between lesions. It has been emphasized that good oral hygiene and regular dental care and evaluation have an essential role in reducing the risk of IE. Aseptic measures are mandatory during manipulation of venous catheters and during invasive procedures. ACHD patients should be discouraged from getting piercings and tattoos.

Current recommendations for antibiotic prophylaxis for prevention of endocarditis in ACHD patients are as follows: (1) patients with a prosthetic valve/material used for cardiac valve repair; (2) patients with previous IE; and (3) CHD patients prior to repair, if they are cyanotic or post repair with residual shunts. These recommendations are limited to dental procedures only, and are not always advocated for respiratory, gastrointestinal, genitourinary, dermatological or musculoskeletal procedures especially in absence of preexisting infections.

## NONCARDIAC ISSUES

ACHD patients are confronted with various challenges aside from their cardiac issues. These include interventions/surgery for noncardiac problems, ability to participate in exercise and sports, psychosocial issues, obtaining/maintaining employment as well as health and life insurance and finally contraception and pregnancy. Multidisciplinary teams caring for these patients need to be aware of these issues and to have established protocols for assisting them into a meaningful social life. Initiation of discussions on the issues mentioned above between treating physicians, family, and the patient needs to start as soon as the decision of transferring the ongoing care from pediatric to ACHD service is made; this process needs to be gradual and comprehensive. We will briefly touch upon these issues; a detailed discussion of

these problems can be found in the ACC/AHA-2008[6] and ESC-2003[5] taskforce guidelines.

## Exercise and Sports

Counseling for participation in sports and exercise needs to be individualized for each patient based on their ability and the impact on underlying hemodynamics and risk of arrhythmias and acute decompensation. Formal testing is of great value in mitigating the fear of physicians and their patients. Participation in regular exercise has well-documented benefits for fitness, psychological well-being, social interaction, and reduction of future risk of developing atherosclerotic disease. In general, dynamic exercise (i.e., running) is safer than static exercise (i.e., weight lifting). Risk of SCD in patients with known cardiac condition during exercise is rare.[15] However, some lesions are not compatible with competitive sports in view of their physiological complexity and tendency to be associated with serious arrhythmias (Eisenmenger syndrome, PAH, single ventricle palliations with Fontan circulation, unoperated coronary artery anomalies, Ebstein anomaly and ccTGA and TGA repaired by atrial switch or Rastelli procedure among others).[16]

## Pregnancy, Contraception, and Genetic Counseling

The majority of ACHD patients tolerate pregnancy well but are best cared for in a clinical setting with inputs from ACHD cardiology, obstetrics, anesthesia, hematology, neonatology, and genetics. Timely counseling and early involvement of this multidisciplinary team is essential to ensure a successful outcome for the mother and the child. Severe PAH (Eisenmenger patients and others) remains a condition with high maternal (50 percent) and fetal (30–40 percent) mortality; women with this condition should be advised against pregnancy.[17] Other conditions associated with high maternal mortality include severe left outflow/inflow obstructive lesions, poor systemic ventricular function [ejection fraction (EF) <40 percent], and aortic root dilation in Marfan and other related syndromes. Cyanosis poses a significant risk to the fetus, with a live birth unlikely (<12 percent) if oxygen saturation is <85 percent.[18] The significant increase in cardiac output and decrease in peripheral vascular resistance in pregnancy, in conjunction with its hemodynamic consequences for different lesions, must be taken into account and recommendations be made on an individual basis for each lesion. Functional status before pregnancy and history of previous cardiac events are of particular prognostic value. A prospective study identified systemic ventricular EF <40 percent, NYHA class II or more, cyanosis, left heart obstruction (aortic valve area <1.5 $cm^2$ and gradient >30 mm Hg, mitral valve area <2.0 $cm^2$), and prior cardiac events (CHF, stroke, arrhythmia) as risk factors.[19] Patients without these findings and no PAH/mechanical valve or aortic dilation can be considered to be at low risk for a poor outcome from pregnancy.

Fetal echo screening should be recommended at 16 to 18 weeks of gestation. Potential for drugs and their teratogenic effects should be considered, in particular, for patients on warfarin, amiodarone, angiotensin converting enzyme inhibitors, and angiotensin-receptor blockers.

For contraception, barrier methods are safe, protect against sexually transmitted disease, and are effective for compliant couples. Hormonal contraception are efficacious but have limited data regarding safety in ACHD patients and combined oral contraceptives are best avoided in patients with preexisting thrombotic risk (Fontan circulation, cyanotic patients, poor systemic ventricular function). Progesterone-only contraceptives, in contrast to combined pills, have lower thrombotic risk. Progesterone-coated intrauterine devices have high efficacy (>95 percent) and seem to be a reasonable alternative. Sterilization should be considered after careful discussion with family/partner, keeping the long-term prognosis and underlying chromosomal aberrations in mind.

The recurrence rate of CHD in offspring ranges from 2 to 50 percent and risk is higher if mother has CHD than when father is affected. Highest recurrence risks are associated with single gene defects such as Marfan, Noonan, 22q11 deletion syndromes, and Holt Oram syndrome. For others, risk of passing on the defect to the offspring lies between 2 and 4 percent on average and may reach 13 to 18 percent for AS and 6 to 10 percent for ventricular septal defect (VSD).[20]

## Insurance

Despite recommendation from cardiac societies, availability of insurance varies considerably not only between but also within countries, with surprising discordance between insurance policies and available outcome data. Health insurance, in particular, may exclude treatment for the cardiac condition in some countries and has important consequences in "insurance-based medical" systems. Patients currently need to shop around. Problem is more acute for patients with moderate-to-high complexity ACHD and if medical care for these patients is not to be compromised by financial considerations, consistent national strategies for health and life insurance need to be developed.

# SPECIFIC ADULTS WITH CONGENITAL HEART DISEASE LESIONS

Detailed anatomical classification, pathophysiology and its impact on treatment decisions in the pediatric age group is detailed in specific chapters devoted to each lesion in this book. In this section, we will try to highlight issues specific to adults (young and old) with CHD. Some of the general considerations discussed previously apply to all the subsequent sections.

## Atrial Septal Defect

ASD may remain undiagnosed until adulthood as patients are asymptomatic well into their 30s. The majority of these patients will be symptomatic by the fourth decade and present with reduced functional capacity, exertional dyspnea, palpitations and occasionally chest infections/right heart failure. Life expectancy is reduced overall. PAP can be normal but tends to increase with age. Severe PAH, however, is rare (<5 percent) and its development requires additional factors like genetic predisposition (similar to idiopathic PAH). With increasing age and PAP, tachyarrhythmias become more common (atrial flutter/fibrillation-AF)[21] and systemic embolism (paradoxically or from AF) results in premature death and morbidity.

### CLINICAL INVESTIGATION

Key clinical findings include fixed splitting of the second heart sound and a systolic flow murmur over the pulmonary area. Presence of cyanosis in ASD patients should make one suspect: (1) shunt reversal as in Eisenmenger complex; (2) large Eustachian valve directing the inferior vena cava (IVC) flow across the ASD, causing large right-to-left shunt; and (3) Sinus venosus defect of the IVC and superior vena cava (SVC) type, with streaming of desaturated blood to the left atrium. ECG shows incomplete right-heart block with right-axis deviation [superior left-axis deviation in partial atrioventricular septal defect (AVSD)]. Chest x-ray frequently will show increased pulmonary vascularity.

Echocardiography remains the key diagnostic modality to distinguish between the different anatomic ASD variants (secundum, primum, sinus venosus and/or coronary sinus type) as well as relative size, rim, presence of associated mitral valve cleft, drainage of pulmonary veins, and hemodynamic assessment (shunt and PAP). TEE is better at delineating anatomy and should be considered for cases in which device closure is being considered. CMR/CT can help in supplementing echo data, particularly for quantification of RV volume overload and pulmonary venous connections. Cardiac catheterization is required for cases of high PAP to determine PVR and assess operability.

### TREATMENT

Surgical repair has low (<1 percent) mortality and good long-term prognosis, with normal life expectancy when performed at <25 years of age and in absence of PAH.[22] ASD closure after 40 years of age does not affect frequency of arrhythmia development during follow-up but should still be considered as correction improves exercise capacity and stabilizes right heart function,[23] especially if amenable to device closure.

Device closure has become the treatment modality of choice for secundum ASDs with a stretched diameter <38 mm and sufficient rim of 5 mm except toward aorta. This is the case for around 80 percent of secundum ASDs. Atrial tachyarrhythmias after device closure tend to be transient, and complications such as erosion into atrial wall/aorta and thrombo–embolic events are reported in <1 percent cases. Patients require antiaggregant therapy with aspirin for at least 6 months. Studies comparing surgery and catheter-based device closure have reported similar success rates and mortality but with lower morbidity and shorter hospital stay in the nonsurgical cohort.[24]

Poor left ventricular function (systolic and diastolic) may cause pulmonary congestion after ASD closure and may require preinterventional testing with balloon occlusion and hemodynamic assessment. In patients with atrial fibrillation, simultaneous modified Maze procedure should be considered during surgical repair. Closure of ASD should not be considered in patients with Eisenmenger complex. In adults with advanced age and ASDs not amenable to device closure, associated comorbidities should allow individualized recommendations to be made.

### FOLLOW-UP

Patients with prior ASD closure should have assessment of residual shunt, RV size and function, presence of TR and PAP. A history of arrhythmias and an ECG should be obtained and Holter monitoring should be requested accordingly. Patients repaired <25 years of age without any sequelae (no residual shunt, normal PAP/RV and no arrhythmias) do not require regular follow-up and should get in touch with their physicians only if they experience any late-onset arrhythmia. Patients with residual shunt, hemodynamic issues and those repaired >40 years age should be followed regularly in ACHD specialist center.

Late arrhythmias after surgical repair at <40 years of age are mostly intra-atrial reentrant tachycardias/atrial flutter, and are easily amenable to radiofrequency ablation. With or without repair >40 years of age, AF becomes increasingly common and patients should be treated with antiarrhythmics and anticoagulation. Limited data exist on the efficacy of ablation therapy in this subgroup of patients.

### NONCARDIAC CONSIDERATIONS

Asymptomatic ASD patients, pre- or postintervention with normal PAP and no significant history of arrhythmia have no restriction for engaging in sports and exercise. Those with PAH should restrict themselves to low-intensity recreational sports.

The risk from pregnancy in patients without PAH is low. Defect closure prior to conception may reduce the chances of paradoxical embolism and worsening ventricular function during gestation. Pregnancy is contraindicated in patients with Eisenmenger syndrome. Recurrence rate of CHD is 3 to 10 percent (excluding familial ASD and Holt–Oram syndrome with autosomal dominant inheritance).

Prophylaxis for bacterial endocarditis is recommended for 6 months after device or prosthetic patch closure of ASD.

## Ventricular Septal Defect

Excluding bicuspid aortic valve, isolated VSD is the most common congenital malformation at birth (30–40 percent). VSD is also common component of complex anomalies like ToF, ccTGA etc. Spontaneous closure can occur, most often in muscular/trabecular defects, occasionally in perimembranous VSDs, almost never in outlet defects and those that close do it during childhood.

The direction and severity of shunt depends on PVR, size of defect, LV/RV systolic & diastolic function and presence of RVOTO. Clinical presentation in adults could be as: (1) VSD closed in childhood with no residual shunt; (2) closed in childhood but with residual shunt, whose severity and above factors will determine the degree of symptoms; and (3) small VSD with nonprogressive small shunt without LV-volume overload, not considered for repair during childhood. These three categories of patients do not require surgery, especially if they remain asymptomatic.[25]

Patients with large VSD/shunt, LV volume overload and PAH, those with Eisenmenger syndrome and few patients with small defects who will have progressive symptoms need to be assessed and put forward for surgical repair.

Several problems may occur in these patients and each of the issues merits consideration for surgical repair:

- Endocarditis, with a reported incidence of two per 1000 patient years (six times higher than in the normal population)
- Heart failure due to increasing L–R shunt
- Double-chamber right ventricle (DCRV) can develop overtime as a result of the high-velocity VSD jet.
- Discrete sub-AS can develop
- In case of supracristal outlet and high perimembranous defects progressive aortic regurgitation (AR) may develop
- Arrhythmias are less frequent than in other forms of CHD.
- Complete heart block, rare these days, was a common surgical complication requiring permanent pacemakers in older patients. Patients who develop bifascicular or transient trifascicular block after repair are at high risk for developing complete heart block in later years.

### CLINICAL INVESTIGATION

Echocardiography remains the standard investigative modality and provides information on location, number, size of defects, severity of LV volume overload, estimated PAP, and AR due to prolapse of right/noncoronary cusp in case of supracristal and high perimembranous defect. Presence of DCRV must be excluded. CMR is an alternative if echo quality is suboptimal and cardiac catheterization is required only if shunt reversal and established PAH is suspected. It helps to quantify PAP and shunt fraction accurately and can also distinguish between fixed and reversible PAH.

### TREATMENT

Surgical closure with a pericardial patch has low (1-2 percent) operative mortality and with good long-term results, remains the treatment of choice. Transcatheter closure can be considered in patients with increased surgical risk and those that are poorly accessible surgically. Muscular VSDs located centrally in the septum are particularly amenable to treatment with this technique. Long-term data regarding safety and efficacy of catheter-based techniques in all other types of VSD are limited.

### FOLLOW-UP

Patients with LV dysfunction, residual shunt, PAH, AR, RVOTO or left ventricular outflow tract obstruction (LVOTO) should be seen annually. Patients with small isolated VSDs with normal LV/PAP, who are asymptomatic, need to be seen once every 3 to 5 years. After device closure of VSDs, patients should be seen regularly for first 2 years and then the interval can be increased to once every 2 to 5 years.

### NONCARDIAC CONSIDERATIONS

Asymptomatic VSD patients, pre- or postintervention with normal PAP and no significant history of arrhythmia have no restriction for engaging in sports and exercise. Those with PAH should restrict themselves to low-intensity recreational sports.

The risk from pregnancy in patients without PAH is low. Pregnancy is contraindicated in patients with Eisenmenger syndrome. Recurrence rate of CHD is 6 to 10 percent.

Infectious endocarditis prophylaxis is recommended only for those with residual shunts. Patients with patch repair of VSD using prosthetic material should also have IE prophylaxis for the first postoperative 6 months.

## Atrioventricular Septal Defect

AVSDs account for around 3 percent of all CHD. Thirty-five percent of patients with AVSD have Down syndrome. Most complete AVSDs occur in Down patients (>75 percent), and most partial AVSDs occur in non-Down patients (>90 percent). AVSD may occur in association with ToF and other complex heterotaxy syndromes.

Since surgical treatment in the past was frequently withheld for Down syndrome patients, they may frequently present as adults with complete AVSD and Eisenmenger syndrome, unless the VSD is small. Unrepaired partial AVSD is not uncommon in adults. The presenting clinical symptoms are those of L–R shunt and left-AV valve regurgitation in the area of the zone of apposition (also known as "left"). Progressive symptoms develop with increasing age and most patients are symptomatic by 40 years if not operated.

### CLINICAL INVESTIGATION

Clinical presentation mainly depends on the presence and size of ASD/VSD, competence of the AV valves, and direction/degree of shunting. With time, exertional dyspnea, arrhythmia, cyanosis, and sub-AS may progressively develop.

Fifty percent of these patients have prolonged AV conduction and virtually all have left axis deviation. Echocardiography remains the key diagnostic technique and provides assessment of each anatomic component of AV valves and their connections (straddling, overriding), the severity and substrate of AV valve regurgitation, degree and direction of shunting, LV and RV function, PAP, and presence of sub-AS. CMR may be required for accurate quantification of ventricular volume, while cardiac catheterization is indicated in those cases with high PAP where surgical repair is being considered.

### TREATMENT

Repair is surgical as no catheter-based options are available. All symptomatic and asymptomatic patients with echo evidence of moderate-to-severe AV valve regurgitation and impaired LV function should be considered for surgical repair. Surgery should be avoided in patients with Eisenmenger syndrome. Of note, patients with residual shunts requiring pacemakers and high PVR should be considered for epicardial leads in view of increased risk of paradoxical embolism associated with the implantation of intracardiac leads.

### FOLLOW-UP

Lifelong follow-up is recommended for all operated and unoperated patients with AVSD. Particular attention should be paid to residual shunts, AV valve malfunction, LV/RV dysfunction, PAP, sub-AS, and arrhythmias. Patients with no significant defect should be seen every 2 to 3 years and those with residual abnormalities more frequently. One of the most common problems arising during long-term follow-up is increasing left AV valve regurgitation and, in order to preserve the functional integrity of the left ventricle, most patients will require further surgery. This may either be in the form of further repair or replacement of the valve.

### NONCARDIAC CONSIDERATIONS

Asymptomatic AVSD patients (postrepair) have no restriction for engaging in sports and exercise. For residual defects, recommendations should be individualized.

The risk from pregnancy in patients with complete repair and no residual defects is low. AVSD closure prior to conception may reduce the chance of paradoxical embolism and worsening ventricular function. Patients with isolated mild-to-moderate left AV valve regurgitation can tolerate pregnancy well.[26] Pregnancy is contraindicated in patients with Eisenmenger syndrome. Recurrence rate of CHD is high (11 percent), and genetic counseling is necessary. Prophylaxis for IE is recommended for high-risk patients.

## Patent Ductus Arteriosus

Presentations of adult patients with PDA include: (1) asymptomatic patients with small ducts and no signs of LV volume overload; (2) moderate-sized PDA with LV volume overload and occasionally signs of CHF; (3) moderate-sized PDA with predominant PAH and RV dysfunction and finally; and (4) large PDA with Eisenmenger physiology with differential cyanosis (lower extremity and left arm cyanotic as compared to right arm). Risk of endocarditis is small, and rarely aneurysmal duct dilation may compress the left main coronary.

### CLINICAL INVESTIGATION

A continuous machinery murmur, which disappears after development of Eisenmenger syndrome, is typical of this malformation. The role of echo is to look for the presenting features mentioned above and associated complications. CMR and cardiac catheterization are occasionally required.

### TREATMENT

Calcification of the duct is very common in adults and hence device closure (Fig. 90-2) rather than surgical closure is the preferred method, even when other concomitant lesions may necessitate an open repair. Results are good and complication rates of device closure are very low.[27] Surgery is reserved for rare patient with large, aneurysmal duct with unsuitable anatomy. All symptomatic PDAs with signs of LV volume overload should be closed to the exception of patients with Eisenmenger syndrome.

### FOLLOW-UP

Echo evaluations should include LV size and function, PAP, residual shunt, and associated lesions. Patients with no residual shunt, normal LV, and PAP do not require follow-up beyond 6 months. Those with residual shunt, LV dysfunction and PAH should be followed regularly every 1 to 3 years depending on rapidity of deterioration.

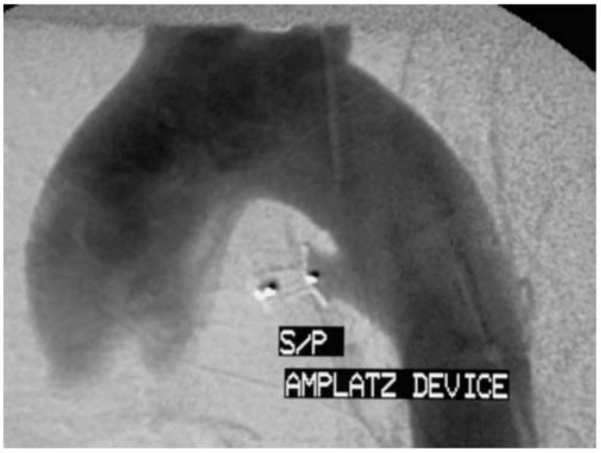

**FIGURE 90-2** Transcatheter closure of patent ductus arteriosus using amplatzer device.

### NONCARDIAC CONSIDERATIONS

Asymptomatic patients, pre- or postintervention with normal PAP have no restriction for engaging in sports and exercise. Those with PAH should restrict themselves to low-intensity recreational sports.

The risk from pregnancy in patients without PAH is low. Pregnancy is contraindicated in patients with Eisenmenger syndrome.

Prophylaxis for IE is recommended for high-risk patients.

## Left Ventricular Outflow Tract Lesions

LVOTO can occur at valvular (most common >75 percent), supra- and subvalvular levels.

## Valvular Aortic Stenosis

Most common cause of valvular AS is congenital bicuspid aortic valve, affecting 1 to 2 percent of the general population. Clinical presentation in adults, management considerations, treatment modalities and follow-up in this group of patients are discussed extensively in the adult cardiac surgery section of this textbook.

## Supravalvular Aortic Stenosis

Supravalvular aortic stenosis (supra-AS) accounts for <7 percent of all forms of fixed LVOTO. It can occur as a localized fibrous diaphragm just distal to coronary ostia or, more commonly, as an external hourglass deformity with corresponding luminal narrowing/diffuse AS. It frequently occurs as a part of the Williams-Beuren syndrome when it is associated with hypoplasia of the entire aorta, involvement of coronary ostia, or stenosis of major aortic branches/PA stenosis. It is important to appreciate that, although site of stenosis may be localized in the ascending aorta, the pathologic process involves the entire aortic root.[28] When present, these lesions are usually significant enough to warrant surgical intervention in infancy/childhood to ensure survival.

Freedom from reoperation at 10 years is 70 to 85 percent with a 10-year actuarial survival of 90 to 95 percent.[29] Reoperation and late death are most commonly related to progressive valve dysfunction and not recurrence of supra-AS.[29] Surgery for diffuse supra-AS as seen with Williams syndrome is less successful, and poor aortic growth persists in both localized and diffuse forms despite successful relief of obstruction initially.[30] These patients are also prone to developing premature CAD.[31]

### TREATMENT

Surgery is the primary treatment. Associated pathologies encountered during follow-up of these patients (AR, recurrent supra-AS, and CAD, which is mostly ostial) needs to be addressed surgically. Indications for surgery include symptomatic patients, asymptomatic patients with Doppler gradient >50 mm Hg, presence of LV dysfunction/severe hypertrophy (LVH, not related to hypertension) and associated CAD. Use of cardiopulmonary exercise testing should be considered when appropriate.

### FOLLOW-UP

Lifelong and regular follow-up including echocardiography is required to determine progression of obstruction/late restenosis, LV size, development of aneurysm and/or pseudoaneurysms postrepair, and presence/progression of CAD.

### NONCARDIAC CONSIDERATIONS

These are similar to valvular AS patients. Genetic evaluation, using fluorescent in situ hybridization, is suggested for family screening in patients with Williams syndrome as their offsprings are at higher risk of recurrence of CHD.

## Subvalvular Aortic Stenosis

Subvalvular AS (Sub-AS) can occur as an isolated lesion, but is frequently associated with a VSD, AVSD, Shone complex or, rarely, may develop after correction of these lesions. The prevalence of 6.5 percent has been reported in the ACHD population and progressive obstruction happens more commonly with increasing age.[32] It is caused by a fibrous ridge/fibromuscular narrowing in the LVOT proximal to the aortic valve and should be distinguished from hypertrophic obstructive cardiomyopathy.

### CLINICAL INVESTIGATION

Clinical findings include ejection systolic murmur at the left sternal border and apex without radiation to the carotid arteries and without any associated ejection clicks. Presence of a diastolic murmur indicates AR.

Echocardiography helps in the initial assessment with visualization of LVOT anatomy, severity of AR, LVH, and LV function. Doppler echocardiography quantifies the severity of subvalvular obstruction but associated LVH and presence of stenotic lesions in series may make the estimate inaccurate. Occasionally, TEE may be required for delineating the membrane.

### TREATMENT

Treatment is indicated in symptomatic patients with mean Doppler gradient of >50 mm Hg and severe AR, in asymptomatic patients with severe AR in presence of LV dysfunction (LVEF <50 percent, LVESD >50 mm), asymptomatic patients with mean Doppler gradient >50 mm Hg, and marked LVH/abnormal blood pressure response on CPET.

Surgical treatment involves circumferential resection of the fibrous ring along with parts of muscular base along the

left septal surface. Diffuse fibromuscular sub-AS requires more extensive root enlargement techniques, such as the modified Konno procedure (Chapter 78). Surgical results are acceptable, but restenosis may occur. In patients with a morphology well-suited for repair and low surgical risk, threshold for intervention should be low, especially since no prosthetic implant is required. In case of moderate-to-severe AR, AVR should be considered at the time of surgery.

### FOLLOW-UP

Lifelong regular follow-up is required to determine progression of obstruction/late restenosis, progression of AR, arrhythmias, heart block, and iatrogenic VSDs.

### NONCARDIAC CONSIDERATIONS

These are similar to valvular AS patients. Pregnancy is contraindicated only in severe symptomatic sub-AS and should be treated to relieve the obstruction before conception.

## Coarctation of Aorta

Coarctation of aorta (CoA) accounts for 5 to 8 percent of all CHD, affecting around 3 per 10,000 live births. Associated lesions include bicuspid aortic valve (up to 85 percent), LVOTO, mitral stenosis (as a part of Shone complex). It is also present in patients with Turner, Willimas–Beuren, congenital rubella syndrome, neurofibromatosis, Takayasu aortitis, and history of trauma.

Key symptoms include headache, epistaxis, dizziness, tinnitus, shortness of breath, abdominal angina, and claudication. The natural course of this malformation may be complicated by the development of left heart failure, intracranial hemorrhage (from Berry aneurysm), IE, aortic rupture/dissection, premature CAD, and stroke.[33]

### CLINICAL INVESTIGATION

Clinical features include upper body systolic hypertension, lower body hypotension and a resulting pressure gradient between the upper and lower halves of the body (>20 mm Hg indicates presence of significant CoA), radio-femoral delay, and palpable collaterals.

Chest x-ray findings may include presence of notched ribs (third–eighth ribs), ectatic ascending aorta, and the "3" sign on chest x-ray secondary to the double contouring of the aorta.

Echocardiography provides information regarding site, structure and extent of CoA, LV function, associated hypertrophy/cardiac anomalies, and aortic and great vessel diameters. Doppler gradients are not useful. Presence of diastolic run-off is a more reliable sign of significance of CoA. In presence of significant collaterals gradients become unreliable and increased systolic flow velocities may develop even in the absence of significant narrowing due to a noncompliant aorta.

CMR/CT are the investigation of choice. Both can evaluate the entire aorta, depict the site and extent of narrowing, and assess the pre- and poststenotic aorta and collaterals. They are extremely useful in detecting complications such as restenosis and aneurysm formation (Fig. 90-1).

Cardiac catheterization with documentation of a peak-to-peak gradient (>20 mm Hg gradient in absence of significant collaterals is significant) still remains the gold standard at many centers for pre- and posttreatment assessment and therapeutic intervention.

### TREATMENT

All symptomatic patients with documented significant gradient across CoA or >50 percent narrowing at the CoA site in comparison with the aortic diameter at the level of diaphragm, presence of upper limb hypertension, significant LVH, and abnormal blood pressure response to exercise are candidates for CoA repair.

Angioplasty and/or stenting has become the treatment of choice in case of native or recurrent/residual CoA in adult patients.[34] The choice between covered or uncovered stents remains controversial. Surgical treatment of coarctation has been extensively covered in Chapter 78.

Repair of recoarctation in adults can be complicated, and ascending-to-descending aortic bypass may be preferable in patients with difficult anatomy. Repair of CoA in older adults carries a significant morbidity, which includes the risk of paraplegia and mortality.[35] Associated lesions such as significant AS/AR, ascending aortic aneurysm, and large Berry aneurysms should be specifically investigated before reintervention for recoarctation is undertaken.

### FOLLOW-UP

Residual sequelae after repair are common and should be screened for during follow-up visits.

- Arterial hypertension at rest or exercise is common even after successful treatment and is an important risk factor for development of premature CAD, CHF, aortic dissection, and stroke.[36]
- Recurrent/residual CoA may exacerbate hypertension and its untoward consequences.
- Aneurysms of ascending aorta/CoA site present a risk of rupture and death.[37] Patch repairs are at particular risk and should be imaged regularly.
- Associated lesions such as bicuspid aortic valve, mitral valve pathologies as a part of Shone complex, premature CAD, and intracranial aneurysm of the circle of Willis should be screened for.

All CoA patients should be followed up at regular intervals with CMR/CT. Frequency of imaging should be based on baseline and postrepair findings.

### NONCARDIAC ISSUES

Patients without residual CoA and with normal blood pressure at rest/exercise can lead a normal life with avoidance of static sports at competition level only. Patients with

hypertension, residual CoA, or other complications should avoid heavy isometric exercises.

Most women after successful treatment of CoA tolerate pregnancy without major problems.[38] Patients with unoperated CoA, postrepair hypertension, residual CoA, or other complications have increased risk of aortic or cerebral aneurysm rupture or dissection during pregnancy/delivery. An excess of miscarriages and hypertensive disorders have been reported in these patients. Prophylaxis for IE is recommended only for high-risk patients.

## Marfan Syndrome

Management of patients with Marfan and other related syndromes have been dealt in detail in the relevant aortic chapters in the adult section of this book as well as in Chapter 82.

## Right Ventricular Outflow Tract Obstruction

RVOTO can occur at the subinfundibular level as seen in DCRV, or at infundibular, valvular, or supravalvular levels; the relevant anatomy, pathophysiological considerations, and syndromic associations of RVOTO have been touched upon within the relevant sections in the congenital cardiac surgery section of this Manual.

Adult patients with unoperated DCRV may be asymptomatic or may present with angina, dyspnea, dizziness, or syncope as the obstruction continues to progress with time.[39] Patients with mild-to-moderate pulmonary valve stenosis (PS) are usually asymptomatic and mild PS in adults usually does not progress.[40] Moderate PS can progress due to valvar calcification reactive myocardial hypertrophy. Once PS is severe almost all patients are symptomatic and have reduced exercise tolerance and, unless operated upon, have poor prognosis. Supravalvar PS is usually seen in syndromic conditions such as Williams, ToF, congenital rubella, etc. and hence should be screened for in the relevant group of patients.

### CLINICAL INVESTIGATION

Clinical findings include a harsh murmur across the obstruction and widely split second heart sound. In peripheral PS the systolic murmur is heard over the lung fields. Findings on CXR may include calcification of pulmonary valve, dilation of main PA, and right heart enlargement.

Echocardiography is essential for anatomic and hemodynamic assessment of lesion severity. It documents the level of RVOTO, pulmonary valve anatomy, and presence of RV hypertrophy (RVH) and coexisting lesions. It provides the gradient across the obstruction, severity of TR/PR (pulmonary regurgitation), and RV pressure overload. Care needs to be taken in distinguishing the jet of DCRV from that of a VSD or infundibular/valvular stenosis. Doppler gradients may overestimate the degree of narrowing in patients with tubular stenosis and in those with stenotic lesions in series. In the patient with DCRV, because of difficulties with axial flow sampling, peak gradients may be underestimated. Use of echo in peripheral PS is less reliable. RVOTO is categorized as mild (peak velocity <3 m/s), moderate (peak velocity 3–4 m/s), and severe (peak velocity >4 m/s). Since Doppler measurements may have an element of uncertainty, accompanying TR velocity assessment with estimation of RV pressure is recommended.[41]

CMR/CT frequently supplement echo assessment and provide additional information in cases with stenosis at subinfundibular/conduit or branch PA levels. CMR is especially suited for evaluating RV function. In conjunction with lung perfusion studies, they are the investigation of choice for peripheral PS. Cardiac catheterization is required only for confirmation of findings of echo/CMR as well as for preoperative coronary angiography.

### TREATMENT

Relief of obstruction with balloon valvotomy is indicated in even in adult patients with severe valvular PS. If unsuitable, surgical valvotomy or rarely surgical valve replacement may be indicated when evidence of progressive RV overload exists (RVSP >80 mm Hg).

Catheter-based intervention is preferable for treating valvular and peripheral PS.[42] Surgery is recommended for patients with DCRV, infundibular PS, hypoplastic pulmonary annulus, and dysplastic pulmonary valve with severe PR/TR. In patients with peripheral PS, surgery may be required in cases of unsuitable anatomy.

The main PA trunk is often markedly dilated in patients with RVOTO; rupture is, however, very rare in this low-pressure system and therefore does not require intervention.[43]

### FOLLOW-UP

Patients with malformations characterized by RVOTO need lifelong annual follow-up with echocardiography except for those with mild PS, who may be seen every 5 years.

### NONCARDIAC ISSUES

Patients with mild PS have no restriction from sports. Those with moderate PS should avoid competitive and static sports, and those with severe PS should restrict themselves to low-intensity recreational sports. Pregnancy is well tolerated except in severe RVOTO with RV failure. Percutaneous valvotomy can be performed during pregnancy is needed. Prophylaxis for IE is recommended only for high-risk groups.

## Ebstein Anomaly

This lesion has also been extensively covered in Chapter 85, and the reader should go back to that section for a detailed description of pathophysiology, anatomical subtypes, techniques of repair, and current surgical results.

### CLINICAL PRESENTATION

Patients not diagnosed until early adulthood may present with a cardiac murmur, cardiomegaly on a chest x-ray, arterial oxygen desaturation, decline in exercise capacity, and/or arrhythmia. Development of atrial flutter or fibrillation may lead to cardiac decompensation in a significant number of patients with this anomaly. The arrhythmia may be caused by progressive tricuspid regurgitation leading to progressive right atrial enlargement. They also may develop Wolff–Parkinson–White syndrome.

### TREATMENT

Medical management of these patients is generally supportive and involves anticoagulation for patients with history of thromboembolism/history of AF. Catheter-based closure of associated ASD/PFO may be considered in acyanotic patients with paradoxical emboli and who are not optimal surgical candidates.

For those patients requiring surgical repair or replacement of the tricuspid valve, cross-sectional echocardiography (both pre- and intraoperatively) has led to a better understanding of valve function. This together with improved surgical techniques has in turn contributed to improved surgical results.

There are several types of surgical repair in the management of Ebstein's anomaly. Tricuspid valve repair and closure of atrial defect is often feasible for symptomatic patients. The atrialized portion of the RV is plicated, the foramen ovale or ASD closed, and either valve repair or replacement is performed. The technique of plication may vary between centers, and would include both a longitudinal and a vertical plication. The technique of valve repair creates essentially a competent monocusp anterior valve leaflet. Closure of the ASD prevents the potential for right-to-left shunting and some may prefer the use of an annuloplasty ring to reinforce the repair. Valve replacement is reserved for significantly dysplastic valves or for reoperative patients. In patients undergoing replacement, a porcine bioprosthesis might lead to improved freedom from structural valve deterioration over bovine pericardial valves.

The Mayo Clinic group reported the surgical results in 189 patients operated between 1972 and 1991. Reoperation was required in 4 patients out of the 110 patients who underwent primary valve repair. This represented 3.6 percent during a follow-up extending to 19 years. In Chavaud's report on 110 patients undergoing surgical intervention for Ebstein malformation only 3 patients underwent valve replacement. Operative mortality was 10 percent in this group. Patients who succumbed in the immediate postoperative period manifested acute right heart failure with severe dysfunction. The addition of a bidirectional superior cavopulmonary shunt was introduced in patients with chronic RV dysfunction to diminish volume load on the RV in the early postoperative phase.

Surgical repair, although challenging, remains the mainstay of treatment. It should be performed only in centers with specific experience with this complex and variable lesion. Tricuspid valve repair or replacement (the latter if repair fails to reduce the residual TR to less than moderate severity) along with closure of ASD is the approach of choice. Tricuspid valve repair by creating a monocusp valve with the mobile anterior leaflet in presence of a functional RV cavity greater than one-third of total RV size has shown good long-term outcomes in experienced hands.[44] Patients with associated tachyarrhythmias should have concomitant surgical flutter ablations or have this addressed in the EP lab. As mentioned above, an additional bidirectional Glenn shunt may be required in cases with small functional RV or preexisting RV dysfunction. In patients with failed repair or severe biventricular failure, heart transplant is an option.

### FOLLOW-UP

Previously reported mortality (>25 percent) has currently fallen to less than 6 percent in specialized centers. Late fatalities are mostly due to arrhythmias. In a large contemporaneous series, survival free of late reoperation was reported at 86, 74, 62, and 46 percent at 5, 10, 15, and 20 years, respectively.[45]

These patients should be followed up annually and be screened for residual/recurrent TR, prosthetic valve complications, RV/LV failure, residual shunts, arrhythmias and high-grade heart block. Recurrent severe TR or failure of the prosthetic valve mandate reintervention.

### NONCARDIAC ISSUES

Patients with no residual anomalies can usually lead normal active lives with the exception of participation in static sports at competitive level. Those with moderate TR, ventricular dysfunction, residual shunts, and arrhythmias should avoid heavy isometric exercises. Women with Ebstein anomaly have carried out successful pregnancies, but those with severe disease are at high risk for both maternal and fetal complications. In some cases, surgical repair should be carried out before a woman becomes pregnant, and careful observation by a specialized obstetric program is indicated following repair and initiation of the gestation.

The spectrum of Ebstein anomaly has perhaps the widest range of presentation of all congenital heart defects, ranging from in-utero demise to the young asymptomatic adult. Adult congenital cardiologists should carefully follow up such patients and be alert for early symptoms of fatigue, cyanosis or rhythm disorders.

Pregnancy is well tolerated in asymptomatic patients with good ventricular function. Those with cyanosis, significant arrhythmias, and right heart failure are significantly increased risk. Risk of CHD to offspring is around 6 percent, and mothers using lithium/benzodiazepines during pregnancy have significantly higher chances of having children with Ebstein anomaly. Prophylaxis for IE is recommended only for high-risk patients.

## Tetralogy of Fallot

ToF is the most common form of cyanotic heart disease after 1 year of age and an overall incidence of 10 percent of all

CHDs. Primary repair between 6 and 18 months is a common practice these days with a perioperative mortality of <1 percent. Late survival after ToF repair is excellent with a 35-year survival around 85 percent.[46]

## Adults without Prior Surgery

In the current era, it is unusual to encounter patients who have not had palliative or corrective surgery for ToF. Many adults with untreated tetralogy may have experienced one or more of the complications associated with cyanosis such as cerebrovascular accident, bacterial endocarditis, paradoxical embolism and brain abscess. Long-term survival without surgery often implies mild pulmonary stenosis during childhood or the development of large-size collateral vessel to augment pulmonary blood flow.

Cardiac catheterization and angiography is indicated to assess RVOTO, the PA anatomy and resistence, as well as the status of the coronary arteries. Patients with favorable anatomy benefit from complete repair, with marked improvement in exercise capacity, elimination of cyanosis, and avoidance of complications associated with right-to-left shunting.

## Adults with Prior Correction of Tetralogy of Fallot

Common complications in adult survivors are:

- Significant PR is present in virtually all patients following transannular patch repair. It is tolerated well hemodynamically for years. Severe chronic PR eventually leads to symptomatic RV dilation and dysfunction.[47] Severity of PR and its deleterious long-term effects on the RV and the tricuspid valve are exacerbated by coexisting PAH and distal PA stenosis.
- Residual RVOTO can occur at any level, from infundibulum to the level of branch PA.
- Tricuspid regurgitation due to RV dilation leads to right atrial enlargement and subsequent development of troublesome atrial tachyarrhythmias.
- Residual VSD due to patch dehiscence or failure of complete closure at the time of surgery leads to progressive LV volume overload.
- Progressive aortic root dilation is seen in 15 percent of adults late after repair and is related to both intrinsic abnormalities of aorta (cystic medial necrosis) and increased flow.[48] It may lead to AR and, very rarely, to true aneurysm formation and aortic dissection or rupture.
- LV dysfunction appearing during follow-up is a risk factor for SCD in ToF patients.[49] It happens due to combination of factors such as inadequate myocardial protection (during operations in the old era), LV volume overload from palliative shunts, and residual VSD and/or AR.
- Tachyarrhythmias are related to progressive hemodynamic sequelae and surgical scarring and are increasingly seen with longer follow-up. SCD is reported in 1 to 6 percent of cases accounting for around a third to half of late deaths.[50]

### CLINICAL INVESTIGATION

Clinical findings in operated patients mostly include a widely split second heart sound, and may include a low-pitched early-ending diastolic murmur of PR, long loud ejection systolic murmur of RVOTO, a high-pitched diastolic murmur of AR, as well as the pansystolic murmur of a residual VSD. ECG shows complete right bundle branch block with wide QRS. A progressively widening QRS >180 ms is risk factor for VT and SCD.[50]

Echocardiography remains the first-line assessment for screening for the above-mentioned issues. CMR has become the method of choice especially for assessment of RV volume and function and provides information about the position of vessels and conduits especially if reoperation is considered. Late enhancement with gadolinium demonstrates extent of fibrosis in the ventricles and has been correlated with the risk of VT and SCD.[51] CT is an alternative to CMR and is especially useful for delineating the extent of conduit calcification, information required for deciding site for percutaneous valve anchorage and for patients with pacemakers and defibrillators in place. Arrhythmias and risk assessment for SCD may need Holter monitoring with event recorder and formal EP testing. Inducible VT in patients with clinical history of arrhythmias and multiple surgeries on RVOT carries a significant risk clinical VT and SCD.[52] Cardiac catheterization is required only for patients undergoing catheter-based interventions (dilation of distal PA stenosis/percutaneous valve implantation) or when noninvasive evaluation is inconclusive.

### TREATMENT

Pulmonary valve replacement and relief of RVOTO can be performed with low mortality (<1 percent) in patients without advanced ventricular dysfunction. Optimal timing of surgery remains a challenge and serial evaluations are more important for making such decisions than isolated measurements. Tissue valves are preferable to mechanical and seem to easily last for 10 to 15 years. Normalization of RV size after reintervention becomes unlikely once the end-diastolic volume index exceeds 160 mL/m$^2$ and recommendation for surgery should be made before reaching this value.[53] Distal PA stenosis, residual VSDs, and AR should also be addressed at the same time. Percutaneous pulmonary valve replacement at present lacks long-term data and is limited by the size range of available prosthesis (16–22 mm only) and the presence of a large outflow tract when a conduit has not been utilized.

EP testing and/or ablation should be performed in patients with symptomatic documented atrial/ventricular arrhythmias. ICD implantation should be considered in appropriate high-risk categories mentioned previously.[50–52] Patients with unexplained syncope should also be formally evaluated and, in absence of reversible cause, undergo placement of an ICD.

### FOLLOW-UP

All patients should have regular follow-up at specialized centers. Frequency of visits and need for echo and/or CMR will be guided by the pathology found and being followed.

### NONCARDIAC ISSUES

There are no restrictions for asymptomatic patients with good hemodynamics. High-risk patients with history of arrhythmias, ventricular dysfunction, and dilated ascending aorta should avoid heavy isometric exercises and only engage in low-intensity sports. Pregnancy is well tolerated in asymptomatic patients with good ventricular function. Those with cyanosis, significant arrhythmias, and right heart failure are at significantly increased risk for maternal and fetal complications. Risk of CHD to offspring is around 3 percent unless the patient has 22q11 deletion when the risk is 50 percent. Prophylaxis for IE is recommended only for high-risk groups.

## Pulmonary Atresia with Ventricular Septal Defect

Pulmonary atresia with VSD (PA-VSD) is at the extreme cyanotic end of the ToF clinical presentation spectrum, and is discussed in detail in Chapter 69.

Late clinical presentation of a repaired PA-VSD patient is similar to that of ToF patients with their associated complications; unrepaired patients will present with exertional dyspnea, fatigue, progressive cyanosis, hemoptysis, CHF, progressive AR and aortic dilation, and arrhythmias.[54]

### CLINICAL INVESTIGATION

Clinical findings may include previously healed thoracotomy or sternotomy scars, cyanosis in unrepaired patients, and continuous murmur in the back, suggesting the presence of multiple aortopulmonary collaterals (MAPCAs). ECG may show right axis deviation and RVH. Chest X-ray will typically disclose a boot-shaped cardiac contour (empty PA bay).

Echocardiography is the first-line investigation and findings will depend on the type of repair. In unrepaired patients, absence of flow from RV to PA and continuous Doppler flow in multiple areas overlying the MAPCAs may be evident. CMR/CT are valuable in the assessment of the lungs and sources of pulmonary blood flow. Cardiac catheterization is, however, mandatory for evaluation of PAH and MAPCAs.

### TREATMENT

Patients surviving to adulthood without repair or those who were palliated[55,56] may benefit from modern surgical and interventional procedures. In particular, patients with good-size confluent PAs, large MAPCAs which are anatomically suited for unifocalization, preserved LV/RV function and absence of severe PAH (due to protecting stenoses) may be considered for repair.[56] All unrepaired patients should be evaluated in centers that specialize in the care of adults with CHD.

By the time of surgical evaluation many patients with severe MAPCAs are not suitable for repair because of complexity of pulmonary vasculature and associated pulmonary hypertension. In rare patients, who are suitable and undergo repair (VSD is closed, RVOTO relief in the setting of normal pulmonary vascular resistance), survival approaches that of ToF patients. Survival, however, falls to 50 to 60 percent at 20 years in patients who are palliated or have incomplete repairs. Heart and lung transplantation outcomes are also worse in this group of patients and, given the paucity of suitable organ donors, they may not have realistic chances of being listed and transplanted.

Catheter-based interventions may include balloon dilation/stenting of collaterals to enhance pulmonary blood flow.[57]

### FOLLOW-UP

These patients should be regularly followed up in specialist ACHD center. Management of cyanosis-related issues and PAH should be carried out according to established guidelines. Patients with changes in their symptoms should be aggressively investigated and treated early.

### NONCARDIAC ISSUES

There are no restrictions for asymptomatic patients with good hemodynamics. High-risk patients with history of arrhythmias and ventricular dysfunction should avoid heavy isometric exercises and only engage in low-intensity sports. Pregnancy is well-tolerated in asymptomatic patients with good ventricular function. Those with cyanosis, significant arrhythmias, and right heart failure are at significantly increased risk of maternal and fetal complications. Risk of CHD in the offspring of patients with 22q11 microdeletion is 50 percent, and screening should be offered to these individuals. Prophylaxis of IE is recommended only for high-risk groups.

## TRANSPOSITION OF THE GREAT ARTERIES

Transposition of the great arteries (TGA) accounts for approximately 5 percent of CHD. It may be an isolated lesion (simple TGA) or associated with other cardiac lesions such as VSD, LVOTO, and CoA (complex transposition). Adult patients present after repair depending on the initial lesion and type of surgical repair.

Most of the present-day adult patients with simple TGA have undergone a Mustard or a Senning atrial switch procedure. Many will have diminished exercise capacity. RV dysfunction (which is the systemic ventricle following these procedures) is a major problem.[58] Tricuspid regurgitation often develops as the RV dilates, and the more severe the systemic dysfunction, the worse the TR. Tachyarrhythmias are also frequent; an atrial flutter, atrial fibrillation and other forms of supraventricular/VT with risk of SCD have been reported.[59] With longer follow-up, worsening sinus node dysfunction requiring permanent pacemaker also becomes common.[60] The atrial baffles can leak (causing either L–R of R–L shunting), or can obstruct (causing either

systemic or pulmonary venous obstruction). The latter (pulmonary venous obstruction) results in PAH. Systemic venous baffle stenosis, mostly superior, is reportedly in up to 25 percent of patients after Mustard repair. This leads to venous congestion of the upper half of body and requires treatment. Similarly, the inferior baffle obstruction causes venous stasis in the lower half of the body and liver congestion. However, systemic venous baffle obstruction can be unnoticed and the patient remains asymptomatic because of presence of decompressing collateral venous drainage in the form of azygos/hemiazygos veins. Narrowing of the subpulmonary outflow tract due to leftward bulging of the interventricular septum can happen but is usually tolerated well by the left ventricle on the right side (subpulmonary) of the circulation.

Young adults who have undergone the arterial switch operation (Chapter 74) largely remain asymptomatic, with majority of them in NYHA functional Class I. Long-term complications include LV dysfunction mainly related to problems with coronary inflow, dilation of ascending aorta with associated AR,[61] supravalvular PS, and PA branch stenosis.

Adult patients with complex transposition who have undergone a Rastelli repair (TGA with PS, in which the anatomical LV is connected through a VSD baffle to the aorta and the RV is connected with a valved conduit to the PA) can be entirely asymptomatic with normal exercise tolerance. Problems encountered during follow-up of these patients are related to conduit stenosis as patients frequently outgrow these residual VSDs and arrhythmias (ventricular/supraventricular).

### CLINICAL INVESTIGATION

Clinical evaluation will involve looking for signs of upper and lower body venous congestion, abnormal murmurs (especially those associated with TR or AR). ECG will frequently show atrial flutter or other arrhythmias. Echo still retains its utility and is very useful in evaluation of ventricular function, TR, baffle leaks, and obstructions including conduit stenosis. TEE is better than TTE (trans-thoracic echocardiogram) in assessing SVC obstruction. CMR/CT supplements echo data on systemic RV function and baffle patency. CPET is very useful in unmasking latent baffle shunts and arrhythmias. Holter monitoring and EP testing are required in high-risk patients. Cardiac catheterization is needed to evaluate PAH and for interventions, coronary flow assessment (radionuclide myocardial perfusion scans may also be used) and when noninvasive investigations are inconclusive.

### TREATMENT

Valve regurgitation in the systemic ventricle should be repaired before the onset of significant dysfunction. Baffle leaks/stenosis (including PA and conduit stenosis) should be treated with catheter-based techniques and, if not successful, then considered for surgical repair. Patients with worsening systemic RV function may be considered for conversion from atrial to arterial switch if the anatomy is suitable[62] or be listed for transplantation. Medical therapy for heart failure with diuretics and digitalis should be commenced as appropriate. The role of ACE inhibitors and β-blockers is less well established in this setting. Coronary malperfusion, AR, and RVOTO gradients >60 mm Hg should be intervened upon in arterial switch patients, based on established guidelines. Percutaneous valve insertion for RV–PA conduit stenosis is an evolving therapeutic modality. Mid-to-long-term data are yet to become available, and this technology cannot be utilized in every patient.[63]

Electrophysiology testing and ablation should be performed by clinicians experienced in treating these conditions because of the complexity of the intra-atrial baffle anatomy. Patients with atrial tachyarrhythmias, impaired RV function, and QRS duration >140 ms are at increased risk of SCD, and should be considered for ICD implant.[64] Epicardial leads should be used whenever feasible.

### FOLLOW-UP

All patients with TGA should be followed up annually in a specialist ACHD center.

### NONCARDIAC ISSUES

Patients with symptoms or history of arrhythmias should be counseled individually. Asymptomatic patients with good hemodynamics should exercise regularly but avoid competitive sports. High-risk patients with history of arrhythmias and ventricular dysfunction should only engage in low-intensity sports. Pregnancy is well tolerated by asymptomatic patients with good ventricular function except by those who have undergone atrial switch procedures who have increased risk of developing serious arrhythmias and irreversible RV dysfunction during pregnancy.[65] Irrespective of the type of repair, TGA patients are at significantly increased risk for premature labor, fetal growth retardation, and miscarriage. Recurrence risk of TGA is low. Prophylaxis of IE is recommended only for high-risk groups.

## Adult Patients with Palliated Univentricular Hearts (Fontan Physiology)

The Fontan operation (Chapter 77) was introduced in 1968, and has become the definitive treatment pathway for a broad range of cardiac malformations characterized by a functionally single ventricle. Currently, total cavopulmonary connection (TCPC) has replaced the atriopulmonary connection (APC) with either an intracardiac or extracardiac conduit between IVC and the PA, together with an SVC–PA anastomosis (bidirectional Glenn). This circulation is established in at least two stages. The operative mortality and subsequent outcome depend on the suitability of the circulation. Strict patient selection (see Chapter 77) gives the best early

and late results with operative mortality of <5 percent in recent series, and includes low PVR and PAP (<15 mm Hg), preserved ventricular function, adequate PA size, absence of significant AV valve regurgitation, and normal regular rhythm.

The lack of a subpulmonary ventricle results in chronic systemic venous hypertension and markedly altered pulmonary hemodynamics. Despite 10 year-survival approaching 90 percent in these patients, it should be appreciated that a premature decline in cardiovascular performance with reduced survival is inevitable even in the best Fontan patient.[66] Hemodynamic derangements contributing to late Fontan failure include a progressive decline in systemic ventricular function, AV valve regurgitation, rise in PVR, atrial enlargement, pulmonary venous obstruction, and consequences of systemic venous hypertension including hepatic congestion.[67] Further complications include atrial and PA thrombus formation, pulmonary arteriovenous malformations, and systemic arterial to pulmonary venous or systemic arterial to PA connection collaterals.

After the Fontan operation, the majority of patients do well during childhood and adolescence albeit with reduced exercise capacity when measured objectively. However, with prolonged (beyond 10 years) follow-up, a notable and progressive decline in exercise performance, development of CHF, cyanosis (especially with a fenestration), and arrhythmias is observed.[68] By 10 years after undergoing the Fontan operation more than 20 percent of patients have supraventricular tachyarrhythmias[69] and it seems that arrhythmias occur less frequent with TCPC than with an APC Fontan.[70]

Protein-losing enteropathy (PLE) is a rare but important complication observed following Fontan palliation, and results in peripheral edema, pleural effusions, and ascites. It can be diagnosed by documenting low serum albumin and elevated α-1-antitrypsin in the stool.[71] It has a very dismal prognosis (5-year survival <50 percent) and available treatments (among which transplantation) are of limited effectiveness.

## CLINICAL INVESTIGATION

Clinical findings include mild nonpulsatile jugular venous distension. Significant jugular venous distension and hepatomegaly should raise the suspicion for Fontan obstruction or ventricular failure. ECG can disclose junctional rhythm or atrial arrhythmias and chest x-ray may show presence of pleural effusion. Annual blood tests should include hematology, serum albumin, and liver and renal function test. When PLE is suspected, α-1-antitrypsin clearance must be calculated. Echo is useful in assessing ventricular and valvular function. For the purpose of imaging the Fontan pathway TEE is somewhat better. CMR/CT can assess the Fontan pathway, collaterals, and pulmonary veins (and rule out right pulmonary venous obstruction by enlarged right atrium or extracardiac Fontan conduit). Liver congestion/cirrhosis (when suspected) is evaluated by ultrasound/CT.

Cardiac catheterization should be performed in cases of unexplained edema, deterioration in exercise capacity, new-onset arrhythmia, worsening cyanosis, and hemoptysis. Catheterization provides information on ventricular and valve function, and hemodynamic measurements including PVR and assessment of obstruction and anomalous vascular connections/collaterals.

## TREATMENT

***Anticoagulation.*** Right atrial blood stasis and disturbed coagulation predispose to thrombosis. The potential for subclinical recurrent pulmonary embolism leading to rise in PVR has led to suggestion by some that lifelong anticoagulation should be considered.[72] However, definitive evidence to support this practice is largely lacking. Anticoagulation is definitely indicated in the presence of atrial thrombus, arrhythmias, or a history of thromboembolic episodes.

***Antiarrhythmic Therapy.*** Loss of sinus rhythm may precipitate rapid hemodynamic decline, and sustained arrhythmia is a true emergency in these patients and should prompt immediate hemodynamic evaluation. Electrical cardioversion is the mainstay of treatment as drug therapy is not as effective and has long-term side effects. There should be a low threshold for radiofrequency ablation in the catheterization laboratory.[73] Antitachycardia atrial pacemakers may help, and if AV pacing is required, epicardial leads should be considered.

***Medical Therapy for PLE.*** Medical therapy remains challenging. After exclusion of hemodynamic problems (Fontan obstruction/occlusion), patients should be put on salt-restricted, high-protein diet, diuretics, ACE inhibitors, steroids, albumin infusion, chronic subcutaneous heparin, and creation of fenestration (by catheter intervention) and eventually, considered for cardiac transplantation.

***Surgical Interventional Options.*** Patients with failing Fontan should be considered for surgery. Conversion of an APC to a more energy efficient TCPC along with arrhythmia ablation at the time of surgery has provided good early results in very experienced hands[74] but has high morbidity and requires permanent pacemaker implantation in majority of cases. Cardiac/heart–lung transplantation remains as options. Significant cyanosis in a fenestrated Fontan or patients with pulmonary arteriovenous malformations may be helped by device closure in the cardiac catheterization laboratory. Fontan pathway obstructions due to clot can also be treated with catheter-directed thrombolysis.

## FOLLOW-UP

Ongoing care of a Fontan patient is highly challenging, and should be performed in an ACHD specialist center annually with echo, ECG, blood tests, and exercise testing. The need for CMR should be based on individual patient status. Comprehensive assessment is mandatory for patients with a

"Failing Fontan" circulation, with particular care to exclude even minor obstruction to cavopulmonary flow and pulmonary venous return.

### NONCARDIAC ISSUES

Patients with Fontan circulation have severely limited exercise capacity and should limit their activities to light recreational sports only. Successful pregnancy is possible in Fontan patients with intensive monitoring during pregnancy and delivery. There is a higher maternal risk if the Fontan circuit is not optimal and higher miscarriage rates if the patient is cyanotic. ACE inhibitors should be withdrawn and anticoagulant management is of course a source of major concern. Prophylaxis for IE is recommended only for high-risk groups including recent redo Fontan (<6 months), cyanosis, prosthetic valve, residual patch leak, and endocarditis.

## Eisenmenger Syndrome and Severe Pulmonary Hypertension

A large proportion of CHD patients (particularly those with relevant systemic-to-pulmonary shunt) will develop PAH if left untreated. Eisenmenger syndrome is seen in CHD with initially large systemic-to-pulmonary shunt, which causes an increase in PVR and ultimately fixed PAH, resulting in shunt reversal and central cyanosis.[75] A recent Dutch registry survey[76] showed the prevalence of PAH (defined by echo RVP measurement) among 1824 ACHD patients with septal defects to be 6.1 percent, with 3.5 percent of patient having Eisenmenger syndrome.

The pathological lesions in ACHD patients with Eisenmenger are very similar to those observed in other forms of PAH.[77] Abnormal vascular shear stress-induced endothelial cell dysfunction plays a major role in its pathogenesis. Initial morphological alterations (medial hypertrophy and intimal proliferation) are potentially reversible; however, with disease progression, advanced changes characterized by plexiform arteriopathy are seen and indicate irreversibility (commonly seen in ACHD).

The current classification[78] of CHD causing PAH takes both clinical and pathological correlates into account and categorizes them into (1) Eisenmenger syndrome (2) moderate-to-large shunt lesions with severe PAH but no shunt reversal/cyanosis yet (3) small defects with PAH (clinical picture similar to idiopathic PAH), and (4) PAH after repair of CHD.

### CLINICAL PRESENTATION

Eisenmenger syndrome is a multiorgan disorder with progressive deterioration. Clinical presentation includes central cyanosis, dyspnea, fatigue, hemoptysis, syncope, and right heart failure in advanced cases. Since patients with reduced arterial oxygen saturation have abnormal hemostasis including thrombocytopenia, they are at risk for both bleeding and thrombosis. In particular, thrombosis of enlarged proximal PA can be found in up to 20 percent of patients and this may cause recurrent pulmonary emboli/infarction and be associated with ventricular dysfunction and reduced pulmonary blood flow.[79]

These patients have reduced survival compared to the age-matched general population[80] although many of them do survive into their 30s and 40s. Survival is, however, better than in patients with idiopathic PAH with comparable functional class. Right heart failure and progressively deteriorating exercise capacity are negative prognostic factors for survival.

### TREATMENT

Use of oral anticoagulation and antiaggregant agents must be individualized to patient-specific risk factors and perceived benefits.

Three classes of drugs, targeted to modifying endothelial cell dysfunction, have recently been approved for treatment of PAH: prostanoids (e.g., epoprostenol), endothelin receptor antagonists (e.g., Bosentan), and phosphodiesterase type-5 inhibitors (e.g., Sildenafil). Their efficacy and safety have been demonstrated in PAH associated with CHD and Eisenmenger syndrome, mostly in the setting of uncontrolled studies. Benefit is mostly in the form of symptom relief and mildly improved exercise capacity but no survival advantage has been shown.

Lung transplantation with repair of cardiac defect or heart–lung transplantation is the final option for these patients especially in those with rapidly declining functional status, and episodes of right-heart failure with elevated levels of B-type natriuretic peptide. Timing of listing remains challenging.

## Management of Cyanotic Patients

Cyanosis is caused by a predominant shunting of deoxygenated blood from the right (pulmonary) to the left (systemic) side. This may occur at the atrial/ventricular level or outside the heart as in pulmonary arteriovenous malformations. Cyanotic patients are broadly categorized within two groups, each with different underlying anatomy and pathophysiology: (1) those with normal or restricted pulmonary blood flow due to an obstruction across RVOTO and (2) those with increased pulmonary blood flow due to the absence of an obstructing lesion and resultant development of PAH and Eisenmenger syndrome. They may have undergone prior palliative procedures.

### ADAPTIVE MECHANISMS

Cyanosis induces adaptive mechanisms to improve oxygen transport and delivery to the tissues. These are secondary erythrocytosis (due to chronic hypoxemia driven erythropoietin secretion), rightward shift of the oxyhemoglobin dissociation curve, and an increase in cardiac output.[81] Compensated erythrocytosis reflects an equilibrium (stable hemoglobin in

an iron-repleted state), and decompensated erythrocytosis indicates failure of an equilibrium (rising hematocrit).

## Multisystem Disorder

Cyanosis and secondary erythrocytosis imply profound consequences on the entire organ system:

- Blood viscosity is increased and is due to increased red cell mass.[82]
- Hemostatic abnormalities are common and attributed to platelet abnormalities (thrombocytopenia and thrombasthenia) and deranged coagulation pathways. Vitamin K-dependent clotting factors (II, VII, IX, and X) and factor V are reduced, fibrinolytic activity is increased, and the levels of von Willebrand factor are low.
- Increased turnover of red blood cells/hemoglobin and impaired uric acid filtration lead to hyperuricemia.[83] The increased concentration of unconjugated bilirubin puts cyanotic patients at risk for calcium bilirubinate stones.
- Severe impairment of endothelium-dependent vasodilation
- Chronic hypoxemia, increased viscosity, and endothelial dysfunction affect microcirculation, myocardial function, and other end-organ function.

### CLINICAL PRESENTATION

Clinical presentation includes central cyanosis, clubbing, and, frequently, scoliosis. Cardiac findings vary depending on the underlying pathophysiology.

These patients have significantly higher mortality compared to their acyanotic ACHD counterparts.[84] Outcome is determined by the underlying anatomy, pathophysiology, palliative procedures, complications of cyanosis, and instituted preventive therapy. Low platelet count, severe hypoxia, cardiomegaly, and elevated hematocrit are useful parameters to predict premature death and adverse events in patients with and without PAH.[85]

### LATE COMPLICATIONS

- Hyperviscosity: symptoms include headache, faintness, dizziness, fatigue, tinnitus, blurred vision, paresthesia in fingers/toes/lips, muscle pain, and weakness. Hyperviscosity symptoms are unlikely in an iron-repleted patient with hematocrit <65 percent.
- Bleeding and thrombotic tendencies cause a therapeutic dilemma. Hemoptysis is the most common major bleeding and is a manifestation of intrapulmonary hemorrhage. Thrombosis occurs due to coagulation abnormalities, blood stasis in dilated chambers and vessels, endothelial dysfunction, presence of thrombogenic prosthetic conduits, and arrhythmias like AF.
- Cerebrovascular accidents may be caused by paradoxical emboli, rheological abnormalities, endothelial dysfunction, and traditional atherosclerotic risk factors. The severity of secondary erythrocytosis was not found to be a risk factor;[86] microcytosis caused by iron deficiency due to inappropriate phlebotomies was the strongest independent predictor of stroke in these patients.[87]
- Paradoxical emboli may be caused by arrhythmias or transvenous leads.
- Iron deficiency is caused by inappropriate phlebotomies.
- Arrhythmias—supraventricular and ventricular.
- Infectious complications include endocarditis, cerebral abscess, and pneumonia.
- Renal dysfunction is common.
- Gall stones.
- Rheumatological complications including gout, hypertrophic osteoarthropathy, and kyphoscoliosis.

### CLINICAL INVESTIGATION

Particular attention must be paid to hyperviscosity symptoms and bleeding/ischemic complications. Oxygen saturation must be obtained with pulse oximetry at rest for at least 5 min and exercise capacity should be assessed on a regular basis, preferably with a 6-min walk test.

Blood work should include tests to screen for all the abovementioned hematological and metabolic derangements.

### TREATMENT

Any proposed intervention should be carefully weighed, and merits particular expertise on the part of the clinician. Acyanotic patients without PAH/Eisenmenger syndrome should be reviewed periodically and, if appropriate, may be considered for Glenn/Fontan-type palliation, while, for those who have not been operated upon, a palliative systemic-to-pulmonary shunt should be considered.

Otherwise, treatment is mostly represented by the medical management of complications.

- Antiarrhythmic therapy should be individualized (medications/ablation/epicardial pacemaker and/or ICD).
- Therapeutic phlebotomy should only be performed in cases with moderate/severe hyperviscosity symptoms (hematocrit >65 percent) and in absence of dehydration and iron-deficiency.
- Blood transfusion may be required in presence of iron repletion.
- Iron supplementation should be performed in presence of iron deficiency (MCV <80 fL) and carefully followed up for rebound effect.
- There are no data to support routine and prolonged therapy with anticoagulants or antiaggregants especially in absence of specific indications such as AF/thromboembolic episodes.
- Hemoptysis requires chest x-ray/CT scan. Bronchoscopy usually is not helpful. Therapy includes general supportive measures and discontinuation of anticoagulation/antiplatelet therapy. Selective embolization of bronchial arteries may be required.
- Asymptomatic hyperuricemia does not need to be treated.

### FOLLOW-UP

All patients require lifelong regular follow-up in a specialist center.

### NONCARDIAC ISSUES

Most patients will only tolerate light recreational sports and should avoid heavy exercise. During daily activities and flights, patients should remain well hydrated. Pregnancy should be avoided because of poor outcomes, and all patients should have prophylaxis for IE.

## MANAGEMENT OF ADULTS WITH CONGENITAL HEART DISEASE BOARD REVIEW QUESTIONS (CHAPTER 90)

1. Echocardiography is superior to CMR for which of the following conditions?
   A. Quantification of RV volumes and function in ToF
   B. Detection of small mobile vegetations
   C. Evaluation of RVOTO
   D. Assessment of pulmonary insufficiency
   E. Evaluation of collaterals and arteriovenous malformations

2. Which of the following is NOT a cause of cyanosis in an adult patient with isolated ASD?
   A. Eisenmenger syndrome
   B. Sinus venosus ASD, IVC type
   C. Directional flow from a large Eustachian valve
   D. Pulmonary embolism
   E. Sudden left-to-right shunting

3. Which of the following is NOT an indication for intervention in an adult with previous surgical repair of ToF?
   A. Severe pulmonary insufficiency with RV dysfunction
   B. Residual VSD with LV dysfunction
   C. RV outflow tract calcification
   D. Combined aortic dilation and aortic insufficiency
   E. Atrial tachycardia

4. Which of the following is NOT a known long-term complication in an adult patient with prior repair of transposition of the great arteries?
   A. Right atrial tachyarrhythmias
   B. Eisenmenger syndrome
   C. Obstruction to pulmonary venous drainage
   D. Rastelli conduit stenosis
   E. Dilation of the ascending aorta

5. Which of the following is the LEAST common complication encountered during the follow-up of Fontan patients?
   A. Thromboembolism
   B. Arrhythmias
   C. Protein-losing enteropathy
   D. AV valve regurgitation
   E. CHF

## ANSWERS

1. **Answer: B.** CMR is an alternative to echo and is superior in many areas, including quantification of RV volume/ejection fraction in ToF, evaluation of RVOTO, quantification of pulmonary regurgitation, and evaluation of collaterals and arteriovenous malformations. Echocardiography, however, is superior to CMR in estimating gradients, PA pressure and detecting small mobile vegetations.
2. **Answer: E.** Cyanosis occurs in an adult patient with isolated ASD when there is an increase in the amount of desaturated blood reaching the left atrium. Conditions that worsen right-to-left shunting, such as acute PAH from pulmonary embolism or fixed PAH in Eisenmenger syndrome, will cause cyanosis. Streaming of desaturated systemic venous return can also result in cyanosis, such as a large Eustachian valve directing flow from the IVC across the ASD, or IVC-type sinus venosus ASD. Left-to-right shunting does not cause cyanosis.
3. **Answer: C.** Adult patients that have undergone prior repair of ToF may develop a wide range of subsequent conditions and should therefore be monitored for life. Any underlying structural problem that affects cardiac performance, including ventricular dysfunction or arrhythmia, should be promptly addressed. Progressive aortic dilation should also be corrected in order to prevent rupture or dissection. Isolated calcification of a pulmonary homograft used for reconstruction of the RVOT is not an indication for intervention unless there is significant stenosis or insufficiency.
4. **Answer: B.** In general, long-term complications associated with various repairs for transposition of the great arteries are not associated with PAH. Right atrial tachyarrhythmias and obstruction to pulmonary venous drainage are associated with the atrial switch operation. Stenosis of the external pulmonary RV-to-PA conduit can occur after Rastelli-type repair. Dilation of the neoaorta can occur after the arterial switch operation.
5. **Answer: C.** Thromboembolism, arrhythmias, AV valve regurgitation, and CHF are all common complications at long-term follow-up for patients having prior Fontan repair. Protein-losing enteropathy is a relatively rare complication.
